We present a case of a 71-year-old male that was involved in a high-speed motor vehicle collision, as an unrestrained back seat passenger. On primary survey, decreased breath sounds and bowel sounds were auscultated in the left thorax. Secondary survey was positive for left anterior chest wall tenderness. Chest radiograph demonstrated multiple rib fractures, hemothorax, and diaphragmatic rupture with herniation of bowel loops into the chest cavity (Figure 1). Upon insertion of a nasogastric tube, repeat radiograph demonstrated the nasogastric tube to be in the left upper abdomen (Figure 2). The patient underwent emergency laparotomy for repair of his injury. Incidentally, a splenic laceration was identified intraoperatively. Successful repair of the diaphragmatic injury as well as splenectomy was achieved.

DISCUSSION

Diaphragmatic rupture is a relatively rare injury with a reported incidence of 1 to 7% of all patients following significant blunt trauma. In a review of 1589 patients, Asensio et al reported that 75% had left sided injuries, 23% had right-sided injuries, and 2% had bilateral injuries. This preponderance for left-sided injuries is thought to be related to the protective effect of the bare area of the liver in contact with the diaphragm in the right thorax. The pathophysiology in blunt trauma is due to the abrupt change in intraabdominal pressure that is thought to cause the majority of injuries, although shearing and/or avulsion can also occur especially following lateral trauma. The differential includes: pneumothorax, hemothorax, liver injury, bowel injury, rib fractures, splenic injury and kidney injury. Radiographically, the diagnosis is made via chest radiograph demonstrating: nasogastric tube in the chest, herniated loops of bowel within the chest, with or without focal constriction of the viscus. The gold standard of treatment is emergent laparotomy. The prompt and accurate diagnosis of diaphragmatic rupture is paramount for optimal patient outcome.
