Sequestering uranium from seawater: binding strength and modes of uranyl complexes with glutarimidedioxime

Guoxin Tian,^a Simon J. Teat,^b Zhiyong Zhang^c and Linfeng Rao*^a

Glutarimidedioxime (H₂A), a cyclic imide dioxime ligand that has implications in sequestering uranium from seawater, forms strong tridentate complexes with UO₂²⁺. The stability constants and the enthalpies of complexation for five U(VI) complexes were measured by potentiometry and microcalorimetry. The crystal structure of the 1:2 metal/ligand complex, UO₂(HA)₂·H₂O, was determined. The re-arrangement of the protons of the oxime groups (-CH=N-OH) and the deprotonation of the imide group (-CH-NH-CH-) results in a conjugated system with delocalized electron density on the ligand (-O-N-C-N-C-N-O-) that coordinates to UO₂²⁺ via its equatorial plane.

Introduction

The concentration of uranium in the ocean is extremely low (3.3 µg/L). However, the total amount of uranium in the ocean is about 4.5 billion tons, a thousand times as much as the amount of uranium in terrestrial ores, because of the huge volume of seawater (1.4 × 10⁹ km³).^{1,2} Therefore, the ocean is an important source of uranium if it can be extracted economically. Extraction of uranium from seawater is very challenging, not only because it is in an extremely low concentration, but also because it exists in seawater as very stable carbonate complexes² in the presence of many other metal ions (Na, K, Ca, Mg, Al, and transition metals), some of which are in overwhelmingly higher concentrations.

Since the 1960's, various techniques have been studied and developed for the extraction of uranium from seawater, including solvent extraction, ion exchange, sorption with biomass, metal oxides (e.g., TiO₂), and functionalized sorbents.²⁻⁶ Among these, the Japanese process using amidoxime-based sorbents prepared by radiation grafting showed the best promise.^{5,6} A sorption efficiency of 1.5 g-U/kg sorbent was achieved in 30-day marine tests and the estimated cost was \$500/kg uranium, about 2-3 times the spot market price of uranium.¹ These results could justify the further development of industrial scale marine systems to extract uranium from seawater at a price competitive with those from conventional uranium resources. Critical aspects for improvements include higher efficiency, higher selectivity, and the recyclability of the sorbent.

A better understanding of the coordination modes and binding strength of the amidoxime group with uranium is the key to improving the extraction efficiency and selectivity. Unfortunately, very limited information on the complexation of

uranium with amidoxime is available in the literature and the nature of the uranium/amidoxime complex has not been clearly illustrated. For example, the amidoxime group -C(NH₂)NOH is expected to form a chelate complex with metal ions via the nitrogen atom of the amino group (-C(NH₂)) and the oxygen atom of the deprotonated -C(NO) group. Crystal structures of some amidoxime complexes with transition metals (Co, Ni, Cu, Mo and Pt) have confirmed the formation of such chelate complexes.⁷⁻¹⁴ However, the amidoxime ligand was found to be monodentate in the crystals of two amidoxime complexes with UO₂²⁺, where the amino group (-C(NH₂)) does not coordinate to UO₂²⁺.^{15,16}

Based on early studies using functionalized ion exchange resins,^{17,18} we have hypothesized that two types of amidoxime groups could form in the preparation of the sorbent, a cyclic imide dioxime and an open-chain diamidoxime (Scheme 1), and that the cyclic imide dioxime could be more effective than the open-chain diamidoxime for complexing UO₂²⁺ because the former can afford tridentate coordination (Scheme 1). To test this hypothesis and help improve the efficiency and selectivity of amidoxime-based sorbents for sequestering uranium, a small molecular ligand, glutarimidedioxime was synthesized and used as the water-soluble surrogate of the cyclic imide dioxime on the sorbent. The conditions for synthesizing the ligand were optimized. Its binding strength with UO₂²⁺, the enthalpy of complexation, and the coordination modes in the uranyl glutarimidedioxime complexes were investigated by multiple techniques including potentiometry, spectrophotometry, microcalorimetry, single crystal X-ray diffraction, and DFT calculations. In addition, the ability of glutarimidedioxime to compete with carbonate for binding UO₂²⁺ under seawater conditions was evaluated by spectrophotometry.

Scheme 1 Schematic idealized formation of open chain diamidoxime (upper) and cyclic imide dioxime (lower), and the possible coordination modes with UO_2^{2+} .

Experimental

5 Chemicals

All chemicals were reagent-grade or higher. Hydroxylamine (50 wt% solution in water, Aldrich), and glutaronitrile (99%, Sigma-Aldrich) were used as received. Boiled Milli-Q water was used in preparation of all solutions. All experiments were conducted at 25 °C and an ionic strength of 0.5 M (NaCl), close to the seawater condition of 3% NaCl. The stock solution of U(VI) was prepared by dissolving UO_3 into HCl. The concentrations of U(VI) and free H^+ in the stock solution were determined, respectively, by fluorimetry¹⁹ using standard solutions of U(VI) in 1 M H_3PO_4 and by the Gran titration.²⁰

Ligand synthesis

A procedure in the literature^{21,22,23} (Scheme 2) was adopted and optimized to prepare the ligand. Using the same starting materials at the molar ratio of 1:2 (glutaronitrile and hydroxylamine), different ligands (the cyclic glutarimidedioxime and the open chain glutardiamidoxime, named as H_2A and H_2B , respectively) could be prepared by controlling the reaction temperature. To obtain H_2A in high yields, 9.4 g glutaronitrile (99%) and 14.5 g hydroxylamine (50% in H_2O) were dissolved in 200 ml of 1/1 (V/V) ethanol/water and reacted at 80-90°C with stirring for 5 days, resulting in H_2A as a white solid with >90% yield.

Scheme 2 Preparation routes for glutarimidedioxime (upper) and glutardiamidoxime (lower).

Ligand H_2A was characterized by ¹H-NMR: H_2A (pyridine-₃₀ d_5), $-\text{CH}_2-\text{CH}_2-\text{CH}_2-$, 1.61 ppm, 2H; $-\text{CH}_2-\text{CH}_2-\text{C}(\text{NOH})\text{NH}-$, 2.49 ppm, 4H; $-\text{C}(\text{NOH})\text{NH}-\text{C}(\text{NOH})-$, 9.52ppm, 1H; $-\text{CH}_2-\text{C}(\text{NOH})\text{NH}-$, 12.16 ppm, 2H. The crystal structure of H_2A was also obtained by single-crystal X-ray diffractometry. The purity of H_2A was determined to be >99.5% with ¹H-NMR and potentiometry by titrating the H_2A solution with standard NaOH.

Potentiometry

The electrode potential (E , in millivolts) was measured with a Metrohm pH meter (Model 713) equipped with a Ross combination pH electrode (Orion Model 8102) under inert atmosphere (Ar). The original inner solution (3 M KCl) of the electrode was replaced with 1 M NaCl. Prior to each titration, an acid-base titration with standard HCl and NaOH solutions was performed to obtain the electrode parameters which allowed the calculation of hydrogen ion concentrations from the electrode potential in the subsequent titration. Multiple titrations were conducted with solutions of different concentrations of U(VI) (C_U as total [U(VI)]), ligand (C_A for the total ligand concentration including H_2A , HA^- , and A^{2-}), and acidity (C_H for total hydrogen ion, where $-C_H = C_{\text{OH}}$). For determining the protonation constant of the ligand, 20 mL of the ligand solution ($C_A = 0.01$ to 0.02 M; $C_H = (-0.02)$ to (-0.04) M), were titrated with 1.0 M HCl. 50–100 data points were collected in each titration. For determining the stability constants of the U(VI) complexes, 20 mL of U(VI)/ H_2A solutions (C_U : 0.20 – 0.50 mM; C_H : 2.0 – 4.0 mM; C_A : 1.0 – 2.0 mM) were titrated with 0.100 M NaOH. About 40 – 50 data points were collected for each titration. The protonation constants of the ligand and the stability constants of U(VI) complexes were calculated using the nonlinear regression program Hyperquad 2008.²⁴

60 Spectrophotometry

Spectrophotometric titrations of U(VI) were carried out on a Cary 6000i spectrophotometer (Varian Inc.) from 350 to 200 nm with an interval of 0.5 nm. Two types of titrations were performed: (1) a U(VI) solution was titrated with the buffered ligand solution; (2) a solution containing both U(VI) and the ligand was titrated with HCl. After each addition of the titrant, the solution was mixed thoroughly (for 1 – 2 minutes) before the spectrum was collected. Preliminary kinetic experiments showed that the complexation reaction was fast, and the absorbance became stable within 30 seconds of mixing. Usually, 15 – 20 additions were made, generating a set of 16 – 21 spectra in each titration.

Microcalorimetry

Calorimetric titrations were conducted at 25 °C with an isothermal microcalorimeter (Model: ITC 4200, Calorimetry Sciences Corp.) to determine the enthalpy of the reactions. Procedures and results of the calibration of the calorimeter were provided elsewhere.²⁵ Multiple titrations with different concentrations of U(VI), ligand and acidity were performed to reduce the uncertainty of the results. For the protonation of the ligand, 0.9 mL solution containing the ligand was placed in the reaction cell and titrated with 0.1 M HCl. For the complexation of U(VI) with the ligand, 0.9 mL solution containing U(VI), the ligand and H^+ was titrated with a solution of NaOH. Usually, n additions (0.005 mL each) of the titrant were made through a 0.250 mL syringe, resulting in n experimental values of total heat ($Q_{\text{ex},j}$, $j = 1$ to n , $n = 40 - 50$). These values were corrected for the heats of titrant dilution ($Q_{\text{dil},j}$) that were measured in a separate run. The net reaction heat at the j th point ($Q_{r,j}$) was obtained from the difference: $Q_{r,j} = Q_{\text{ex},j} - Q_{\text{dil},j}$. The value of $Q_{r,j}$ is a function of the concentrations of the reactants (C_U , C_A , and C_H), the equilibrium constants, and the enthalpies of the reactions that occurred in the titration. These data, in conjunction with the protonation constants and the stability constants of U(VI)

complexes obtained by potentiometry, were used to calculate the enthalpy of ligand protonation and complexation with U(VI) with the computer program HypDeltaH.²⁶

Single-crystal X-ray diffractometry

Colorless crystals of H₂A were grown by recrystallization in water solutions. Pale brown crystals of the 1:2 (metal:ligand) complex, UO₂(HA)₂(H₂O), were obtained by slow evaporation from 1 mL solution containing 1.0 mM UO₂²⁺ and 2.0 mM H₂A at pH 6-7. Representative crystals were mounted on the goniometer and crystallographic data were collected on the Small-Crystal Crystallographic Beamline 11.3.1 at the Advanced Light Source of Lawrence Berkeley National Laboratory (LBNL), using the Bruker APEX II CCD diffractometer of ω rotation with narrow frames at a wavelength of 0.77490 Å. Intensity data were collected within one hour using Bruker Apex 2 software.²⁷ Intensity data integrations, cell refinement, and data reduction were performed using the Bruker SAINT software package.²⁸ Absorption correction was made with SADABS.²⁹ Dispersion factors (*f'* and *f''*) at 16 keV for C, N, O and U atoms were calculated using CROMER for Windows.³⁰ The structure was solved with direct methods using SHELXS and refined using SHELXL.³¹ Non-hydrogen atoms were refined anisotropically. For the H₂A compound, hydrogen atoms on carbon atoms were placed geometrically and refined using a riding model. All other hydrogen atoms were found in the difference map and allowed to refine freely. For the compound UO₂(HA)₂(H₂O), the hydrogen atoms were found in the difference map and allowed to refine freely, except for those on the water molecules that are restrained and refined using a riding model. Details of the crystallographic data are provided in Table 1.

DFT calculation

Density Functional Theory (DFT) calculations with relativistic core potentials (RECP) were carried out to get the information of the electronic interactions in the U(VI) complex, UO₂(HA)₂. Starting from the geometry obtained from the crystal structure of UO₂(HA)₂(H₂O) in C₁ symmetry without including the water molecule, the calculations were performed with the generalized gradient approximation exchange and correlation functional using the NWChem program suite.^{32,33} We used the Stuttgart_RSC_1997_ECP effective core potential and basis set for U, and the Stuttgart_RLC_ECP effective core potential and basis set for C, N, and O, and the DZVP_(DFT_Orbital) basis set for H in the EMSL (Environmental Molecular Sciences Laboratory) Basis Set Library.^{34,35}

Results

Protonation of glutarimidedioxime

Figure 1 shows a representative potentiometric titration for the protonation of glutarimidedioxime. The titration curve can be fitted with three steps of protonation, from A²⁻, through HA⁻ and H₂A, to H₃A⁺. The calculated protonation constants are listed in Table 2. The first stepwise protonation constant (12.06) is typical for the oxime group (-NOH).^{36,37} The second stepwise protonation constant (10.7) is lower, indicating that the two oxime groups in H₂A are not completely independent and the protonation of one group reduces the basicity of the other

group.³⁶ The low value of 2.1 for the third protonation step indicates that the imide group in H₂A is a weak base and it can only be protonated at low pH.

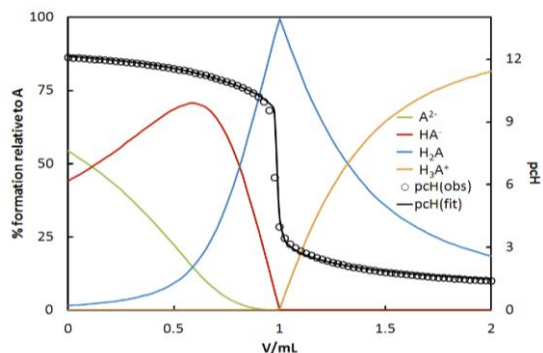

Fig. 1. Protonation titration of glutarimidedioxime. Initial cup solution: V = 20 mL, C_A = 0.016 M, C_H = -0.018 M. Titrant: 1 M HCl.

Complexation of U(VI) with glutarimidedioxime

Stability constants. Figure 2 shows a representative potentiometric titration of the complexation of U(VI) with glutarimidedioxime. The best model to fit the potentiometric data includes the formation of five U(VI) complexes, UO₂HA⁺, UO₂A, UO₂(HA)₂, UO₂(HA)₂A⁻, and UO₂A₂²⁻, as represented by eq.(1):

where *m* = 0, 1, or 2 and *n* = 1 or 2. The calculated stability constants for UO₂H_{*m*}A_{*n*}^{(2*n*-*m*-2)-} are listed in Table 2.

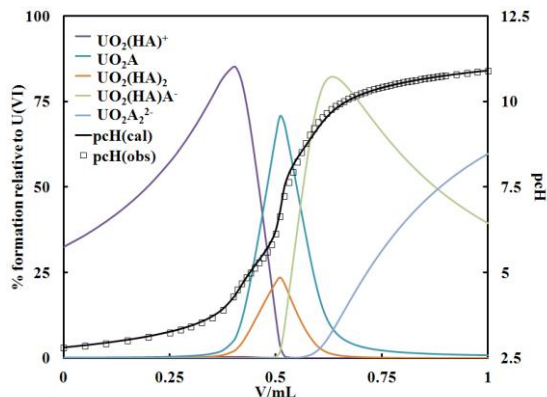

Fig. 2 Potentiometric titration for the complexation of H₂A with U(VI). Initial cup solution: V = 20 mL, C_T = 0.5 mM, C_A = 1.25 mM, C_H = 4.06 mM. Titrant: 0.1 M NaOH.

Spectrophotometric titrations were also conducted to study the U(VI) complexation with glutarimidedioxime. Figure 3a shows a titration of a U(VI) solution with the neutralized ligand, A²⁻. two significant changes in the spectra were observed as the ligand concentration was increased: 1) In the early part of the titration, two absorption bands at 230 and 280 nm appeared and increased; 2) after the ratio of the ligand to U(VI) reached 2, the intensity of the 280 nm band remained almost constant while that of the 230 nm band continued to increase. These features suggest that, as the ligand concentration was increased, U(VI)/H₂A complex(es) formed and the limiting species (in terms of the metal/ligand ratio) was the 1:2 U(VI)/H₂A complex(es).

Figure 3b shows a titration of U(VI)/H₂A complexes with HCl. As the acidity was increased, the intensity of the 280 nm band decreased and that of the 230 nm band increased (with slight red-shifts). In comparison with the reference spectra of the ligand at different pH, the spectra changes in Figure 3b indicate that the U(VI)/H₂A complexes dissociate in strongly acidic solutions due to the competition of H⁺ with U(VI).

Efforts were made to calculate the stability constants of U(VI) complexes with glutarimidedioxime, but these proved to be unsuccessful. The reason for the failure probably lies in the fact that we were monitoring the absorption spectra of the ligand. The absorption spectra of the ligand in different U(VI) complexes, such as UO₂HA⁺, UO₂A, UO₂(HA)₂, UO₂HA₂⁻, and UO₂A₂²⁻, may be too similar to be distinguished from each other.

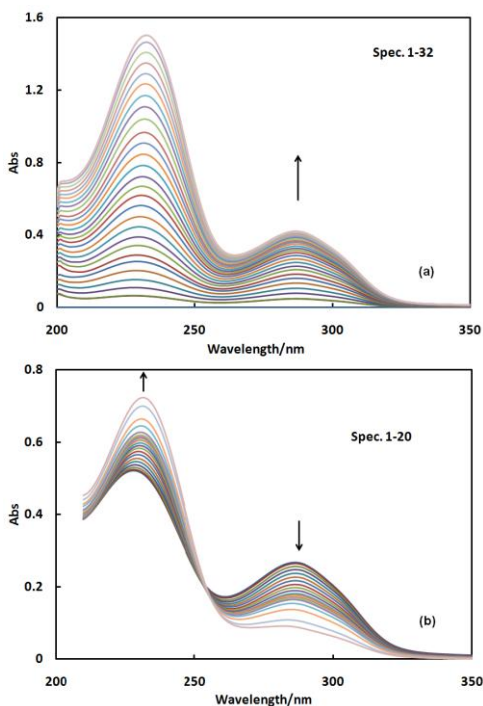

Fig. 3 Spectrophotometric titrations of complexation of U(VI) with H₂A. (a) Initial solution: $V = 2$ mL, $C_U = 0.05$ mM, $C_H = 0.005$ mM; titrant: $C_A = 1$ mM. (b) Initial solution: $V = 2$ mL, $C_U = 0.0261$ mM, $C_H = 0.106$ mM, $C_A = 0.05$ mM; titrant: $C_H = 1.0$ mM HCl.

Enthalpy of complexation. Figure 4 shows a representative calorimetric titration of U(VI) complexation with glutarimidedioxime. The total reaction heat, $Q_{r,i}$, as well as the distribution of U(VI) species, is shown as a function of the titrant volume. From the reaction heat and the stability constants of the U(VI) complexes, the enthalpies as well as the entropies of complexation were calculated and listed in Table 2.

Crystal structures of H₂A and UO₂(HA)₂(H₂O)

Single-crystal structures of the ligand H₂A, and the neutral 1:2 UO₂²⁺/HA⁻ complex, UO₂(HA)₂H₂O are shown in Figure 5. The U(VI) complex, UO₂(HA)₂H₂O, crystallized in a highly symmetrical structure with the *Pccn* space group symmetry. The uranium atom is at the center of inversion. The two HA⁻ ligands coordinate to the uranium center in a tridentate mode *via* the equatorial plane. The HA⁻ ligands are almost coplanar except for

the middle methylene groups. The O=U=O moiety is perfectly linear and symmetrical, with an angle of 180° and typical U=O distances of 1.7846 Å.

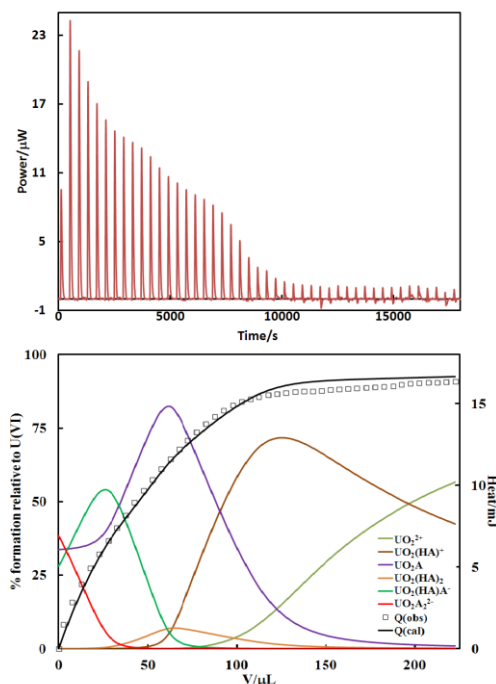

Fig. 4 Calorimetric titration of the complexation of U(VI) with H₂A at 25°C. Initial solution: $V = 0.9$ mL, $C_U = 0.6$ mM, $C_A = 1.0$ mM, $C_H = 0.11$ mM; titrant: 0.01 M HCl, 5.0 μL per addition. (upper) thermogram; (lower) total heat (right y axis) and speciation of U(VI) (left y axis) vs. the titrant volume.

Fig. 5 Crystal structures of H₂A (left) and UO₂(HA)₂·H₂O (right). 50% probability ellipsoids. All hydrogen atoms are found experimentally. The H₂O molecule is not shown for clarity.

Discussion

Electronic bonding interactions in UO₂(HA)₂(H₂O)

Two unusual and remarkable features are observed in the structure of the UO₂(HA)₂ complex: (1) the protons of both oxime groups (-CH=N-OH) are rearranged from the oxygen atom to the nitrogen atom; (2) the middle imide group (-CH-NH-CH-) is deprotonated, resulting in a -1 charged HA⁻ ligand that coordinates to UO₂²⁺ in a tridentate mode (*via* the two oxime oxygen atoms and the imide nitrogen atom). With such configuration, the electron density on the HA⁻ ligand could actually be delocalized on -O-N-C-N-C-N-O-, forming a conjugated system that strongly coordinates to UO₂²⁺. In fact, the bond length of the N-O bond of the oxime group is 1.42 Å in the H₂A molecule, but 1.35/1.36 Å in the UO₂(HA)₂ molecule (Figure 5). The significant shortening of the N-O bond upon complexation with UO₂²⁺ supports the above arguments for a

conjugated ligand system with delocalization of electron density on -O-N-C-N-C-N-O-.

DFT geometry optimization was carried out and the calculated bond lengths are compared with the experimental values in Table 3. For the U-O₃ (the axial O) and N₁-O₁ bonds, the difference between the calculated and the experimental is small (0.013 and 0.018 Å, respectively) and within the accuracy of typical DFT calculations. For the equatorial U-O₁, U-O₂ and U-N₃ bonds, the differences between the calculated and the experimental are 0.034, 0.066, and 0.128 Å, larger than those that can be explained by the uncertainties of DFT geometry optimization. Crystal packing effects, if there are any, could probably be the reason for such relatively large differences.

Table 3 Comparison of bond lengths (Å) in UO₂(HA)₂ between the experimental and calculated (same atom labeling as in Figure 5)

	U-O ₃	U-O ₁	U-O ₂	U-N ₃	N ₁ -O ₁
Experimental	1.785	2.535	2.430	2.563	1.362
Optimized	1.798	2.501	2.495	2.691	1.380
Difference	0.013	-0.034	0.066	0.128	0.018

The UO₂(HA)₂ complex can be formally described as UO₂²⁺(HA⁻)₂. For the UO₂²⁺ moiety, the Mulliken charges on the U and the axial O were calculated to be +0.51 and -0.07, respectively, indicating large donation of 1.63 e⁻ from the ligand to UO₂²⁺ and strong covalent bonding between UO₂²⁺ and HA⁻. For the ligand HA⁻ in the UO₂(HA)₂ complex, the calculated Mulliken charges on the oxime O and imide N are -0.38, and -0.42, respectively. In comparison, the Mulliken charges on the oxime O and imide N in the free HA⁻ ligand are -1.03, and -0.66, respectively, again indicating the donation of significant electron density from the ligand to UO₂²⁺ and strong covalent bonding.

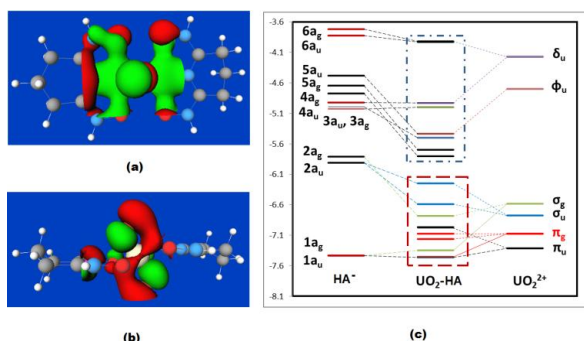

Fig. 6 Selected bonding orbitals in UO₂(HA)₂. (a) A strong bonding orbital between the uranyl σ_u and ligand $2a_u$; (b) a bonding orbital involving strong hybridization of the occupied σ and π orbitals on uranyl and hybridization between the N p orbitals in and perpendicular to the ligand plane; (c) molecular orbital diagram.

Two molecular orbitals (Figure 6a and 6b) and an orbital energy diagram (Figure 6c) are shown to illustrate the bonding interactions between UO₂²⁺ and the ligand (HA⁻) moieties. The highest occupied orbitals of UO₂(HA)₂ can be divided into two sets, the upper and lower sets spanning an energy range of 1.9 eV and 1.2 eV respectively, as indicated by the two boxes with dotted lines (Figure 6c). The upper set of orbitals of UO₂(HA)₂ are mostly non-bonding, essentially localized on the ligand moiety, with some contributions from the uranyl f δ and f ϕ orbitals as indicated by the dotted lines connecting the UO₂²⁺ and

HA⁻ orbitals. The lower set of orbitals of UO₂(HA)₂ are mostly comprised of the bonding orbitals of uranyl (π_u , π_g , σ_u and σ_g) and the $1a_u$, $1a_g$, $2a_u$ and $2a_g$ orbitals of HA⁻. Analysis of the calculated molecular orbitals indicates that the strongest bonding interactions between the ligand and uranyl are from the σ_u and σ_g orbitals on uranyl and the $2a_u$ and $2a_g$ orbitals on the ligands, as shown by the two molecular orbitals in Figure 6a and 6b, and the energy diagram in Figure 6c. The π_u and π_g orbitals of uranyl contribute to the bonding interactions but only to a modest extent. The bonding interaction of the orbital in Figure 6a results from the uranyl σ_u and ligand $2a_u$ orbitals. The interaction involves predominantly the ligand N lone pair p orbital with π character perpendicular to the ligand plane. The bonding interaction of the orbital in Figure 6b, on the other hand, results from the uranyl σ_g and ligand $2a_g$ orbitals. The interaction predominantly involves the ligand N lone pair p orbitals, but with strong hybridization between the N p orbitals with σ and π character, in and perpendicular to the ligand plane, respectively. The analysis unambiguously shows the critical role of the orbitals on the imide N atom, particularly the orbitals with π character perpendicular to the ligand plane, in binding the uranyl. Maximizing the electron donating ability of the imide N atom should result in stronger interactions with uranyl.

The ability of glutarimidedioxime to compete with carbonate for the sequestration of U(VI) under seawater conditions

Under the conditions of seawater (pH ~ 8.3), the predominant species of uranium is the very stable tricarbonate U(VI) complex, UO₂(CO₃)₃⁴⁻. Therefore, to be effective, the sequestering agent must be able to replace the carbonate in UO₂(CO₃)₃⁴⁻. With the stability constants of U(VI) complexes with glutarimidedioxime from this work (Table 2) and with carbonate from the literature,³⁸ the speciation of U(VI) under seawater conditions ($C_U = 3.3$ ppb, $C_{\text{carbonate}} = 0.0023$ M) is calculated with the speciation program associated with Hyperquad²⁴ and shown in Figure 7. At the seawater pH (8.3) and in the presence of 0.001 M glutarimidedioxime, more than 95% U(VI) is complexed by glutarimidedioxime (86% UO₂HA₂⁻, 8% UO₂A₂²⁻, 2% UO₂A) while UO₂(CO₃)₃⁴⁻ only accounts for 2% U(VI). This means that glutarimidedioxime is a much stronger complexant for U(VI) than carbonate at the seawater pH.

Fig. 7 Speciation of U(VI) ($C_U = 3.3$ ppb, $C_{\text{carbonate}} = 0.0023$ M, $C_A = 0.001$ M). 1 - UO₂A, 2 - UO₂HA⁺, 3 - UO₂A₂²⁻, 4 - UO₂HA₂⁻, 5 - UO₂H₂A₂, 6 - UO₂(CO₃), 7 - UO₂(CO₃)₂²⁻, 8 - UO₂(CO₃)₃⁴⁻.

It should be emphasized that the speciation of uranium in seawater is much more complex than what is indicated in Fig. 7.

As stated in the introduction section, many other metal ions (Na, K, Ca, Mg, Al, and transition metals) exist in seawater and some of them are in overwhelmingly higher concentrations than uranium. They will compete with uranium for the sorption sites of the amidoxime-based sorbents. Therefore, the ability of glutarimidedioxime to sequester U(VI) should be further evaluated in the presence of other major ions that exist in seawater. A study of the complexation of glutarimidedioxime with transition metals is underway.

Optical absorption spectra of U(VI) in the presence of glutarimidedioxime and carbonate were collected to further illustrate the competition between glutarimidedioxime and carbonate. As shown in Figure 8, ligand H₂A absorbs very strongly in the UV region (an absorption band centered around 230 nm). The complexes with U(VI) have absorption bands around 280 nm. As the concentration of carbonate was increased, the intensity of the 280 nm band gradually decreased, but remained significantly strong even if the concentration of carbonate was 10 times as high as the concentration of glutarimidedioxime. This means that glutarimidedioxime can effectively compete with carbonate for complexing U(VI) at seawater pH conditions. It should be noted that the aqueous complexation experiments provide only qualitative evaluation of the ability of glutarimidedioxime for sequestering U(VI). When glutarimidedioxime is grafted on solid substrates, its effective concentration and ability of sequestering U(VI) could be higher than those observed in the above experiments.

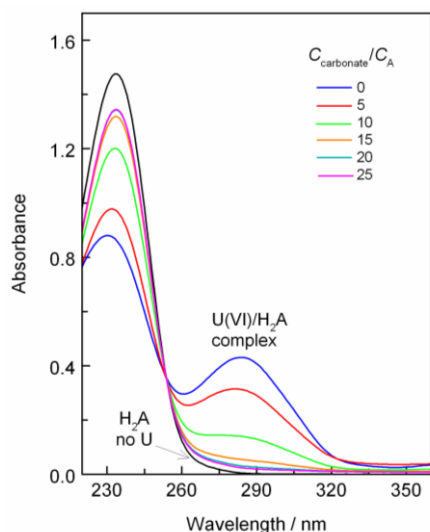

Fig. 8 Absorption spectra showing the competition of H₂A with carbonate for complexing uranium. $C_U = 0.05$ mM except for one spectrum where $C_U = 0$ mM. $C_A = 0.10$ mM; $C_{\text{carbonate}}/C_A = 0 - 25$; pH 8.1 – 8.3.

Effect of temperature on the complexation

The temperature of seawater changes with locations, season and time, which could have significant impact on the efficiency of U(VI) sequestration from seawater if the sequestration reaction has strong temperature dependency. The enthalpies of complexation measured in this work allow the evaluation of the effect of temperature on the complexation of glutarimidedioxime with U(VI) under seawater conditions.

Based on the thermodynamic parameters on the speciation of

carbonate,³⁷ glutarimidedioxime and its complexes with U(VI) (Table 2), the dominant species under seawater pH are HCO₃⁻, H₂A, UO₂(CO₃)₃⁴⁻, and/or UO₂(HA)A⁻, respectively. Therefore, the major overall reaction can be written as:

Using the enthalpy values for HCO₃⁻ and UO₂(CO₃)₃⁴⁻ in the literature^{37,38} and for H₂A and UO₂(HA)A⁻ from this work (Table 2), the enthalpy of reaction (2) is calculated to be +16.7 kJ/mol. This means that the overall sequestration of U(VI) from seawater by glutarimidedioxime is endothermic, and that the efficiency of sequestration is enhanced at higher temperatures. This thermodynamic analysis confirms the observation in the marine experiments in Japan that the U(VI) extraction efficiency was higher from warmer seawaters.^{5,6} The marine experiments in Japan showed a 1.5 times increase in the efficiency when the seawater temperature increased by 10°C.^{5,6} In fact, using the van't Hoff equation and the enthalpy of reaction (2) (+16.7 kJ/mol), it is estimated that the equilibrium constant of reaction (2) at 20°C would be 1.3 times that at 10°C, in excellent agreement with the observations in the marine experiments.

The enthalpies of complexation for the five U(VI) complexes with glutarimidedioxime are all negative (Table 2), but the enthalpy of reaction (2) is positive (unfavorable to the sequestration of U(VI) from seawater by glutarimidedioxime). One of the reasons for the endothermic enthalpy of reaction (2) is that the dissociation of UO₂(CO₃)₃⁴⁻ is highly endothermic (+39.2 kJ/mol).³⁸ Based on this observation, we hypothesize that direct sorption of UO₂(CO₃)₃⁴⁻ with an anionic sorbent could be favored by the enthalpy of reaction, a research area to be explored in future studies.

Summary

Glutarimidedioxime (H₂A) was synthesized with high yields by controlling the temperature of the reaction between glutaronitrile and hydroxylamine. It was studied as the small molecular water-soluble surrogate for the amidoxime-based sorbents that have been used for the sequestration of uranium from seawater. Glutarimidedioxime was found to form very strong tridentate complexes with UO₂²⁺. At the seawater pH, glutarimidedioxime could effectively compete with carbonate for complexing UO₂²⁺. The crystal structure of a 1:2 uranyl/ligand complex, UO₂(HA)₂, in conjunction with DFT calculations, reveals the coordination modes and the nature of the electronic interactions in UO₂(HA)₂.

Results from this work reveals that the unusual deprotonation of the imide group and the rearrangement of the protons in the oxime groups result in a large conjugated ligand system that strongly coordinates to UO₂²⁺ via its equatorial plane in a tridentate mode. This work also suggests that conducting the grafting/reaction process for preparing the sorbent at 80-90°C helps to achieve high yields of glutarimidedioxime, a preferred cyclic imide dioxime ligand, and that increasing the electron donation ability of the imide nitrogen atom in glutarimidedioxime could significantly enhance the binding ability of the ligand towards UO₂²⁺.

Acknowledgments

This work was supported by the Uranium Resources Program, Fuel Cycle Research and Development Program, Office of Nuclear Energy of the U.S. Department of Energy (DOE) under Contract No. DE-AC02-05CH11231 at Lawrence Berkeley National Laboratory (LBNL). Single-crystal X-ray diffraction data were collected and analyzed at the Advanced Light Source (ALS). ALS is supported by the Director, Office of Science, Office of Basic Energy Sciences, U.S. DOE under Contract No. DE-AC02-05CH11231. The National Nanotechnology Infrastructure Network (NNIN) of Stanford University is acknowledged for computational resources.
