Abstract

Improving security of tenure over agricultural land has recently been the focus of a number of large land certification programs. While the main justification for these efforts was to increase productive investments and facilitate land rental transactions, we show that if access rights were tied to actual land use in the previous regime, these programs can also lead to increased outmigration from agrarian communities. We analyze the Mexican ejido land certification program which, from 1993 to 2006, awarded ownership certificates to 3.6 million farmers on about half the country's agricultural land. Using the program rollout over time and space as an identification strategy, we show that households that obtained land certificates were 28% more likely to have a migrant member. The effect was larger for households with ex-ante weaker property rights and with larger off-farm opportunities. At the community level, certificates led to a 5% reduction in population, and the effects were larger in lower land quality environments. We show evidence of certificates leading to sorting, with larger farmers staying and land-poor farmers leaving in high productivity areas. We use satellite imagery to determine that, on average, cultivated land was not reduced because of the program, consistent with increases in agricultural labor productivity. Furthermore, in high productivity areas, the certification program led to an increase in cultivated land compared to low productivity areas.

1 Introduction

Property rights over land can be partitioned into right of access, extraction, management, exclusion of others, and alienation, where the last is the right to sell or transfer in perpetuity (Ostrom, 2001). Incomplete property rights in which the right of exclusion is missing or uncertain implies insecurity of continued access to land and fear of expropriation. Typical of this situation are squatter and usufruct rights that are contingent on presence of the user and on active use to demonstrate property rights and to defend the asset against seizure by others.

The canonical method for reducing uncertainty regarding exclusion rights is through land titles that assign unconditional and unique access, extraction, management, and exclusion rights to beneficiaries. The establishment of a public registry mapping plots of land to rightsholders, and the use of certificates as proof of ownership instead of physical presence has long been proposed as an institutional change that can have profound economic implications. The effects of improving land tenure security on investment and production have been discussed in Besley (1995); Alston, Libecap, and Schneider (1996); Jacoby, Li, and Rozelle (2002); Field (2005); Deininger and Jin (2006); Goldstein and Udry (2008). Its effects on land markets and on- and off-farm labor reallocation are documented in Macours, de Janvry, and Sadoulet (2010), Ravallion and Van de Walle (2003) and Do and Iyer (2008). Previous work has also argued that title-based property rights can lead to land being used as collateral to obtain loans (Chalamwong and Feder, 1988; De Soto, 2000). The agricultural productivity effects of improving exclusion of others was studied by Hor using the case of barbed-wire in the US midwest.

In the developing world, the main source of inefficiency in agricultural land use that originates in incomplete property rights is due to lack of the right to exclude, creating insecurity of continued access (Besley and Ghatak, 2010). Land insecurity is a widespread phenomenon: In rural China land is subject to reallocation by village authorities, while in most of Sub-Saharan Africa local communities maintain jurisdiction over land allocation. In Mexico, the case we study here, half of the country was not under a land title regime until recently.

The need to improve property rights by granting the right to exclude, and reciprocally the guarantee not to be expropriated by others, has led many countries to engage in certification programs. Most notable are the certification programs in Mexico, Ethiopia, and China (Deininger and Jin, 2006; Deininger, Jin, and Rozelle, 2006). Certificates formally recognize land boundaries, and grant exclusive right of continued access to beneficiaries even if the land is left idle or rented to others. A key difference between certification and titling programs is that the former does not provide full collateral for obtaining loans, as there are restrictions on who can own the land. However, it is common that certificates can be easily traded in for full titles, as done in Mexico and Vietnam (Deininger and Jin, 2008). While short of full titling, certification programs can induce efficiency gains through security of investments and land rentals. In any case, the role of full titling in providing collateral for bank loans has proven disappointing. This has been due to either lack of a credit market or lack of an insurance market to help protect the collateral from exposure to weather and other shocks (Boucher, Carter, and Guirking, 2008).

In this paper, we focus on a hitherto unexplored aspect of property right improvement programs in rural areas, which is their effect on migration behavior. The classical argument for improving property rights suggests an overall increase in labor allocated to agriculture given that productive investments and farm labor are complementary. However, if presence of the owner or active use of the asset by the owner is necessary to demonstrate property rights, labor may be inefficiently tied to the land under the insecure property rights regime, an effect working in the opposite direction. We show in a simple household optimization model that the introduction of a land certification program that severs the link between presence and ownership is likely to lead to increased outmigration.

We test this hypothesis using data from Mexico’s large-scale land certification program (Programa de Certificación de Derechos Ejidales y Titulación de Solares, or Procede). Mexico’s Procede program was rolled out nationwide over the 1993-2006 period to issue certificates of ownership over ejido land. Ejidos are agrarian communities that were created starting in 1914 as part of an ambitious land reform program in which members (ejidatarios) were granted usufruct rights over individual plots and common use lands. However, because of lack of a formal title, security of access for individuals was limited. For example, any land that was left fallow for more than two years could be reassigned to another person, or plots of land could be reassigned under simple majority agreement of other members of the community. Procede gave ejidatarios land certificates declaring the name of the owner of each agricultural plot alongside a GIS map of the plot, and similarly for residential plots. Additionally, a certificate was issued to each ejidatario giving ownership of a share of common use lands. Procede was massive in scale, providing certificates to over 3.6 million families by the end of the program in 2006. In essence, Procede provides a large scale institutional change, from use-based ownership to a certificate based one. We use this exogenous land certification program to test the migration impact of property rights improvements.

Because the program provided certificates to the entire community simultaneously, we are in a rare position to use a fixed-effects econometric specification that compares *changes* in migration between households in early titled and later titled ejidos. We establish the migration result using three independent datasets. Using a household survey, we find that households in ejidos that obtain land titles are 28% more likely to have a migrant household member. Using a community level dataset, we find that certificates lead to an overall reduction in population of 5%. Thirdly, we use the ejido census to confirm that certification lead to more young people leaving the ejido for work reasons. Once the main result is established, we document that the migration response is larger for households with ex-ante weaker property rights, and those with more attractive off-farm wage potential.

The migration result prompts the analysis of two important additional questions regarding agricultural land use. The first is whether there is evidence of sorting at the community level regarding *who* migrates. In this respect, we find evidence that farmers with larger land endowments are less likely to migrate as a result of the program than the relatively land-poor. The model predicts this differential magnitude, as the use restriction in the insecure property rights regime is more onerous the smaller the plot the households have access to.

According to the model, the difference in migration response between large and small landholders in a community is expected to be sharper in high land productivity environments. We find clear evidence of this in the data. The overall effect of certification for land-rich households in high productivity areas is not statistically different from zero. This suggests that households are sorted according to their landholdings: larger, more productive farmers stay on the farm, whereas smaller more marginal farmers respond to improved security of tenure by having more members migrate.

The last question we study is whether, with more secure property rights, land-poor households simply decided to leave their farmland fallow, meaning that the certification program in the end led to a reduction in cultivated land, or whether we see evidence that land markets were working to reallocate land from those who left to those who stayed behind, so that acreage under cultivation did not decrease. We use three rounds of satellite land use data to determine that, on average, farmland in ejidos did not decrease after introduction of the program, lending credence to the hypothesis that labor productivity of those who stayed behind increased because they were each operating more farmland. Furthermore, we actually see a difference in land acreage under cultivation according to land quality: ejidos in high land productivity areas saw an increase in farmland after the certification program was introduced compared to those in low productivity areas. Finally, we show that changes in migration and changes in farmland acreage are related: areas with more outmigration after certification are exactly those where agricultural land was reduced.

The closest papers to ours are Field (2007) and Galiani and Schargrodsky (2010), both of who study the role of improved property rights in freeing up labor in urban areas. In that setting, the focus is on hours dedicated to house vs market labor, whereas here we focus a) on rural areas and b) on actual migration. The remainder of the paper is organized as follows. In section 2 we provide further details on *Procede*. Section 3 develops some basic theory on the effects of property rights on migration. Section 4 discusses the data and identification strategy. Section 5 presents the results. Section 6 provides robustness checks and section 7 concludes.

2 The *Procede* Land Certification Program

During the period from 1914 to 1992, Mexico's first land reform involved government expropriation of large private landholdings and redistribution of these tracts of land to groups of peasant farmers organized in agrarian communities called ejidos (Sanderson, 1984).¹ Once awarded, the land was managed by the assembly of farmers under the guiding hand of the state. Beneficiaries enjoyed usufruct rights to a land plot for individual cultivation, access to common-use land (for example forests, pastures and surface water), and a residential lot. With the objective of limiting land concentration, ejidatarios faced strict legal restrictions on rentals and sales of land.² Furthermore, the Constitution itself ruled that any individually tilled land that was not cultivated in two consecutive

¹The program also certified land to indigenous communities. In the remainder of the paper we do not differentiate ejidos from indigenous communities.

²Although there is evidence that a black market for ejido lands existed in some parts of the country (Cornelius and Myhre, 1998).

years was to be reassigned to a member of the community willing and able to do so, imposing a permanent “use it or lose it” restriction.

Giving access to land to those who are willing to cultivate it is an important objective of land redistribution programs. For example, the United States Homestead Act of 1862 and the Reclamation Act of 1902 only awarded title to the land after five years of actual and continuous residence in order to guard against “dummy filings, speculation, and the accumulation of large estates” (Coman, 1911). In contrast, the Mexican ejido imposed the use requirement permanently. Political scientists have argued before that providing small plots that could not be consolidated was purposefully done to create a clientelistic relationship between farmers and the party in power, in spite of the economic inefficiencies it entailed (Magaloni, 2006).³

This first land redistribution program, one of the largest in the world (Yates, 1981), eventually resulted in low agricultural productivity and high levels of poverty (de Janvry, Gordillo, and Sadoulet, 1997). With the advent of NAFTA, the Mexican government introduced a major Constitutional reform in 1992 to improve efficiency in the ejido by certifying individual land plots to current users. The reform was clearly intended to improve security of access to land in the ejido by delineating individual property boundaries within the ejido, thus encouraging long-term productive investments by ejidatarios in their land (Heath, 1990). The reform created Agrarian Tribunals to resolve conflicts over the issuance of certificates, created an ejido National Land Registry where individuals would be assigned parcels in the ejido, allowed rental and sales between ejidatarios, and established a well defined procedure to turn ejido certificates into full titles that could be sold to non-ejidatarios.⁴

The program was massive in scale and took 13 years to complete. The registration process began with officials from the Agrarian Attorney’s Office (PA) approaching ejido officials and offering information about *Procede*. An ejido assembly was called to approve initiation of the certification process. Except for a few conflict zones, the program progressed remarkably smoothly. After the first assembly, government officials from the National Institute of Statistics and Geography (INEGI) worked with the ejido to identify owners of plots and to produce GIS maps of the ejido. Any disputes over property ownership had to be resolved during this stage of the process by the agrarian courts especially created to resolve such conflicts (Deininger and Bresciani, 2001). After all conflicts had been resolved, the maps showing individual ownership were submitted for approval at a final ejido assembly. Final approval resulted in issuance of certificates by the National Agrarian Registry (RAN) *simultaneously* to all rights-holders in the ejido.⁵

³In a recent paper, we find evidence of voting behavior consistent with that hypothesis (de Janvry, Gonzalez-Navarro, and Sadoulet, 2011).

⁴See de Ita (2006) for a description of the reforms.

⁵Appendini (2002) provides a thorough description of the certification process.

3 Theory

The traditional land insecurity model treats insecurity of property rights similarly to a tax on production. Because improving property rights in the canonical model leads to a higher expected output, this naturally leads a household to optimally allocating more labor to the farm, ie. reducing the equilibrium level of outmigration.

In this section, we instead model land insecurity as a requirement to cultivate the land in order to maintain property rights to it. This, together with the prohibition of land sales and rentals, prevents farms from operating at efficient scale. The model seeks to make clear how these two requirements can cause inefficient tying of labor to the land, and how relaxing those restrictions can provoke increased outmigration. Once that is established, the model is used to generate predictions about heterogenous effects which can be tested in the data.

3.1 Setup

We use the standard agricultural production model in which farm labor h_e produces expected output Y_e according to $Y_e = \gamma A^\alpha h_e^\beta$, where $0 < \alpha, \beta < 1$, A is land, and γ is a total factor productivity parameter. We incorporate migration as households having the option of supplying labor h_m in the non-farm market at the wage w_m , for which they earn $w_m h_m$. Household utility is quasi-linear:

$$u(C, \ell) = C + v(\ell),$$

where C is consumption, ℓ is leisure, and utility of leisure is concave ($v' > 0$, $v'' < 0$). Households are endowed with time T which is spent working on the farm, on wage labor off the farm, and on leisure, so that $T = h_e + h_m + \ell$ is the time constraint. The household's budget constraint is $C = \gamma A^\alpha h_e^\beta + w_m h_m + I$, where I is non-labor income.

3.2 Traditional land insecurity model

Insecure property rights are usually modeled as reducing the expected product that the household reaps from farm labor (for instance Besley and Ghatak (2010)). In particular, expected farm production becomes $Y_e = (1 - \tau)\gamma A^\alpha h_e^\beta$, where $\tau \in [0, 1]$ reflects the degree of insecurity in property rights.

Obtaining the first order conditions of the household's problem and differentiating with respect to τ provides the following prediction:

$$\frac{\partial h_e}{\partial \tau} = \frac{-h_e}{(1 - \tau)(1 - \beta)} < 0.$$

Thus, in the standard setup, improving property rights results in an increase in farm labor.

3.3 When farm labor preserves property rights to the land

In line with the context of the property rights in the Mexican ejidos, we instead incorporate land insecurity as a minimum production level per unit of land:

$$\frac{Y_e}{A} \geq \frac{\pi_m}{s},$$

where π_m is the minimum yield, and $s \in (0, 1)$ is a parameter representing the household's specific strength of property rights. The parameter s captures the idea that households with weaker property rights have to maintain a higher production level to keep their land. Because we do not have stochastic output, the minimum yield requirement can alternatively be thought of as a minimum labor requirement per unit of land. However, in deference to the principal-agent literature, we use the minimum yield requirement as it is more realistic.

In line with the rules regulating the *ejido* sector in Mexico, there is neither rental nor sales markets for land, and farmers are not allowed to hire workers. Hence A is the exogenously allotted land to the household, and h_e can only be family labor. Lack of land markets and farm sizes below the optimal scale can be thought of as generating non-decreasing return to scale ($\alpha + \beta \geq 1$). Non-decreasing returns to scale can arise out of small landholdings or production indivisibilities. In any case, there is evidence for this assumption in the Mexican ejido context.⁶

Without constraint, the optimal allocation to farm production would be:

$$h_e^* = \left(\frac{\gamma\beta}{w_m} \right)^{\frac{1}{1-\beta}} A^{\frac{\alpha}{1-\beta}}, \quad (1)$$

which is an increasing and convex function of land A . The minimum yield constraint requires the household to allocate a minimum amount of labor ($\underline{h_e}$) to agricultural production.

$$\underline{h_e} = \left(\frac{\pi_m}{s\gamma} \right)^{\frac{1}{\beta}} A^{\frac{1-\alpha}{\beta}}, \quad (2)$$

or else lose its land. This minimum labor requirement is an increasing and concave function of land A . The restriction will bind for farm sizes that are smaller than the threshold A_0 defined by $h_e^* = \underline{h_e}$:

$$A_0 = \left[\frac{1}{\gamma} \left(\frac{\pi_m}{s} \right)^{1-\beta} \left(\frac{w_m}{\beta} \right)^{\beta} \right]^{\frac{1}{\alpha+\beta-1}} \quad (3)$$

⁶In the 1994 ejido survey, which was administered to around 1300 ejido households by the World Bank, we estimated a production function of the form $\ln(\text{production}_{is}) = \beta_0 + \beta_1 \ln(\text{hectares}_{is}) + \beta_2 \ln(\text{labor}_{is}) + \alpha_s + \varepsilon_{is}$, where i indexes households and s indexes states. Standard errors were conservatively clustered at the state level. The estimates from this regression are $\hat{\beta}_1 = 0.933$ and $\hat{\beta}_2 = 0.176$. The sum of the two coefficients is significantly larger than 1 with a p-value of 0.048. While these estimates certainly can not be interpreted causally, the results provide some suggestive empirical evidence in support of non-decreasing returns to scale in Mexican ejidos.

At the constrained labor allocation, the average on-farm return to labor is:

$$\frac{Y_e}{h_e} = \gamma A^\alpha h_e^{\beta-1} = \gamma^{\frac{1}{\beta}} \left(\frac{\pi_m}{s} \right)^{1-\frac{1}{\beta}} A^{\frac{\alpha+\beta-1}{\beta}},$$

When this restriction binds, although households allocate more time to the farm than under unrestricted optimization, it is still advantageous to allocate $\underline{h_e}$ to the farm as long as the average return to farm labor is as large as the off farm wage, i.e., $Y_e/h_e \geq w_m$. This defines a threshold A_1 below which households will prefer to lose their land and fully work off-farm:

$$A_1 = \left[\frac{1}{\gamma} \left(\frac{\pi_m}{s} \right)^{1-\beta} w_m^\beta \right]^{\frac{1}{\alpha+\beta-1}} = \beta^{\frac{\beta}{\alpha+\beta-1}} A_0 \quad (4)$$

Equilibrium Labor Allocation. *The labor allocation solution to this restricted optimization is represented in Figure 1 and summarized as follows:*

- *Leisure is determined by: $w_m = v'(\ell)$*
- *On farm labor given by:*

- (i) $h_e = h_e^*$, if $A \geq A_0$
- (ii) $h_e = \underline{h_e}$, if $A_1 \leq A \leq A_0$
- (iii) $h_e = 0$, if $A \leq A_1$,

where A_0 is defined by $h_e^* = \underline{h_e}$, and A_1 is defined by $Y_e/h_e = w_m$

- *Migrant/off-farm labor given by:*

$$h_m = T - h_e - \ell \quad (5)$$

The results have simple interpretations since land is the key complementary input to farm labor. Households with a sufficiently small land endowment cannot obtain their opportunity cost by staying and cultivating land; they choose to surrender their land and work off-farm. Households with a large land endowment have a high marginal product of labor and are thus unaffected by the production constraint. These households optimally allocate all their labor to agriculture while at the same time producing enough output to keep their land. Only households with intermediate levels of land find themselves allocating more labor than they would want to under unrestricted optimization.

We argue that in the context of Mexican ejidos one can think of most households as belonging to this intermediate range. First, consider that the objective of the original Mexican land redistribution program was to provide land to as many landless peasants as possible. This gave the government an incentive to minimize plot size subject to providing the household a livelihood (the opportunity cost in the model). Secondly, because land transactions were not allowed prior to the Procede program, farms sizes were maintained at an inefficiently small scale.

3.4 Land security and migration

The Procede certificates can be interpreted as allowing the farmers to move from the restricted optimization situation to the unrestricted one. If the minimum labor allocation restriction was binding (regime (ii) with $A_1 \leq A \leq A_0$), farm labor *decreases with the improvement in property rights*:

$$\Delta h_e = h_e^* - \underline{h_e}$$

And migrant labor increases by the opposite amount:

$$\Delta h_m = \underline{h_e} - h_e^* = \left(\frac{\pi_m}{s\gamma} \right)^{\frac{1}{\beta}} A^{\frac{1-\alpha}{\beta}} - \left(\frac{\gamma\beta}{w_m} \right)^{\frac{1}{1-\beta}} A^{\frac{\alpha}{1-\beta}}. \quad (6)$$

In Figure 1, certification is represented by a vertical move from the restricted to the unrestricted on-farm labor schedule. Leisure is unaffected because it is solely determined by the outside wage w_m .

3.5 Heterogeneity in migration response to certification

This simple framework can also be used to obtain comparative statics predictions resulting from household level heterogeneity. Note that, while the level of migration h_m of a household depends on family size (equation 5), this is not the case for the out-migration Δh_m induced by the increase in property rights security (equation 6). This migration response however varies with the strength of informal property rights previously enjoyed, outside wages, farm size, and land productivity. All comparative statics results are obtained by simple differentiation of equation (6).

Degree of security of informal property rights

Heterogeneity of the degree of land insecurity under the old regime can be thought of as heterogeneity in the s parameter. More insecure property rights are reflected in a lower s and a higher required farm activity $\underline{h_e}$ under the prior system. Deriving (6) with respect to s :

$$\frac{\partial \Delta h_m}{\partial s} = \frac{\partial \underline{h_e}}{\partial s} < 0$$

shows that, *ceteris paribus*, this generates a higher migration response the more insecure property rights are in the old regime.

Off-farm wages

Higher wages commanded higher levels of migration h_m through lower optimal leisure. They also induce a higher migration response to the increased security of property rights:

$$\frac{\partial \Delta h_m}{\partial w_m} = -\frac{\partial h_e^*}{\partial w_m} > 0$$

Because the unrestricted on-farm labor schedule is lower the more attractive outside opportunities

(w_m) are, the regime change leads to larger migration responses from households with better off-farm opportunities.

Farm productivity

Differing farmland quality in the model can be understood as heterogeneity in the productivity parameter γ . Higher land quality reduces the minimum labor necessary to reach the required yield under insecurity and increases the optimal labor that the household should allocate to the farm. Both effects contribute to a reduction in the excess labor imposed by insecure property rights, and hence the migration response to increased security:

$$\frac{\partial \Delta h_m}{\partial \gamma} = \frac{\partial \underline{h_e}}{\partial \gamma} - \frac{\partial h_e^*}{\partial \gamma} < 0$$

This suggests that farms with lower land productivity have more outmigration when moving from a restricted to an unrestricted property rights regime.

Farm size

Differentiation of (6) with respect to A gives:

$$\frac{\partial \Delta h_m}{\partial A} = \frac{\partial \underline{h_e}}{\partial A} - \frac{\partial h_e^*}{\partial A} = \left(\frac{\pi_m}{s\gamma} \right)^{\frac{1}{\beta}} \frac{1-\alpha}{\beta} A^{\frac{1-\alpha-\beta}{\beta}} - \left(\frac{\gamma\beta}{w_m} \right)^{\frac{1}{1-\beta}} \frac{\alpha}{1-\beta} A^{\frac{\alpha+\beta-1}{1-\beta}}$$

This expression can be shown to be negative for land size A greater than a threshold A_2 where the two curves $\underline{h_e}$ and h_e^* have parallel slopes.

$$A_2 = A_1 \left[\frac{(1-\alpha)(1-\beta)}{\alpha\beta} \beta^{\frac{-1}{1-\beta}} \right]^{\frac{\beta(1-\beta)}{\alpha+\beta-1}}$$

The first term in the square bracket is smaller than 1, while the second term is greater than 1, meaning that A_2 can either be greater or smaller than A_1 . Hence, the migration induced by relaxing the yield constraint decreases with farm size, except possibly for the smallest farms still operating with $A \in [A_1, A_2]$, if it is the case that $A_1 < A_2$. The case where $A_2 < A_1$ is depicted in Figure 1. In this case the vertical distance between the two curves is clearly decreasing in A . This expression suggests that if there is heterogeneity in land holding size (A) within ejidos, the larger landholders should outmigrate less in response to the program. This can be thought of as a sorting effect in which the larger farmers are more likely to stay behind while the smaller more marginal farmers migrate.

It is also straightforward to see that this expression implies that the differential induced migration across farm size is sharper in areas with higher land quality:

$$\frac{\partial^2 \Delta h_m}{\partial \gamma \partial A} < 0.$$

This prediction is economically important. It can be interpreted as saying that the migration response of larger landholders in high productivity areas is lower than the migration response of

larger land holders in low productivity areas. An equivalent interpretation is that in low productivity areas, the difference in migration response between small and large landholders is not as different as that which arises in high productivity ones.

In conclusion, we expect increased land security to allow households to allocate the optimal amount of labor to their farm activity instead of the inefficiently high level required by the “use-it or lose it” restriction. The out-migration response is expected to be larger for households that had weaker property rights under the prior informal regime, that have better outside opportunities, smaller farms, and lower land quality. We also expect that the differential migration response between small and large farms is stronger in areas with better land. These are the results to be taken to the data in sections 5.2 to 5.5.

4 Data

In this section we provide a brief overview of the datasets we use to test the various predictions of the theoretical model. We leave specific details on data construction to the appendix.

Our source of information on the rollout of Procede is a set of GIS ejido boundaries for 26,481 ejidos that completed the program during the period from 1993-2006.⁷ The ejido contour maps were created during the certification process by INEGI and managed by RAN. The curve in Figure 2 gives the share of these ejidos that had completed the program by each year from 1993-2006. The rollout of the program was quite rapid. Nearly half of all ejidos were fully titled by 1997 while all but a small subset of ejidos had completed the program by 2006. Figure 2 also shows the dates of the other data sets used: the Progreso surveys (ENCEL), the population censuses, the ejido censuses, and the land use maps. Figure 3 shows the rollout of Procede at the national level, helping visualize the extensiveness and national scope of the program.

We use the 1998-2000 ENCEL surveys administered in the evaluation of Progreso to study individual migration behavior.⁸ The ENCEL data consist of a panel of approximately 25,000 households located in 506 localities in the states of Guerrero, Hidalgo, Michoacan, Puebla, Queretaro, San Luis Potosi, and Veracruz. We matched the localities to ejidos using the coordinates of the centroid of the locality. We considered the locality to match to an ejido if the centroid of the locality was located inside the boundaries of one of the ejidos that was included in the database of ejido contours. This process matched 200 localities to 186 different ejidos. Of these ejidos, 65 were titled in 1993-1996, 49 in 1997-1999, and 73 after 1999. It is the households in the ejidos certified in 1997-1999 that we use to identify the effect of certification on migration. The final data consist

⁷These data also include 246 ejidos that were in the process of certification but had not yet completed the program during 2007.

⁸Progreso is the Mexican conditional cash transfer program started in 1997. The program is now referred to as Oportunidades. Progreso localities were selected to have more than 50 but less than 2,500 inhabitants and have a high marginality index as computed from the 1990 population census and the 1995 population count information. We use the 1998, 1999, and 2000 ENCEL surveys. The 1997 migration data were derived from recalls in the 1998 ENCEL survey. The 1997 ENCASEH baseline survey did not have comparable migration information.

of an unbalanced panel of 7,577 households that were certified after 1996. Approximately 2.2% of these households had a migrant leave during 1997. Between 1998 and 2000 an additional 5.9% of households sent a migrant.

For the community level analysis, we use the 1990 and 2000 population censuses at the locality level from INEGI. Figure 2 shows that approximately 75% of ejidos completed the program between the two censuses. We matched locality centroids to ejidos using the spatial matching technique mentioned above. The final data used in the regressions is a balanced two year panel of population and certification status for 27,261 localities. These data cover all states of Mexico and therefore have broader geographic coverage than the panel of Progresa households. Figure 4 gives the distribution of population growth from 1990 to 2000 in these localities. 59.7% of the localities in ejidos experienced a decline in population during this period, losing in aggregate 175,000 persons or 9.1% of their population over 10 years.

The fourth dataset we use is the Ejido Census (Censo Ejidal) from INEGI that was administered to all ejidos in Mexico in the years 1991 and 2007. The 1991 and 2007 matched surveys are not publicly available and were merged by INEGI specifically for this study. Because the Ejido Census data that were made available to us did not identify the ejido by name, we created a matching algorithm that builds on common variables in the two censuses and the RAN GIS contour maps to construct a matched dataset of 19,713 ejidos. The details of the matching algorithm are given in the appendix.

Finally, we use INEGI GIS land use maps for the whole country. The data consist of Series II, III, and IV of the INEGI land use/land cover maps. The data are based on a combination of Landsat imagery taken during 1993, 2002, and 2007 and a series of field verifications by INEGI. The digital ejido boundaries were overlaid on the land use layers to create a panel of land use at the ejido level for the years 1993, 2002, and 2007. The median amount of agricultural land during 1993 in the ejidos titled in 1993-2006 is roughly 240 hectares, while the median share of total ejido area that is in agriculture is 27%. These figures rose slightly to 275 hectares and 32% in 2007.

5 Results

5.1 The impact of land certification on migration

We establish our basic result that rural land certification lead to increased outmigration in three independent datasets. First, we consider the panel of households from Progresa, which contains detailed demographic variables and migration status of household members over the four years 1997-2000. The unit of analysis is the household and the dependent variable is an indicator for whether the household has a permanent migrant living outside the ejido. The main estimating equation is:

$$y_{ijt} = \delta Certif_{jt} + \gamma_j + \alpha_t + x'_{ijt}\beta + \varepsilon_{ijt}, \quad (7)$$

where y_{ijt} is an indicator for whether household i in ejido j has a permanent migrant by year t ,⁹ $Certif_{jt}$ is an indicator for whether the ejido j was certified at the beginning of year t , γ_j is an ejido fixed effect, α_t is a time fixed effect, x_{ijt} is a column vector of household level covariates, and ε_{ijt} is a random error term. This is a standard fixed effect regression where identification is coming from changes in migration behavior correlated to changes in certification status. Any time-invariant ejido characteristic that is correlated with the program rollout is accounted for by the ejido fixed effects. The identifying assumption is therefore that any time-varying ejido characteristics that affect migration trends are orthogonal to the distribution of certificates. We provide support for the validity of this identification assumption in the next section, focusing first on the results.

The first column in Table 1 gives the basic result with no household controls. In this basic specification, the probability of a household having a migrant increases by approximately 0.015 after being reached by Procede. The magnitude of this estimate corresponds to an approximate 28% increase in the probability that a household has a migrant as a result of being certified. This happened against a background of intense migration. While in 1997 2.2% of the households had a migrant, the natural trend (year fixed effects in the regression) increased that number to 7.2% by 2000. Hence Procede is estimated to have contributed to an additional 28% in the number of households with migrants during these 3 years.

The second column shows that the estimated program effect is almost identical when household level covariates are included in the regression. The fact that certificates were distributed to all ejidatario households in the ejido is consistent with this minimal change when including household covariates. The third column shows that the estimated coefficient is essentially the same if ejido fixed effects are replaced by household fixed effects. Hence, the behavior of families in the Progreso dataset points to land certificates increasing the probability that a household member migrates.

Next, we study migration behavior at the community level using the matched 1990 and 2000 population censuses. The community level analysis captures both individual and whole family migration behavior. Two differences of this alternative dataset are its geographical coverage (nationwide) and longer time span (up to 7 years with certificate).

By the year 2000, 73% of the ejidos had been awarded a certificate, while the other ejidos were still in the pre-certification regime. We first compare the evolution of their population in a standard two-period fixed effect regression:

$$Pop_{jt} = \gamma_j + \beta I(t = 2000) + \delta I(Certified\ by\ 2000_j = 1)I(t = 2000) + \varepsilon_{jt}. \quad (8)$$

We then allow for a linear effect of certification over time by estimating:

$$Pop_{jt} = \gamma_j + \beta I(t = 2000) + (\delta_0 + \delta_1 Years\ Certified_j)I(Certified\ by\ 2000_j = 1)I(t = 2000) + \varepsilon_{jt}. \quad (9)$$

The dependent variable is the total population (or logarithm) of locality j in year t (1990 or 2000). The first specification (8) is a simple fixed effect regression where δ identifies the average effect of

⁹Once a household has had a migrant leave, its value of y remains at one for the remainder of the sample period.

the ejido getting certification on the change in locality population. The second specification (9) takes into account the number of years since certification, allowing the migration response to take effect over several years in a linear way.

Regression results are reported in Table 2, where standard errors are clustered at the ejido level. The first row in the table shows that ejido localities lost around 12% of their population between 1990 and 2000 (the time effect). The coefficient on the interaction term in the second row (column 1) indicates that Procede was associated with an *additional reduction* in population of approximately 3 individuals, in a setting where the average locality has 67 individuals. Consistent with this, the coefficient from the second column, in which the dependent variable is logarithmic, shows that the average reduction in local population is 5%. The third column shows that the loss of population is progressive over time, with a decline of approximately 0.9% of the population per year after Procede certification. This last result suggests that the effect of certification on population size is not immediate, but rather occurs over time. Ubiquity of the emigration effect across the whole distribution of change in population is illustrated in Figure 5. The solid black line represents the empirical distribution function for the change in population from 1990 to 2000 for localities in ejidos that were treated in between the two censuses. The dashed line represents localities in ejidos treated in 2000 or later.¹⁰ The distribution for localities in untreated ejidos stochastically dominates that for treated localities. This indicates that the effect of certification on migration is not a feature of some specific localities but occurs throughout the distribution of population changes.

In the last column of the table we limit the sample to Progreso localities. Doing so allows us to make a better comparison between household and community level results. While the migration effect is less precisely estimated, the point estimate suggests an approximate 2% decrease in population. Returning to our household level estimates, if the average household size is approximately 5, then the decrease in population attributable to movement of individuals within households is approximately 0.3%. The comparison of these two results suggests that approximately 85% of the migration response to certification comes from migration of entire households.

The locality level database captures movements of entire families rather than solely migration of household members. However, migration is not the sole factor affecting total population. One potential confounding factor is fertility. Galiani and Schargrodsy (2010) find that titling of an urban slum in Argentina caused households to reduce fertility. Although plausible in the Argentinian context, the age of the ejidatario population in Mexico makes a fertility response unlikely.

Finally, we analyze migration behavior using the 1991 and 2007 ejido censuses. By 2007, all the ejidos in our dataset had been certified. Hence we can only identify the effect of certification coming from the differential number of years an ejido has been certified. Furthermore, because the migration question was not asked in the first round, we can only perform a cross sectional regression. Our dependent variable is the question from the 2007 Ejido Census asking if the majority of young people leave the ejido. We estimate a cross-sectional regression of the form:

¹⁰The top and bottom 5% of observations were removed for the graph.

$$Y_{js} = \alpha + \gamma_s + \delta \text{Years Certified}_{js} + x'_{js}\beta + \varepsilon_{js}. \quad (10)$$

where γ_s are state fixed effects and x'_{js} is a column vector of ejido level covariates in 1991 (before Procede). The dependent variable Y_{js} is an indicator variable for whether the majority of young people emigrate from the ejido.

This is obviously a less well identified regression than those reported using the previous two datasets. However, this specification is justified by the result in Table 2 suggesting that the effect of certification is increasing over time. Second, the ejido census has the advantage that the unit of observation coincides perfectly with the population of interest, because questions are asked about the group of ejidatarios in each particular ejido. Finally, this is the only dataset we use not necessitating a geographical merge. Hence, we see this as a important verification of the results presented in the previous two tables.

Results are reported in Table 3. Column (1) shows a positive association between the years since certification and the probability that the majority of young people emigrate from the ejido. This result is robust to the addition of ejido covariates measured in 1991 (column 2). Columns (3) and (4) suggest that most of this effect is driven by increased migration to the United States, consistent with the results reported in Valsecchi (2011). The average ejido had been titled 9.5 years in 2007, meaning that for the average ejido, the probability that a majority of young people would be leaving the ejido increased by 7.8% due to the Procede program.

By presenting results from three independent datasets, we seek to credibly establish that increased security of property rights generated by the assignment of land certificates led to increased migration from agrarian communities. The number of households having a migrant increased by 28%, the locality population declined by 5%, and ejidos were 0.35% more likely to report that a majority of their youth were leaving the community for every year they had been certified. Applying these results to the almost 2 million population of the localities matched to ejidos suggests that Procede would have been responsible for an outmigration of about 100,000 people in addition to the natural trend leading to a decline of 230,000 people.

These results should not be interpreted as suggesting a reduction in welfare. On the contrary, as the model suggests, we interpret this as evidence that inefficient amounts of labor had been allocated to the land under the regime with more insecure property rights. The program merely allowed households to adjust from an inefficient equilibrium with too much farm labor to an efficient equilibrium with less farm labor. Our next step is to test whether the heterogeneity of migration effects for different types of households is consistent with the predictions of the model.

5.2 Heterogeneity in pre-reform property rights security

The model predicts that the migration response to land certification should be larger when pre-reform property rights are weaker ($\frac{\partial \Delta h_m}{\partial s} < 0$). As a measure of *between ejido* security, we use a question from the 1991 ejido census on the presence of boundary problems within the ejido. Column

1 of Table 4 shows that the point estimate of the migration effect of certification is approximately double for households in ejidos where boundary problems were present. The difference between ejidos with and without boundary issues becomes larger when differential time trends are controlled for (Column 2). The effect of certification on the probability of having a migrant household member increases from 0.007 for households in ejidos without boundary problems to 0.032 for households in ejidos with problems. This difference is significant at the 10% level.

Next, as a measure of *within ejido* security heterogeneity, we use an indicator for female headed household. Work by anthropologists indicates that, prior to Procede, female ejidatarias held low status inside the ejido (Stephen, 1996; Deere and León, 2001; Hamilton, 2002). For example Stephen (1996, p.291) quotes an ejidataria from Oaxaca as stating, “Women don’t participate in ejido assemblies. The men in our community don’t let us participate in meetings.” Based on interviews conducted in four ejidos in northern and central Mexico, Hamilton (2002) points out that women were susceptible to expropriation by male relatives or friends of high level ejido officials. This anecdotal evidence prompted the use of a female headed household dummy as a proxy for weaker ex-ante property rights.

Columns 3 and 4 of Table 4 show that indeed the effect of certification on migration of household members is significantly larger for female headed households. The magnitude of the coefficient is quite large. The subset of households with female heads is small but not trivial, consisting of around 10% of the population. The marginal effect of certification for these households represents an approximate doubling in the probability that the household has a migrant. These effects contrast with the smaller impact for male-headed households.

The results are consistent with property right improvements brought about by land certificates having much larger effects for households with weaker rights prior to certification. In terms of the model, we interpret this as individuals with weaker property rights (lower s) being more constrained prior to the program and thus having to dedicate more labor to the farm to maintain their land. Hence, receipt of land certificates resulted in a larger migration response for these households.

5.3 Heterogeneity in off-farm wages

We derive an empirical measure of off-farm wage opportunities by using the 1994 ENIGH household survey to estimate off-farm wages as a function of gender, years of education, the interaction between gender and years of education, and a quadratic function of age. We limit this estimation to individuals that are 50 or below since this population is more representative of the population of potential migrants. We then used the wage equation to predict wages for each adult in the set of Progreso households matched to ejidos. The maximum predicted off-farm wage amongst adults 18-50 was taken as the household’s off-farm wage opportunity.¹¹ In Columns 5 and 6 of Table 4 we estimate a separate certification effect for households above and below median values of off-farm wage opportunity. The difference in migration response to certification between households with high and low wage opportunities is statistically significant at the 10% level. Using the results from

¹¹Predicted wage was set to 0 if the household did not have any individuals younger than 50.

Column 6, the estimated certification effect for male headed households that have above median off-farm wage opportunities is 0.026 and is statistically significant at the 10% level. These results are consistent with the theoretical prediction that the migration response should be larger for households that have higher wage opportunities outside of agriculture ($\frac{\partial \Delta h_m}{\partial w_m} > 0$).

5.4 Heterogeneity in farm productivity

The theory predicts that certification leads to a dampened migration response in places with higher land productivity ($\frac{\partial \Delta h_m}{\partial \gamma} < 0$). To test this prediction, we define agricultural land as high or low productivity using maize yield information at the municipality level from SAGARPA (Ministry of Agriculture), in which we partition land quality at the median yield of 1.29 tons/ha. Columns 1 and 2 of Table 5 show that, as predicted, the migration response to certification is weaker in ejidos where land is more productive.

5.5 Certification, sorting, and migration

The final prediction derived in the model is that large farms in productive regions are expected to respond less to certification with labor re-allocation ($\frac{\partial^2 \Delta h_m}{\partial \gamma \partial A} < 0$). We test for this by splitting the sample into low and high productivity areas (using the maize yield variable defined above) and creating an indicator variable which is equal to one if a farmer has more land than the median farmer in his ejido.¹²

Comparison of the first row coefficients between high (columns 3 and 4) and low productivity ejidos (columns 5 and 6) confirms that the migration response was stronger in lower yield areas among the land-poor farmers ($\frac{\partial \Delta h_m}{\partial \gamma} < 0$).

The results in row 3 are striking. In low productivity areas, larger landholders are not significantly less likely to migrate than land poor farmers. The coefficient is negative but insignificant. In contrast, in high productivity areas, larger landholders increase their migration *significantly less* than land poor farmers. In fact, the overall effect of certification for land-rich households in high productivity areas is not statistically different from zero. In sum, these results are consistent with the prediction of the model that households are sorted according to their landholdings: larger, more productive farmers stay on the farm, whereas smaller more marginal farmers respond to improved security of tenure by having more members migrate.

5.6 Certification, land use, and migration

The model we presented considered an autonomous household deciding how to allocate labor on and off the farm. According to the model, the security of tenure provided by certification made households allocate less labor to the farm. A logical byproduct of this phenomenon is that less labor on farm should be reflected in more land being left fallow. In reality, certification can

¹²Families are ranked in each ejido in the Progreso dataset according to their landholdings into those with more and less than the median land per adult household member in the ejido in 1997.

also be expected to have an effect on local land markets, because it reduces uncertainties in land transactions. There are two reasons why certificates may have had land reallocation effects. First, the idea that ejidos were inefficiently small to begin with suggests there are gains from trade to be had by consolidating land holdings. Second, if some farmers are more productive than others, certification can lead to gains from trade.

While we do not observe land transactions (rentals or sales), we can determine if the certification program lead to changes in the amount of cultivated land. If security of tenure meant that families could now leave the land fallow without risk of loss, cultivated land would decrease. Alternatively, if land was rented out or sold to other community members by households with migrants, we should observe no changes in cultivated land. Finally, if the certification program provided better incentives to invest in agriculture, we would observe increases in cultivated acreage.

For this exercise, we use panel data from Landsat providing area cultivated at three points in time, 1993, 2002, and 2007 (INEGI GIS land use series II, III and IV). At each of the three points in time we observe the amount of land allocated to agriculture, pasture, forest, jungle, and thicket in the ejido. We estimate the reduced form impact of certification on the logarithm of cultivated area in a standard fixed effect framework with panel data:

$$\log(Agland_{jt}) = \gamma_j + \alpha_t + \delta Certified_{jt} + \varepsilon_{jt}, \quad (11)$$

where j indexes ejidos and t refers to the year of the land use layer. Results reported in column (1) of Table 6 show that certification had no effect on total area used for agriculture in Mexican ejidos. The coefficient is actually positive but very small (0.1%) and not significant. This suggests that migration driven by improved tenure security did not lead to a proportional fall in area dedicated to agriculture. If marginal farmers were fallowing land in order to migrate, then we should see a strong decrease in agricultural land after certification. The absence of this decrease suggests that unused land was being cultivated by larger farmers that did not send additional migrants.

In columns 2 and 3 we show that the overall land use response actually masks some interesting heterogenous effects by land quality. Column 2 shows that cultivated land actually increased with certification in agriculturally favorable areas but decreased in poorer areas. In column 3, we further control for differential time trends in high and low yield areas. The estimated coefficient shows that certification is associated with an insignificant decline of cultivated land in low-yield regions. Point estimates range from -0.8 to -1.8%. In contrast, agricultural land increases with certification in high agricultural productivity areas. The point estimate ranges from 1.3 to 1.6%, and the difference between favorable and non-favorable areas is significant.¹³

We showed in section 5.1 that improvements in property rights are associated with a decline in locality population. We conclude our analysis by verifying that the decline in population is actually taking place in areas where cultivated land decreased the most. For this analysis, we consider the

¹³ As a robustness check on the resolution of the landsat images, we ran all the regressions in Table 6 after dropping the smallest 5% of ejidos. The coefficients change only minimally and statistical significance is unaffected (results not reported).

overall change in log agricultural land between 1993 and 2007 using the Landsat data. The 10th and 90th percentiles of this measure are -0.17 and 0.54 log points. The median change in log of agricultural land in these data is .0001 while the mean is 0.111. To limit the influence of outliers, we use the rank of the ejidos in the distribution of change in cultivated land.¹⁴ The first two columns of Table 7 repeat the basic fixed effects regression of the locality population on whether the ejido has been certified separately for the localities with agricultural land use change below and above the median value. The table shows that the negative effect of certification on population size is confined to localities that also saw the largest decreases in agricultural land. For these localities, certification is associated with a 7.6% loss of population. The results are also presented in Figure 6. The leftward shift in the empirical distribution for localities in ejidos that were certified early is more pronounced in areas with changes in log agricultural land less than the median value (left panel). In column (3), this correlation is further verified with an interaction with the continuous variable for the rank in the distribution of agricultural land change. The triple interaction is positive and of the same order of magnitude as the double interaction between certification and year 2000. Hence, localities with the most pronounced declines in agricultural land ($rank = 0$) experienced a decline in population of 9.4% in response to certification, while localities in ejidos with the largest increase in agricultural land saw no effect of certification on population.

Figure 7 depicts the estimated marginal effect of certification, (i.e. $\delta = -0.0944 + 0.0993rank$), across the whole range of changes in agricultural land, with the corresponding 95% confidence band. The vertical line corresponds to approximately the 43rd percentile. Above this value, localities are in ejidos that experienced an increase in crop land between 1993 and 2007, and below in ejidos that experienced a decline. The effect δ of certification is estimated to be negative in all but those ejidos with the largest relative increases in agricultural land, and statistically negative in about 60% of the localities.

Wealth effects are an alternative explanation for our results. One possibility is that land certification increases liquid wealth and thus allows greater flexibility in sending migrants. The payments received from the renting out of land could be used to cover the fixed cost of migration. If this is the key mechanism driving our results then we should expect to see larger effects of certification in villages that were control villages for the experimental evaluation of Progresa. Households that were not receiving Progresa payments would have been more affected by limited liquidity and therefore more likely to respond to certification by increasing migration. In results not reported we split the localities according to Progresa treatment status and estimate separate versions of Equation (7). The coefficient on certification for Progresa treatment villages is .021 and that for control villages is .008. These results suggest that wealth effects are not a key driver of our results.

In summary, we interpret this last exercise as providing evidence that migration and land use are two sides of the same behavioral response induced by Procede. In areas of low land quality, land certification induced a strong migration response accompanied by a decline in cultivated land.

¹⁴The value of the variable Rank corresponds to the empirical distribution function of the change in the logarithm of agricultural land.

In more favorable areas, only the less well endowed households responded with migration, while the larger farmers did not migrate, and total land in agriculture did not decrease. This suggests that some land reallocation occurred within the ejido from smaller to larger farmers. There is unfortunately no direct evidence on these transactions, but our results are consistent with this interpretation.

6 Validity checks

We present several tests that support the validity of the identifying assumptions of the paper. The main threat to identification in the Progreso dataset is correlation between the timing of Procede and the time-path of migration in the ejido. The estimated average treatment effect would be biased if completion of Procede were correlated with pre-program changes in migration. To investigate the possibility of bias in program timing, we use a standard regression of *pre-program* changes in ejido level migration rates on indicators for the year Procede was completed:

$$\Delta y_{jt} = \gamma + \alpha_t + \sum_{k \geq t} \delta_k I(\text{Procede Year}_j = k) + \varepsilon_{jt} \quad \forall t \leq \text{Procede Year}_j. \quad (12)$$

The dependent variable Δy_{jt} is the change in the average level of the has-migrant household indicator in ejido j from year $t - 1$ to year t . The key independent variables are a set of dummy variables, $\text{Procede Year}_j = k$, for the year in which the program was completed in the ejido. Since the panel data covers the years 1997 to 2000, only three such variables are necessary for the ejidos certified in 1999, 2000, or after 2000.¹⁵ *Procede Year* effects that are jointly significant would indicate that year of program completion was correlated with pre-program changes in migration. The results are reported in Table 8. In the first column, we consider all the ejidos that completed certification during or after the year 1998 (and hence did not appear as certified in the data until 1999), and regress the change in migration between the 1997 and 1998 surveys on the set of dummy variables for the year of Procede completion. In column two, we restrict the analysis to the 94 ejidos that were certified during or after the year 1999, and for which we therefore observe two pre-program periods 1997-98 and 1998-99. We regress changes in migration in these two periods on ejido fixed effects, period fixed effects, and the year Procede was completed. And similarly with three pre-treatment observations for the 76 ejidos certified in 2000 or after, in column (3). The p-value of joint significance is 0.19, 0.49 and 0.74. Lack of a significant correlation between the year of Procede completion and changes in ejido level migration rates over time provides evidence that pre-program time trends in migration were not correlated with completion of the program.

Another possibility is that the timing of Procede is correlated with sharp changes in migration prior to the program. If Procede was rolled out in response to sharp declines in migration prior to the program, then our estimate would simply reflect reversion to mean migration levels and not the

¹⁵The base group would be ejidos certified in 1998 since we require the ejido to be certified at the start of the year to be considered as certified for that year.

desired treatment effect. Perhaps more likely, if households anticipated the program and reduced migration to oversee the certification process, then post-program returns to normal migration rates would confound our estimate. We estimate the following specification to consider this potential Ashenfelter dip effect,

$$y_{jt} = \gamma_j + \alpha_t + \beta_0 \cdot \text{Year of}_{jt} + \beta_1 \cdot \text{Year before}_{jt} + \beta_2 \cdot 2 \text{ Years before}_{jt} + \varepsilon_{jt}, \quad (13)$$

where y_{jt} is average migration at the ejido level, and other variables are indicators for the year of, year before, and two years before program completion. The β coefficients indicate whether migration levels were significantly different than average in the ejido during the years directly before the program. The fourth column of Table 8 gives the results of estimating (13). The point estimates are small and statistically insignificant, yet the standard errors are large. An ideal result of the regression would be a set of precisely estimated zeros on the three indicator variables. While we can not reject large coefficients, it is reassuring that there are no obvious significant changes in migration in the years leading up to completion of the program. We interpret the combined results in the table as providing no clear evidence that our identification strategy is biased by correlation between program completion and pre-program migration.

Another potential issue of concern is attrition of households from the ENCEL survey. Since migration recall from the 1998 survey was used to construct data for 1997, only households not being surveyed in 1999 and 2000 could bias results if attrition were non-random. Descriptively, 11.2% of households with an interview completed in 1998 did not have an interview completed in 1999. The percentage rose slightly to 12.7% in 2000.¹⁶ In Table 9 we run the basic regression used to identify the role of *Procede* on migration, equation (7), on attrition. The coefficient of the certified variable is both insignificant and very small. There is therefore no evidence that the migration effect we document in the previous section is due to selective attrition.

7 Conclusions

Improving property rights over rural land by guaranteeing security of access has been the objective of certification programs recently pursued in several countries. While the main argument for these efforts is that they should increase investment and production, we show that if property rights were tied to actual land use in the previous regime, these policies can also induce increased outmigration from agricultural communities. We provide evidence on this phenomenon by analyzing the Mexican ejido land certification program which, from 1993 to 2006, awarded ownership certificates to 3.6 million farmers on about half the country's farm land.

We documented a strong migration response in agricultural communities that obtained certificates along both the intensive and extensive margins. Families that obtained certificates are 28% more likely to have a migrant household member and the overall locality population falls by 5%. These effects are increasing over time.

¹⁶We define attrition as the interview not being conducted for any purpose.

We also documented heterogeneity in migration response according to the ex-ante level of property rights insecurity and the level of off-farm opportunities. At the community level, we find that the migration response is larger in lower land quality environments.

There is also evidence of sorting within the community: larger farmers stay, whereas land-poor farmers leave, and this effect is starker in high productivity areas. This prompts the question of whether total acreage under cultivation decreased with the program. We found that, on average, cultivated land was not reduced because of the program, which is consistent with gains in agricultural labor productivity. Additionally, we showed that in high productivity areas, the certification program actually led to increases in cultivated land compared to low productivity areas. Overall, the evidence shows that improvement in the security of access to land via certification increases the efficiency of labor allocation across space by inducing low productivity farmers to migrate, while leaving higher productivity farmers in place and allowing them to consolidate land.

One key implication of this result is that studies on the agricultural productivity effects of land titling programs need to pay careful attention to changes in the study population over time. Our results indicate that more marginal and less productive farmers are more likely to migrate after obtaining more secure ownership of land. This change in the composition of the population has important implications for studying productivity effects. Estimates of the effects of titling on productivity could be *biased upwards* if this migration/attrition is not properly addressed.

An important policy implication of the results is that the benefits of formal land certification in rural areas may be more complex than simple increases in agricultural productivity. Certification often removes a key distortion that resulted in an inefficient allocation of household labor between uses. Removal of this distortion allows households to more efficiently allocate labor between agricultural and off-farm activities.

Data Appendix

In this section we provide more details on construction of some of the data used in the analysis.

Progresa Data

Household level migration was taken from the 1998-2000 fall versions of the ENCEL survey. The survey was conducted each fall from 1998-2000 in the 506 localities that were part of the experimental evaluation of Progresa. Since no ejido identifiers were included in these data, we matched the 506 localities to ejidos using a spatial merge in ARCGIS. We only observe the coordinates of the centroid of each locality and therefore match localities to ejidos if the center of the locality is located inside the boundaries of the ejido. The digital maps of all ejidos certified from 1993-2006 were obtained from RAN. The spatial merge resulted in 234 of the localities falling into one of 219 different ejidos.¹⁷ The number of households from the 1998 survey that fell inside ejidos as a result of this process is 13,212. Another 4,893 households were removed from the sample as a result of being in ejidos that were certified before 1997. Since permanent migration is being measured, trends in migration are unlikely to be the same in ejidos certified prior to 1997 as those certified later. These ejidos are removed for this reason. It is also important to note that the spatial matching approach does not result in a perfect match between households and ejidos. It is possible that while the centroid of a locality falls into a particular ejido, the outskirts of the locality fall into a different ejido. This is more likely to be an issue in localities that are large. We used census population data to construct the ratio of the population of the locality to the number of ejidatarios in the matched ejido. The matching is more likely to be inaccurate when the locality is large relative to the ejido. We therefore retained only the 200 localities with the lowest values of this metric. This amounted to removing an additional 742 households from the sample. The total number of ejidos in the sample is 127.

1991 and 2007 Ejido Census

The 1991 and 2007 ejido censuses consist of a set of 28,752 ejidos that were surveyed in both 1991 and 2007. We were unable to obtain the name of each ejido due to confidentiality concerns. Further, the 2007 census did not contain information on the time of completion of *Procede*. A matching process was therefore necessary to make these data usable. The key information used were the state, municipality, and name of the locality where the majority of the ejidatarios live. We used this information along with some common key variables between the census data and the GIS database from RAN to match ejidos based on a 4-step process:

1. There were 22,473 ejidos for which the locality where a majority of the ejidatarios live is located inside the boundaries of the ejido. For these ejidos we were able to use our spatial

¹⁷This number is roughly consistent with half of Mexico's land being in ejidos. The large number of localities that were not matched to ejidos is therefore not a concern. The matching rate of 46% is actually in line with 50% of land being in ejidos.

merge between localities and ejidos to identify the corresponding ejido in the GIS database. There are of course numerous instances where the boundaries of an ejido contain more than one locality centroid. We were unable to include these ejidos in this matching round. This round matched a total of 14,128 ejidos.

2. The second round of matching is meant to partially correct for the fact that matching localities to ejidos in the previous step using only the centroid of the locality is imperfect. The reason for this is that the centroid of the locality could fall outside of the boundaries of the ejido even if there is substantial overlap between the locality and ejido. Further, ejidos with multiple disjoint patches of land pose problems to matching based on locality centroids and ejido boundaries. The distance between the locality centroid for each unmatched census ejido and the center of each unmatched ejido from the GIS database was calculated using a simple distance calculation in ARCGIS. An ejido from the GIS data was matched to an ejido from the census data if the locality where the majority of the ejidatarios live was the closest locality to the center of the ejido. Since this match is not perfect, we attempt to minimize errors by only retaining matches where the percentage difference between the number of ejidatarios in the 1991 census and the GIS database was between -46.8% and 29%.¹⁸ This round generated an additional 1,787 matches.
3. In this round we considered the remaining unmatched ejidos for which the locality where the majority of the ejidatarios live is located inside the boundaries of the ejido. We defined a potential candidate match from the GIS database as an unmatched ejido that was located in the same state and municipality. For each of these potential matches we considered 4 metrics of comparison. The first was the similarity between the name of the locality where the ejidatarios live and the name of the ejido in the GIS database.¹⁹ We generated a spelling similarity index using a combination of the COMPARE and SPEDIS functions in SAS. A match was identified for sufficiently low values of this index. The second metric was the distance between the centroid of the locality and ejido. The ejidos were considered to match if the distance was less than 5.1 kilometers.²⁰ The third metric was the number of ejidatarios. A match was determined using the same cutoffs as in the previous round. The final metric was the difference between the size of the ejido (in hectares) in the two datasets. The percentage cutoffs were -32.4 and 41.6. We required at least two of these criteria to be satisfied to identify a match between the ejidos. For each census ejido we selected the ejido from the GIS database which matched on the most of these criteria (from 2 to 4). In order to break ties we used the percentage difference in the number of ejidatarios. This round generated a total of 1,878 matches.
4. The fourth round of matches considers the census ejidos where it was stated that the locality

¹⁸These numbers were chosen as the 10th and 90th percentiles of the percentage difference from the ejidos matched in the previous round.

¹⁹It is common for ejido names to be the same as locality names in Mexico.

²⁰This value was chosen since it was the 10th percentile in the list of candidate matches.

where the majority of ejidatarios live is *not* inside the boundaries of the ejido. We used a similar process as in the previous round with only two modifications. First, similarities between the name of the locality and the ejido were not used. Second, the distance requirement was relaxed to 8.6 kilometers (25th percentile). This round generated 1,920 matches.

Tables

Table 1: Effect of Procede on Household Migration Behavior

	Progresa Households Matched to Ejidos					
	(1) Has Migrant	(2) Has Migrant	(3) Has Migrant	(4) Has Migrant	(5) Has Migrant	(6) Has Migrant

R squared	0.047	0.058	0.043	0.048	0.059	0.048

Standard errors that allow for clustering at the ejido level are reported in parentheses. Asterisks indicate statistical significance at the 1% ***, 5% **, and 10% * levels. Data include observations on all households in ejidos that completed the Procede process after 1996. All regressions are linear probability models. The dependent variable is 1 if the household had a migrant leave during the year or any previous sample year. Certified indicator = 1 if ejido was certified at the start of the year. Ejido characteristics in Column 6 are number of ejidatarios, number of posesionarios + avecindados, the total size of the ejido, longitude, and latitude.

Table 2: Effect of Procede on Locality Level Population, 1990-2000

	Census Localities Matched to Ejidos				Progresa Eligible Localities

Electrical Lighting in 1991		0.0384*** (0.0108)		0.0514*** (0.0110)
Log of Distance Between Ejido and PA Office		0.0528*** (0.0113)		0.0110 (0.0113)
State Fixed Effects	Yes	Yes	Yes	Yes
Mean of Dep Variable	0.426	0.426	0.297	0.297
Number of Observations	19670	19600	19670	19600
R squared	0.086	0.092	0.128	0.131

Standard errors that allow for clustering at the municipality level are reported in parentheses. Asterisks indicate statistical significance at the 1% ***, 5% **, and 10% * levels. The dependent variable in columns 1 and 2 is an indicator for the majority of the young people leaving the ejido. The question in the 2007 census identifies the ejidos where a majority of young people are integrated in the activities of the ejido or remain in the ejido but work in nearby localities. Finally, if neither of the prior conditions was true, the destination of the majority of the young people is identified. The variable "migrate" takes on a value of 1 if neither of the first two conditions was true. The dependent variable in Column 3 and 4 takes on a value of 1 only if the answer to the location of the majority of young people was the United States.

Table 4: Heterogeneous Effects of Certification on Migration

Mean of Dep Variable	5.718	5.714	5.714
Number of Observations	63392	58763	58763
R squared	0.012	0.012	0.012

Standard errors that allow for clustering at the ejido level are reported in parentheses. Asterisks indicate statistical significance at the 1% ***, 5% **, and 10% * levels. The dependent variable is the log of the area in agriculture in the ejido. *High Yield* is 1 if 2002-2007 average maize yield in the municipality of the ejido is larger than 1.293.

Table 7: Population Regressions by Change in Agricultural Area

	Rank>0.5	Rank<0.5	All
	(1) ln(Population)	(2) ln(Population)	(3) ln(Population)
Year=2000	-0.1523*** (0.0148)	-0.1194*** (0.0207)	-0.1097*** (0.0260)
Certified 1993-1999*Year=2000	-0.0144 (0.0189)	-0.0764*** (0.0237)	-0.0944*** (0.0305)
Rank of Ag Change * Year=2000			-0.0538 (0.0398)
Rank of Ag Change * Certified 1993-1999 * Year=2000			0.0993** (0.0483)
Ejido Fixed Effects	Yes	Yes	Yes
Mean of Dep Variable	3.378	3.557	3.455
Number of Observations	24526	18454	42986
R squared	0.007	0.009	0.008

Dependent variable in all regressions is log of locality population. Standard errors that allow for clustering at the ejido level are reported in parentheses. Asterisks indicate statistical significance at the 1% ***, 5% **, and 10% * levels. Data come from the 1990 and 2000 locality population censuses. The first column limits to localities in ejidos that experienced above the median change in log agricultural area from 1993-2007. The second column limits to localities in ejidos that experienced below the median changes. The final column is for all localities in ejidos that had nonzero agricultural land area in both 1993 and 2007.

Table 8: Relationship Between Procede and Pre-Program Migration

Number of Ejidos	111	94	76	127
R squared	0.047	0.019	0.002	0.774
Pvalue of joint test	0.190	0.493		

Standard errors are reported in parentheses. Robust standard errors are used in column 1. In columns 2-4, standard errors are clustered at the ejido level. Asterisks indicate statistical significance at the 1% ***, 5% **, and 10% * levels. The dependent variable in columns 1-3 is the change in ejido migration rate. The dependent variable in column 4 is the ejido migration rate. Both regressions are for the pre-treatment period. Columns 1 is for 1998. Column 2 is for 1998-1999. Column 3 is for 1998-2000. Column 4 is for 1997-2000.

Table 9: Regressions of Attrition on Certification Status and Household Covariates

	All	Progresa Control	Progresa Treatment

Standard errors that allow for clustering at the ejido level are reported in parentheses. Asterisks indicate statistical significance at the 1% ***, 5% **, and 10% * levels. Data are for all households that were surveyed in the Fall 1998 ENCEL survey. Observations are from 1999 and 2000. Dependent variable = 1 if household did not have survey completed. Certified indicator = 1 if household held title at the start of the year. 446 households attrited in 1999 but not in 2000. 331 households attrited in both 1999 and 2000. 554 households attrited in 2000 but not in 1999.

Standard errors that allow for clustering at the ejido level are reported in parentheses. Asterisks indicate statistical significance at the 1% ***, 5% **, and 10% * levels. Data include observations on all households in ejidos that completed the Procede process after 1996. Households in localities located within 1km of ejidos are included as additional controls. All regressions are linear probability models. The dependent variable is 1 if the household had a migrant leave during the year or any previous sample year. Certified indicator = 1 if ejido was certified at the start of the year.

R squared	0.029	0.041	0.047	0.032	0.043

Standard errors that allow for clustering at the ejido level are reported in parentheses. All non-ejidos are treated as a single ejido for generation of fixed effects and clustering of standard errors. Asterisks indicate statistical significance at the 1% ***, 5% **, and 10% * levels. Data include observations on all households in ejidos that completed the Procede process after 1996 and before 2000. Households in localities located within 1km of ejidos are the only controls. All regressions are linear probability models. The dependent variable is 1 if the household had a migrant leave during the year or any previous sample year. Certified indicator = 1 if ejido was certified at the start of the year.
