1. Introduction

Coupled modeling of subsurface multiphase fluid and heat flow, solute transport and chemical reactions can be used for the assessment of mineral alteration in hydrothermal systems, waste disposal sites, acid mine drainage remediation, contaminant transport, and groundwater quality. A comprehensive non-isothermal multi-component reactive fluid flow and geochemical transport simulator, TOUGHREACT, has been developed. A wide range of subsurface thermo-physical-chemical processes is considered under various thermohydrological and geochemical conditions of pressure, temperature, water saturation, and ionic strength. The program can be applied to one-, two- or three-dimensional porous and fractured media with physical and chemical heterogeneity. The model can accommodate any number of chemical species present in liquid, gas and solid phases. A variety of equilibrium chemical reactions are considered, such as aqueous complexation, gas dissolution/exsolution, and cation exchange. Mineral dissolution/precipitation can proceed either subject to local equilibrium or kinetic conditions. Changes in porosity and permeability due to mineral dissolution and precipitation can be considered. Linear adsorption and decay can be included. For the purpose of future extensions, surface complexation by double layer model is coded in the program.

Xu and Pruess (1998) developed a first version of a non-isothermal reactive geochemical transport model, TOUGHREACT, by introducing reactive geochemistry into the framework of the existing multi-phase fluid and heat flow code TOUGH2 (Pruess, 1991). Xu, Pruess, and their colleagues have applied the program to a variety of problems such as: (1) supergene copper enrichment (Xu et al, 2001), (2) caprock mineral alteration in a hydrothermal system (Xu and Pruess, 2001a), and (3) mineral trapping for CO₂ disposal in deep saline aquifers (Xu et al, 2003b and 2004a). For modeling the coupled thermal, hydrological, and chemical processes during heater tests at proposed nuclear waste disposal site at Yucca Mountain (Nevada), Sonnenthal and Spycher (2000) and Spycher et al. (2003) enhanced TOUGHREACT on (1) high temperature geochemistry, (2) mineral reactive surface area calculations, and (3) porosity and permeability changes due to mineral alteration. On the other hand, Pruess et al. (1999) updated the TOUGH2 simulator to TOUGH2 V2. The present version of TOUGHREACT was developed by introducing the work of Sonnenthal and Spycher (2000) to the original work of Xu and Pruess (1998), and by replacing TOUGH2 (Pruess, 1991) by TOUGH2 V2 (Pruess et al, 1999).

The TOUGHREACT program makes use of “self-documenting” features. It is distributed with a number of input data files for sample problems. Besides providing benchmarks for proper code installation, these can serve as self-teaching tutorial in the use of TOUGHREACT, and they provide templates to help jump-start new applications. The fluid and heat flow part of TOUGHREACT is derived from TOUGH2 V2, so in addition to the current manual, users must have manual of the TOUGH2 V2 (Pruess et al., 1999).

The present version of TOUGHREACT provides the following different TOUGH2 fluid property or “EOS” (equation-of-state) modules: (1) EOS1 for water, or two waters with typical applications to hydrothermal problems, (2) EOS2 for multiphase mixtures of water and CO₂ also with typical applications to hydrothermal problems, (3) EOS3 for multiphase mixtures of water and air with typical applications to vadose zone and nuclear waste disposal problems, (4) EOS4 that has the same capabilities as EOS3 but with vapor pressure lowering effects due to capillary pressure, (5) EOS9 for single phase water (Richards’ equation) with typical applications to ambient reactive geochemical transport problems, (6) ECO2 for multiphase mixtures of water, CO₂ and NaCl with typical applications to CO₂ disposal in deep brine aquifers.

2. Requirements

2.1. Computer Requirements and Code Installation

Like TOUGH2, TOUGHREACT is written in FORTRAN 77. It has been tested on various computer platforms, including PCs, SUN Ultrasparc systems, Compaq Alpha-based workstations, and IBM RISC System/6000 workstations. An effort was made to have the TOUGHREACT source code comply with the ANSIX3.9-1978 (FORTRAN 77) standard, and on most machines the code should compile and run without modification. TOUGHREACT (like TOUGH2 V2) requires 64-bit arithmetic (8 byte word length for floating point numbers) for successful execution. Two versions of TOUGHREACT source program are available on the distribution compact diskette (CD). One contains IMPLICIT DOUBLE PRECISION (A-H, O-Z) and IMPLICIT INTEGER*8 (I-N) statements that will automatically generate 64-bit arithmetic on 32 bit processes. Another contains the same but only without the INTEGER*8 statements, because most PC compilers do not recognize the *8 statements. The latter version may require special compiler options to generate 64-bit code at compile time. The distribution CD includes a README file, the documentation (this manual), source files, some executable files generated from COMPAQ Visual Fortran compiler 6.6 on PC, and sample problems. Several MAKEFILES for different computer platforms such as SUN SPARC Workstation, Compaq (DEC) ALPHA Workstation, Intel Fortran Compiler on linux, Mac PPC, and IBM RISC System/6000 workstation are provided in a subdirectory of the CD. Details on compilation, linking, and program installation and execution are given in the README file.

2.2. Memory Requirements

The computer memory required by TOUGHREACT depends on the problem size. Parameter statements are used in two INCLUDE files: T2 (for fluid and heat flow dimension parameters) and CHEMPAR23.INC file (for chemistry dimension parameters). All major arrays in the problem are automatically adjusted according to these dimension parameters. Different problems can be modeled by changing the dimensions in the parameter statements, and subsequently compiling all source files, and then linking them for creating an executable file. In the distribution CD, some major dimensioning variables, MNEL = 8000 (maximum number of

grid blocks), MNCON = 20000 (maximum number of connections), MPRI = 20 (maximum number of primary species), MAQX = 70 (maximum number of secondary species), MMIN = 32 (maximum number of minerals), and MGAS = 5 (maximum number of gaseous species), and MEXC = 5 (maximum number of cation exchanged species) are specified in the two INCLUDE files.

At the beginning of a simulation, the program automatically checks the array dimensions related to reactive geochemistry. If the dimensions are insufficient for the specific problem, it provides the user a message to change the parameter statements.

As an example, a 2-D problem of the Drift Scale Test at Yucca Mountain (Nevada) with 8,000 grid blocks, 22 minerals, 14 primary aqueous species, 46 secondary aqueous species, and 2 gaseous species were handled with TOUGHREACT on a Compaq (DEC) ALPHA Workstation (similar to Sample Problem 4 presented in this manual).

2.3. User Knowledge Requirements

The correct implementation, setup, problem formulation, and interpretation of the results of TOUGHREACT requires knowledge of the basic equations of multiphase non-isothermal fluid flow and transport in geologic media and a basic understanding of the numerical solution of the equations that are used to describe these processes. In addition, the formulation of the geochemical problem requires familiarity with geochemical modeling and an in-depth understanding of the system that is being modeled and of the data used for input to the model. The model boundary conditions, time step length, convergence criteria, and grid properties are crucial elements for a realistic and accurate solution to a problem. The input for flow parameters is exactly the same as in the original TOUGH2. A comprehensive reference of TOUGH2 input formats along with illustrative sample problems is provided in the TOUGH2 user's guide (Pruess et al., 1999). This information is essential for successful application of TOUGHREACT; it is not duplicated in the current manual.

3. Model Description

3.1. Main Scope of the Model

TOUGHREACT is applicable to one-, two-, or three-dimensional geologic domains with physical and chemical heterogeneity. TOUGHREACT can be applied to a wide range of subsurface conditions. Temperature ranges from 0 °C to 300 °C, because the present most available geochemical database is up to 300 °C such as EQ3/6 (Wolery, 1992). Pressure can be from 1 bar (atmospheric pressure) to several hundred bars (at several thousand meter depth). Water saturation can range from completely dry to fully water saturated. The model can deal with ionic strength from diluted to highly saline water (up to 6 mol/kg H₂O for NaCl dominant solution, see Appendix H for details).

TOUGHREACT is applicable to a variety of reactive fluid and geochemical transport systems, including (1) contaminant transport with linear K_d adsorption and decay (Sample problem 1), (2) natural groundwater quality evolution under ambient conditions (Sample 2), (3) assessment of nuclear waste disposal sites (Samples 3-4), (4) sedimentary diagenesis and CO₂ disposal in deep formations (Sample 5), (5) mineral deposition such as supergene copper enrichment (Sample 6), and (6) mineral alteration and silica scaling in hydrothermal systems under natural and production conditions (Samples 7-8),

3.2. Major Processes

The present model for fluid flow and geochemical transport has three important features: (1) the gas phase is active for multiphase fluid flow, mass transport and chemical reactions, (2) we consider not only porous media, but also reactive fluid flow and transport in fractured rocks, (3) the effects of heat are considered, including heat-driven fluid flow, and temperature-dependent thermophysical and geochemical properties (such as fluid density and viscosity, and thermodynamic and kinetic data).

Transport of aqueous and gaseous species by advection and molecular diffusion is considered in both liquid and gas phases. Any number of chemical species in liquid, gas and solid phases can be accommodated. Aqueous complexation, acid-base, redox, gas dissolution/exsolution, and cation exchange, are considered under the local equilibrium

assumption. Mineral dissolution and precipitation can proceed either subject to local equilibrium or kinetic conditions. Linear adsorption and decay can be included.

3.3. Governing Equations

The primary governing equations for multiphase fluid and heat flow, and chemical transport have the same structure, derived from the principle of mass (or energy) conservation. These equations are presented in Appendix A. Major processes considered for non-isothermal fluid and heat flow are: (1) fluid flow in both liquid and gas phases occurs under pressure, viscous and gravity forces; (2) interactions between flowing phases are represented by characteristic curves (relative permeability and capillary pressure), (3) heat flow occurs by conduction and convection. Aqueous (dissolved) species are subject to transport in the liquid phase as well as to local chemical interactions with the solid and gas phases. Transport equations are written in terms of total dissolved concentrations of chemical components, which are concentrations of the basis species plus their associated aqueous secondary species (Yeh and Tripathi, 1991; Steefel and Lasaga, 1994; Walter and others, 1994; Lichtner, 1996; and Xu and Pruess, 2001b). If kinetically-controlled reactions occur between aqueous species, then additional ordinary differential equations need to be solved to link the total concentrations of the primary species with the evolving concentrations of the secondary species (Steefel and MacQuarrie, 1996). Kinetically-controlled reactions between aqueous species are not considered in the present version. Slow aqueous phase reactions are common in the case of redox reactions and will be addressed in future development. Advection and diffusion processes are considered for both the liquid and gas phases, and their coefficients are assumed to be the same for all species. The local chemical interactions in the transport equations are represented by reaction source/sink terms.

The primary governing equations must be complemented with constitutive local relationships that express all parameters as functions of fundamental thermophysical and chemical variables. Expressions for non-isothermal multiphase flow are given by Pruess (1987). The equations for chemical reactions are presented in Appendix B. Mass conservation in the closed chemical system is written in terms of basis (component) species. The species distribution must be governed by the total concentrations of the components. The oxygen approach is used for formulating redox reactions which is based on attributing the oxidizing potential to the dissolved oxygen (Nordstrom and Muñoz, 1986; Wolery, 1992). In contrast to the free electron in the

hypothetical electron approach (Yeh and Tripathi, 1991), oxygen can be present and be transported in natural subsurface flow systems. The formulation for cation exchange is similar to Appelo and Postma (1993). A formulation for surface complexation (Dzombak and Morel, 1990) is implemented in the program but it has not been tested. Further details on model formulation are given in Xu et al. (1997). For kinetically-controlled mineral dissolution and precipitation, a general form of rate law (Lasaga, 1984; and Steefel and Lasaga, 1994) is used (see Appendix B). Thermodynamic and kinetic data are functions of temperature, which are solved from fluid and heat flow equations.

Temporal changes in porosity and permeability due to mineral dissolution and precipitation processes can modify fluid flow. This feedback between transport and chemistry can be important (Raffensperger, 1996), and can be considered in our model. Changes in porosity during the simulation are calculated from changes in mineral volume fractions. The porosity-permeability correlation in geologic media is very complex, depending on an interplay of many factors, such as pore size distribution, pore shapes, and connectivity (Verma and Pruess, 1988). Several functional porosity-permeability relationships are included in the model (see Appendix F). Alternatively, the model can only monitor changes in porosity and permeability during the simulation from changes in mineral volume fractions, but neglect their effects on fluid flow. By neglecting porosity and permeability change we obtain quasi-steady flow conditions. This greatly simplifies the numerical solution and makes it possible to consider geochemistry in great detail. In addition, changes in porosity may be small over limited time spans.

3.4. Simplifying Approximations

Hydrodynamic dispersion is an important solute transport mechanism that arises from an interplay between non-uniform advection and molecular diffusion. In geologic media, velocities of fluid parcels are spatially variable due to heterogeneities on multiple scales, all the way from pore scale to basin scale. The process is often represented by a Fickian diffusion analog (convection-dispersion equation), which has fundamental flaws and limitations, as has been demonstrated in numerous studies in the hydrogeology literature of the last twenty years. Although field tracer tests can generally be matched with the convection-dispersion equation, such matching and associated parameters have little predictive power. There is much evidence that when a Fickian dispersion model is calibrated to field tracer data, such success does not

indicate that a realistic description of in-situ solute distribution has been attained. Dispersivities are generally found to increase with space and time scale of observation (Gelhar et al., 1992). Observed dispersivities are only partly due to mixing and dilution in-situ; they also reflect the mixing that occurs when subsurface flow systems are observed (perturbed) and sampled, as when fluids are extracted from wells (Chesnut, 1994). It has been established that Fickian dispersion implies an unrealistically large level of mixing and dilution (Kapoor et al., 1997). Fickian plumes represent a probability distribution, not a distribution of solute; they strongly overestimate dilution in any particular representation of a heterogeneous medium. This can produce erroneous predictions for transport, and even more unrealistic consequences for reactions that depend on concentrations in a non-linear manner. Fickian dispersion also gives rise to spurious upstream dispersion opposing the direction of advective flow. For these reasons, we are not using a Fickian model for dispersion. Instead, hydrodynamic dispersion is modeled through appropriate spatial resolution on multiple scales, using multiple continua (or multi-region) models (Pruess and Narasimhan, 1985; Gwo et al., 1996) to describe interactions between fluid regions with different velocities.

We currently neglect deformation of the porous skeleton. Heat effects from chemical reactions are neglected in our current model, as are changes in thermophysical properties of fluid phases (such as viscosity, surface tension, and density) due to changes in chemical composition.

4. Solution Method

Figure 4.1 shows the flow chart for solving the coupled non-isothermal multiphase fluid flow, solute transport and reactive geochemistry.

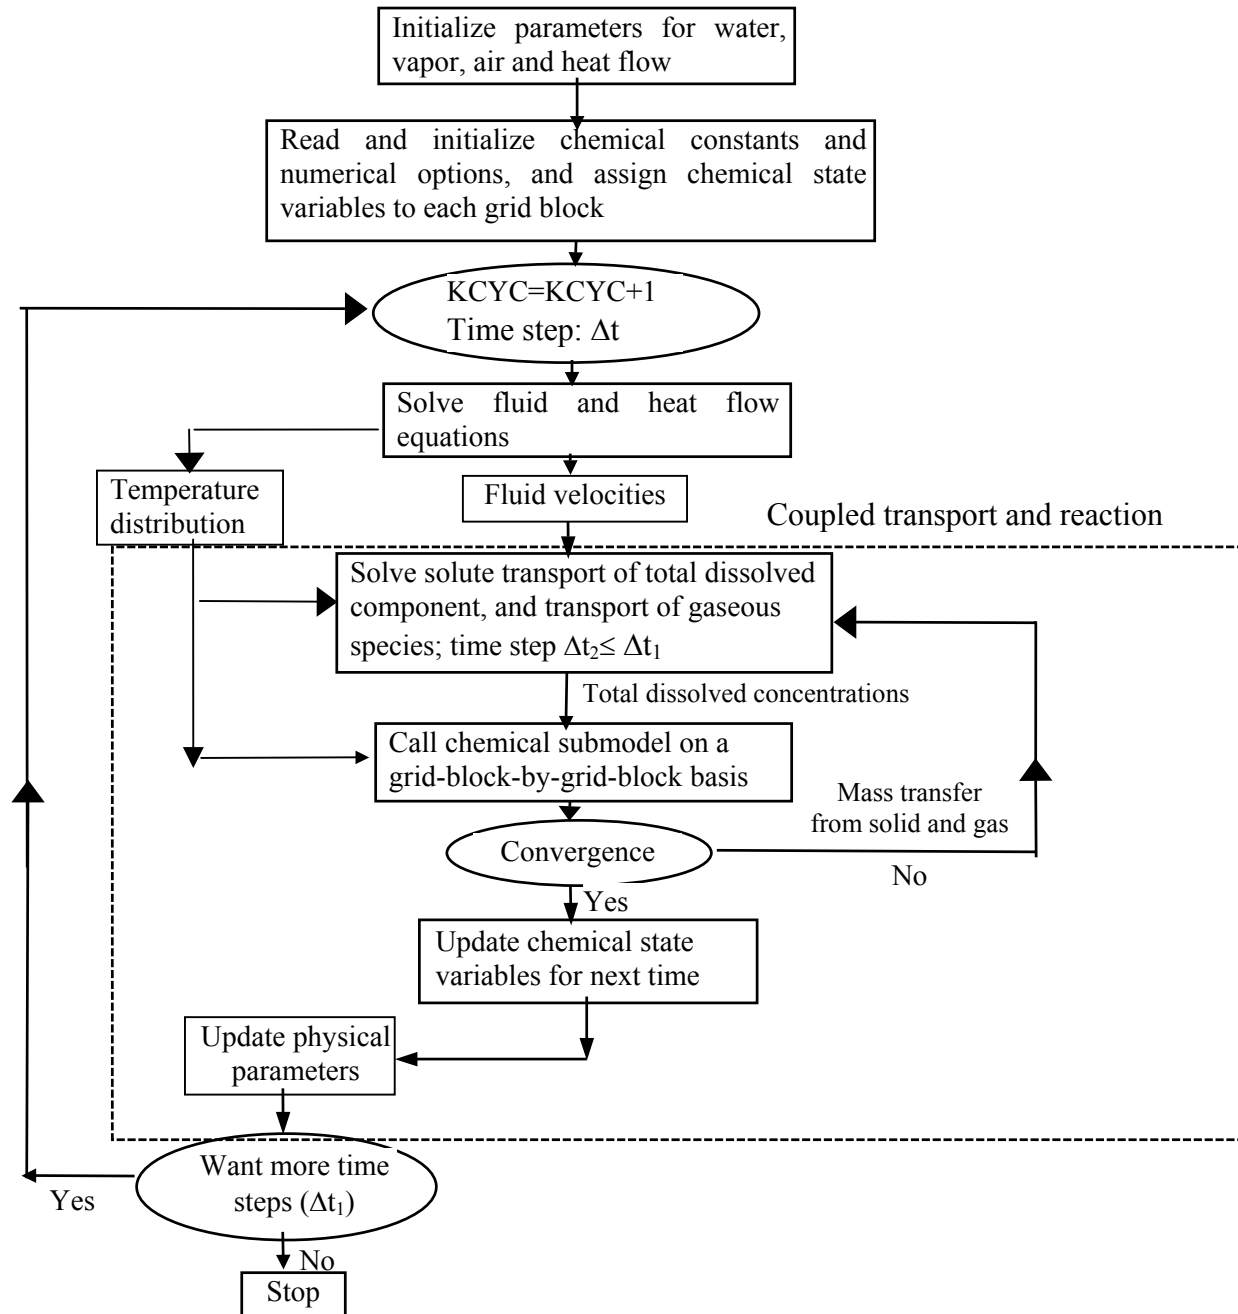

Figure 4.1. Flow chart of TOUGHREACT program.

The numerical solution of multi-phase flows proceeds as in TOUGH2. We employ space discretization by means of integral finite differences (IFD; Narasimhan and Witherspoon, 1976). Because chemical transport equations (derived from mass conservation) have the same structure as fluid and heat flow equations, the transport equations can be solved by the same numerical method. The discretization approach used in the IFD method and the definition of the geometric parameters are illustrated in Figure 4.2. The basic mass- (for water, air, and chemical component) and energy (for heat) balance equations are written in integral form for an arbitrary domain V_n

$$V_n \frac{\Delta M_n}{\Delta t} = \sum_m A_{nm} F_{nm} + V_n q_n \quad (4.1)$$

where subscript n labels a grid block, subscript m labels grid blocks connected to grid block n , Δt is time step size, and M_n is the average mass or energy density in grid block n . Surface integrals are approximated as a discrete sum of averages over surface segments A_{nm} , F_{nm} is the average flux (of mass or energy) over the surface segment A_{nm} between volume elements n and m , and q_n is the average source/sink rate in grid block n per unit volume. Time is discretized fully implicitly as a first-order finite difference to achieve unconditional stability. More detail on the numerical discretization is given in Pruess and Narasimhan (1985). The IFD method gives a flexible discretization for geologic media that allows to use irregular grids, which is well suited for simulation of flow, transport, and fluid-rock interaction in multi-region heterogeneous and fractured rock systems. For systems with regular grids, IFD is equivalent to conventional finite differences.

Figure 4.2. Space discretization and geometry data in the integral finite difference method.

Time discretization of fluid and heat flow equations results in a set of coupled non-linear algebraic equations for the thermodynamic state variables in all grid blocks as unknowns. These are solved by Newton-Raphson iteration method as implemented in the original TOUGH2 simulator (Pruess, 1991). The set of coupled linear equations arising at each iteration step is solved iteratively by means of preconditioned conjugate gradient methods (Moridis and Pruess, 1998).

TOUGHREACT uses a sequential iteration approach (SIA) similar to Yeh and Tripathi (1991), Engesgaard and Kipp (1992), Simunek and Soares (1994), and Walter et al. (1994). After solution of the flow equations, the fluid velocities and phase saturations are used for chemical transport simulation. The chemical transport is solved on a component basis (Details on solution method are given in Appendix C). The resulting concentrations obtained from the transport are substituted into the chemical reaction model. The system of mixed equilibrium-kinetic chemical reaction equations is solved on a grid-block basis by Newton-Raphson iteration (details are given in Appendix D). The chemical transport and reactions are iteratively solved until convergence. An automatic time stepping scheme is implemented in TOUGHREACT, which includes an option to recognize "quasi-stationary states" (QSS; Lichtner, 1988) and perform a "large" time step towards the end of a QSS.

As an alternative to the sequential iterative approach, a sequential non-iterative approach (SNIA) may be used, in which the sequence of transport and reaction equation is solved only once (Walter and other, 1994; Steefel and MacQuarrie, 1996; and Xu et al., 1999a). Xu et al. (1999a)

analyzed the accuracy of SIA and SNIA using several test cases. They concluded that the accuracy of SNIA depends mainly on the Courant number, which is defined as $C = v\Delta t/\Delta x$, where v is fluid velocity and Δx is grid spacing. For small Courant numbers, satisfying the stability condition $C \leq 1$, the differences between SNIA and SIA are generally small. The accuracy of SNIA also depends on the type of chemical process. Therefore, the applicability of the decoupling of chemical reactions from transport will depend on time and space discretization parameters, the nature of the chemical reactions and the desired accuracy. When SNIA is used, the Courant number condition $C \leq 1$ can be automatically enforced during the simulation.

When analyzing water flow through partially saturated porous media, the gas phase may often be considered a passive bystander and not be represented explicitly (Richards, 1931). This means that for the purpose of solving for water flow, the entire gas phase is at the same pressure (usually the atmospheric pressure). TOUGHREACT allows a choice of considering saturated-unsaturated liquid phase flow in which case only molecular diffusion can be considered for gaseous species transport. Alternatively, the full non-isothermal multi-phase flow equations (liquid, gas and heat) may be solved. To test the passive gas phase approach under ambient conditions, Xu et al. (2000) performed numerical simulation experiments on pyrite oxidation in a variably saturated porous medium. They found that under ambient conditions the effects of partial pressure reduction due to oxygen consumption on the fluid flow is not significant, and oxygen diffusion is the dominant gas phase transport process. However, when fluid flow and chemical reactions are strongly coupled, e.g. in boiling hydrothermal reservoirs, gas phase advection could be essential (White, 1995).

5. General Description of Input and Output Files

5.1. Input Files

Three user-specified input files are required. The input file names have been fixed in the program (i.e. names cannot be specified by the user). Descriptions of these input files are given below. Details on input formats and contents are given in Chapter 6.

flow.inp - Flow input. This file mainly includes rock properties, time-stepping information, geometric grid information, initial and boundary conditions, and data related to multi-phase fluid and heat flow simulation. The flow input is the same as the original TOUGH2 V2 (see the manual; Pruess et al, 1999), with an additional data block REACT (see Section 6.1).

solute.inp - Transport and other run parameters. This file contains various flags and input parameters for calculations of reactive transport, such as diffusion coefficients, tolerance limits for convergence of transport and chemical iterations, printout flags for mineral and aqueous species, and the configuration of model zones with different chemical composition (the composition of each zone, however, is defined in the following file CHEMICAL.INP).

chemical.inp - Geochemical parameters and properties. This file is used to define the geochemical system (i.e. the type and number of aqueous component species, minerals, gases, and sorbed species considered in the simulation). It also includes the initial compositions of water, mineral, and gas zones configured in file solute.inp, and kinetic data for minerals (rate constants, surface areas, etc.).

In addition to the above mentioned three input files, the program needs a thermodynamic database file. The file name is specified in solute.inp file. This file contains reaction stoichiometries, dissociation constants ($\log(K)$), and regression coefficients of $\log(K)$ as a function of temperature (see Section 6.4 for details).

5.2. Output Files

Two types of output files are generated from TOUGHREACT: (1) fixed file names, and (2) user-specified file names.

5.2.1. Fixed-name output files

flow.out - Flow output. This file is identical to the original TOUGH2 output file, including data on temperature, pressure, liquid saturation, mass flux, and phase velocities for all grid blocks of the model.

solute.out - Echo of input file solute.inp. This file lists the data read from input file SOLUTE.INP, including all transport parameters, chemical zone configuration, and other run-specific parameters.

chemical.out - Echo of input file chemical.inp. This file lists the data read from input files chemical.inp and chemical database, including initial water, rock, and gas compositions, equilibrium constants and stoichiometries of chemical reactions, kinetic data, and linear adsorption Kd values and decay constants for certain species.

runlog.out - Log of the simulation progress. This file is constantly updated during a simulation. It lists some run input parameters and all run-related messages, including error messages (Chapter 7).

chdump.out - chemical speciation data. This file contains results of geochemical speciation calculations for each initial water composition input into the model. It also lists these data for grid blocks where chemical convergence fails (not reaching specified convergence criteria). They include a printout of chemical mass balances (total mass balance and aqueous species mass balance). For debugging purposes or for small grids, if the flag ICHDUMP in the solute.inp input file is set equal to 1, geochemical speciation results will be output in the *chdump.out* file for every grid block at every time step. As a precaution to avoid filling up disk space, results of speciation calculations are output only for the first thousand grid blocks and/or time steps, after which the program will abort.

savechem - save of geochemical data for restart. This can be used to perform a series of TOUGHREACT runs, in which geochemical conditions obtained in one run, and written to disk file *savechem*, are used as initial conditions in a subsequent run. The restart run for reactive

geochemical transport simulation must be used together with a restart of the flow simulation (see p. 61 of the TOUGH2 V2 manual; Pruess et al., 1999). For a restart run, file name *savechem* must be changed to, *inchem*, and *save* to *incon* (same as in the original TOUGH2). A restart example is given in Sample problem 5 (Section 8.5).

In addition, TOUGHREACT has two optional output files, one for mass balance information and the other for mineral saturation index vs. grid block at specified times. The two file names are fixed as *mbalance.out* and *min_SI.dat*. Printing the two files or not is controlled by parameter MOPR(9) in *flow.inp* file, which is described in Section 6.1.

5.2.2. User-specified output files

The names of these files must be specified in the input file SOLUTE.INP, and cannot be left blank. The output files are described below:

Iteration Data. This file lists numbers of flow, transport and chemical iterations used to reach convergence at each time step.

Aqueous species plot data. This file contains times, grid block coordinates (m), liquid saturation, temperature (°C), pH, and aqueous species concentrations at all grid blocks for times specified in the FLOW.INP file. The number and type of species to this output is specified by flags in the input file SOLUTE.INP. This file is in a TECPLOT-compatible format.

Solid phase plot data. This file contains time, grid point coordinates (m), temperature (°C), mineral abundance, exchanged species concentrations at all grid blocks for time steps specified in the FLOW.INP file. This file is also in a TECPLOT-compatible format.

Gas phase plot data. This file contains time, grid point coordinates (m), temperature (°C), and gaseous partial pressures at all grid blocks for times specified in the FLOW.INP file. This file is also in a TECPLOT-compatible format.

Plot data at specified grid blocks (time evolution). This file contains grid block identifier, time, liquid saturation, temperature, pH, aqueous species concentrations, mineral abundances, and gas pressures, exchanged species concentrations for specific grid blocks and time intervals, as specified in the input file SOLUTE.INP.

6. Input File Formats and Contents

6.1. Flow Input (flow.inp)

Input formats are identical to TOUGH2 Version 2.0 (Pruess et al., 1999) except that for reactive geochemical transport simulation, an additional keyword block 'REACT' with one record must be included. This record specifies option parameters related to reactive transport. Without this block, the program only runs a flow simulation. In addition, one variable in keyword block 'PARAM' in the original TOUGH2 input was slightly extended.

REACT Parameter choices for reactive transport simulation

Variable: MOPR(20)

Format: 2011

- MOPR(1) = 0 perform reactive transport
 = 1 no reactive transport, but input files with chemical data are read
 = 2 no reactive transport, no chemical data files are read
- MOPR(2) > 0 writes the transport coefficient matrix, darcy velocities, porosities, and other transport data in the *runlog.out* file during calculations of aqueous species and gas transport. For debugging uses only.
- MOPR(3) > 0 writes source terms, old and new aqueous concentrations, and various other parameters in the *runlog.out* file during transport calculations. Also outputs the permeability, porosity, and capillary pressure correction factor at each grid block in the *runlog.out* file. For debugging uses only.
- MOPR(4) ≠ 1 Force at least one fluid flow step to be calculated (MOPR(4)=2 is normally suggested to use)
 = 1 does not force at least one fluid flow step to be calculated. It can be useful to compute chemical reaction only in single-grid block problems. When chemical quasi-stationary states (QSS) option is considered, MOPR(4) must be set equal to one.
- MOPR(5) = 0 Subroutines MULTI, RELP (relative permeability), and PCAP (capillary pressure) provided by original TOUGH2 V2 are used. This option is normally used.
 = 1 Subroutines MULTI, RELP_YMP and PCAP_YMP are used.
 = 2 Subroutines MULTI_YMP, RELP_YMP and PCAP_YMP are used (YMP: Yucca mountain project, see sample problem 4 of Section 8.4).

- MOPR(6) = 0 No Leverett scaling for capillary pressure when porosity and permeability changed due to mineral dissolution and precipitation. This option is normally used.
= 1 Leverett scaling (Eq. F.9 in Appendix F) is performed for capillary pressure when porosity and permeability changed due to mineral dissolution and precipitation.
- MOPR(7) This option to allow the # of digits past the decimal to be printed out for chemistry output files. Zero or blank gives the earlier default, which was originally 4 digits. The # of digits is up to 8.
- MOPR(8) = 1 Printout two files for (1) mass balance information and (2) mineral saturation index vs. grid block at specified times. The two file names are fixed as mbalance.out and min_SI.dat.
= 0 No printout the two output files.
- MOPR(9)-MOPR(20): Not used now. Leave them blank.

PARAM The meaning of variable MCYC (maximum number of time steps to be calculated) in Record PARAM.1 was slightly extended from the original TOUGH2 input. In TOUGHREACT, if MCYC = 9999, the simulation time is not controlled by MCYC, and is only controlled by TIMAX in Record PARAM.2. IF MCYC \leq 9998, it's the same as the original TOUGH2.

6.2. Transport Input (solute.inp)

The first record of this input file is for writing title, comments and remarks; followed by 12 data records. Some records can be omitted in certain conditions. Prior to each record there is always a heading (comment) line (see inputs of the sample problem such as Figure 8.1.3). Some variables in data records are not required under certain conditions. In such cases one should leave them blank or input an arbitrary value. Next, we describe the content of each record, indicating the description of each variable and its corresponding FORTRAN format for appropriate reading.

Record_1. Title

Variable: TITLE
Format: A76

TITLE: title, comments and remarks.

Record_2. Option variables for reactive geochemical transport (1)

Variable: ISPIA INIBOUND ISOLVC RCOUR NGAS1 ICHDUMP KCPL
ICO2H2O NUMDR
Format: I5 I5 I5 F5.2 I5 I5 I5
I5 I5

ISPIA : indicator of iteration scheme between transport and reaction. ISPIA = 2 is normally used.

- 0 - sequential iteration between transport and chemistry
- 2 - sequential no iteration (fully explicit reaction source terms)

INIBOUND : indicator of identifying boundary water solution (including pumping/injection at the internal grid blocks).

- 0 - not identifying
- 1 - identifying (normally used)

ISOLVC : a flag of the linear equation solver for transport. It is the same as the original TOUGH2 V2 (see p. 73 of the manual, Pruess et al., 1999). ISOLVC = 5 is normally used.

- 2 - DSLUBC, a bi-conjugate gradient solver
- 3 - DSLUCS, a Lanczos-type bi-conjugate gradient solver
- 4 - DSLUGM, a general minimum residual solver
- 5 - DLUSTB, a stabilized bi-conjugate gradient solver

RCOUR is both a variable and a flag to limit the time step size. RCOUR > 0.0 limits the maximum time step size to RCOUR × Courant Number.

- RCOUR should be a fractional number, or $0 < \text{RCOUR} \leq 1$. This option is disabled if $\text{RCOUR} = 0.0$.
- NGAS1 : indicator of including gaseous chemical species transport
 0 - not included
 1 - included
 If gas partial pressure remains constant with time, put $\text{NGAS1}=0$. For using EOS2 and ECO2 modules, always put $\text{NGAS1}=0$ because CO2 pressure is already handled in the flow simulation.
- ICHDUMP is a flag to enable printing of chemical speciation results at each grid block and each time step (0 = disabled, 1=enabled). It should be enabled for debugging purposes only, or to track small problems. If this option is enabled, the program will abort after outputting speciation results for the first 1000 grid blocks and/or time steps, to avoid accidentally filling up disk space.
- KCPL is a flag to consider feedback effects of changes of porosity, permeability, and capillary pressure due to mineral dissolution and precipitation on fluid flow.
 0 - not considering
 1 - considering
 2 - only monitor the changes (printout), but does not affect fluid flow.
- ICO2H2O is a flag to consider effects of CO2 and H2O reaction source/sink terms on fluid flow calculations. ICO2H2O is only used for EOS2 and ECO2 flow modules. For other flow modules, put $\text{ICO2H2O} = 0$.
 0 - not considering
 1 - considering only CO2 reaction source/sink terms
 2 - considering both CO2 and H2O reaction source/sink terms
- NUMDR is flag of method for calculating derivatives of mineral kinetic rates with respective to concentrations of primary species.
 0 - Analytical method (normally used)
 1 - Numerical method

Record_3. Option variables for reactive geochemical transport (2)

Variable: SL1MIN, D1MIN, STIMAX, CNFACT

Format: 4E10.4

The first three parameters are used for skipping geochemical speciation calculations at grid blocks where conditions of saturation, inter grid block distance, or ionic strength are outside of the valid ranges of the model. The geochemical calculations are skipped at grid blocks where: the liquid saturation is less than SL1MIN; the minimum distance to the center of any adjacent block is less than D1MIN; or the stoichiometric ionic strength is more than STIMAX. For typical boiling simulations, use SL1MIN less or equal to 10^{-3} . Set D1MIN = 0.0 (disabled) unless absolutely necessary. With this program version, STIMAX can be up to 6 mol/kg H₂O for NaCl dominant solution (see Appendix H for details). STIMAX should not be

greater than 2.0 because of limitations regarding the calculation of activity coefficients at elevated ionic strength.

CNFACT is a weighting factor for mineral and gas reaction source terms in the transport equations (1.0 = fully implicit source terms, 0.0 = fully explicit source terms). This parameter has an effect only if sequential iterations are enabled (ISPIA = 0). In this program version, CNFACT always defaults to 1.0 if a non-zero value is input (implicit only). Simulations with CNFACT = 0.0 using sequential iterations will produce the same results as simulations without sequential iterations (explicit source terms) but requires increased computing time and therefore should be avoided.

Record_4.1 through 4.6. Output files names

Variable: THERMO_in , OUTiter, OUTplot, OUTsolid, OUTgas, OUTtime
Format: A20, each file name occupies one line.

THERMO_in : name of thermodynamic data file
OUTiter : iteration information
OUTplot : aqueous concentrations for all grid blocks at specified times defined in FLOW.INP
OUTsolid : solid concentrations (mineral abundances and exchanged species concentrations) for all grid blocks at specified times defined in FLOW.INP
OUTgas : gas pressures for all grid blocks at specified times defined in FLOW.INP
OUTtime : aqueous and solid concentrations vs. time at specified grid blocks defined in SOLUTE.INP

Record_5. Weighting parameters and diffusion coefficients

Variable: WTIME, WUPC, DIFUN, DIFUNG
Format: 2F10.0, 2E10.3

WTIME : time weighting factor, ranging from 0 to 1. WTIME = 1 (implicit) is suggested.
WUPC : upstream weighting factor, ranging from 0 to 1. WUPC = 1 (fully upstream) is suggested.
DIFUN : diffusion coefficients (m^2/s) of the medium for aqueous species. The tortuosity (τ) is defined in rock property block of the flow input. If τ in flow input is zero, the program computes τ from $\tau_{\beta} = \phi^{1/3} S_{\beta}^{7/3}$ (Millington and Quirk, 1961), where ϕ is porosity, S is phase saturation, and β is phase index.
DIFUNG: diffusion coefficients (m^2/s) of the medium for gaseous species. If DIFUNG < 0, the program computes gaseous diffusion coefficient as function of temperature and pressure according to Eq. A.1 (in Appendix A) .

Record_6. Data related to convergence criteria

Variable: MAXITPTR, TOLTR, MAXITPCH, TOLCH, MAXITPAD, TOLAD, TOLDC, TOLDR

Format: I5, E10.3, I5, E10.3, I5, E10.3, E10.3, E10.3,

MAXITPTR: maximum number of iterations allowed between solving transport and geochemistry; if MAXITPTR=1, it executes sequential non-iterative approach where transport and chemistry are sequentially solved without iteration procedure (normally is suggested).

TOLTR: relative tolerance of concentration for transport iteration; a value between 1.0E-03 to 1.0E-06 is suggested.

MAXITPCH: maximum number of iterations allowed for solving whole geochemical system.

TOLCH: relative tolerance of concentration for whole chemical system; a value between 1.0E-03 to 1.0 E-06 is suggested.

MAXITPAD: maximum number of iterations allowed for solving sorption via surface complexation.

TOLAD: relative tolerance of concentration for solving sorption; a value between 1.0E-03 to 1.0E-06 is suggested.

TOLDC: relative concentration change (between two consecutive time steps) tolerance for quasi-stationary state (QSS); a value between 1.0E-03 to 1.0E-06 is suggested; if not using QSS approximation set equal to zero. When KCPL>0 and ICO2H2O>0 in Record_2, set equal to zero.

TOLDR: relative dissolution and/or precipitation rate change tolerance for quasi-stationary state (QSS); a value between 1.0E-03 to 1.0E-06 is suggested; if not using QSS approximation set equal to zero. When KCPL>0 and ICO2H2O>0 in Record_2, set equal to zero.

Record_7. Writing control variables

Variable: NWTI, NWNOD, NWCOM, NWMIN, IWCOMT, ICONFLAG, MINFLAG

Format: 7I5

NWTI : writing frequency in time for some selected grid blocks (NWNOD)

NWNOD : number of grid blocks for writing time evolution

NWCOM : number of chemical components (specious) for writing

NWMIN : number of minerals for writing

IWCOMT: 0 - writing the aqueous species concentrations

1 - writing the total aqueous component concentrations;

ICONFLAG: A flag for aqueous concentration unit in output files

0 – mol/kg H₂O

1 – mol/l liquid

MINFLAG: A flag for unit of mineral abundances in output files

0 – Change (from t=0) of mineral abundance in mol/m³ medium

1 – Change of mineral abundance in volume fraction (dimensionless)

2 – Mineral abundance in volume fraction (dimensionless)

Record_8. List of grid blocks for printing time evolution results

Variable: EL

Format: 15A5

Five-character code name of a grid block. The name must be specified in flow.inp input file or mesh file. If NWNOD=0 in Record_7, leave a blank line.

Record_9. Pointer of the number of components to be printed out

variable: (IWCNOM(I), I=1,NWCNOM)

Format: 15I5

IWCNOM(I): vector component numbers

Record_10. Pointer of the number of minerals to be printed out

Variable: (IWMIN(I), I=1, NWMIN)

Format: 20I5

IWCNOM(I): vector of the number of minerals for writing. If NWMIN=0 in Record_7, leave a blank line.

Record_11. Default values for chemical property zone related to grid blocks

Variable: IZIWDF, IZBWDF, IZMIDF, IZGSDF, IZADDF, IZEXDF, IZPPDF, IZKDDF

Format: 8I5

IZIWDF, IZBWDF, IZMIDF, IZGSDF, IZADDF, IZEXDF, IZPPDF, and IZKDDF are default values of IZIW, IZBW, IZMI, IZGS, IZAD, IZEX, IZPP, and IZKD in the following record, respectively.

Record_12. Chemical property zone related to grid blocks

Variable: EL, NSEQ, NADD, IZIW, IZBW, IZMI, IZGS, IZAD, IZEX, IZPP, IZKD

Format: A5, 10I5

Remark: Repeat as many times as required, and ends with a blank record.

EL: grid block name

NSEQ: number of additional grid blocks having the same chemical properties

NADD: increment between the code numbers of two successive grid blocks

IZIW: initial water zone number

IZBW: boundary inflow (including injecting at internal blocks) water zone number

IZMI: mineral zone number

IZGS: gas zone number

IZAD: adsorption zone number

IZEX: ion exchange zone number

IZPP: zone number for porosity-permeability relation

IZKD: linear adsorption Kd zone number

The chemical properties for each zone are specified in chemical.inp file.

Record_13. List of grid blocks connected to external gas reservoir (such as atmosphere)

Variable: EL, DISG, (PFUGB(IG),IG=1,NGAS)

Format: A5, 5E10.3

Remark: Repeat as many times as required, and ends with a blank record.

EL: grid block name

DISG: $=A/D$, where A is interface area and D is distance to the interface (m)

PFUGB: gaseous species partial pressure (bar) at the reservoir, repeat as the number of gaseous species

6.3. Geochemical Input (chemical.inp)

An example of chemical.inp is given in Figure 8.2.2.

Record-1. Title

Variable: TITLE

Format: A76 (write TITLE within 'single quotes')

TITLE: title, comments and remarks in one line

Record-2. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

6.3.1. Definition of the geochemical system

It contains the information on the aqueous species, minerals, gases, surface complexes, species with linear adsorption Kd and decay, and exchangeable cations involved in the system. The names must be written according to those labeled in the thermodynamic database file.

Record-3. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Primary species

Record-4. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-5. Primary aqueous species

Variable: NAPRI

Format: A20 (write NAPRI within 'single quotes' such as 'h+')

Remark: Repeat Record-5 as many times as number of primary species

NAPRI: name of the primary species. It must be consistent with that in the thermodynamic database file. If redox reactions are preset in the system the species 'o2(aq)' must be included as a primary species. The species '*' is needed to indicate the end of the list of the primary species.

Aqueous complexes

The aqueous complex block (Records 6 and 7) can be omitted. In this case, all possible aqueous complexes found in the database file are automatically used.

Record-6. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-7. Aqueous complexes

Variable: NAAQX

Format: A20 (write NAAQX within 'single quotes')

Remark: Repeat Record-7 as many times as number of aqueous complexes

NAAQX: name of the aqueous complex. It must be consistent with that appeared in the database file. Omit NAAQX if no aqueous complexes are required. However, the species '*' is always needed to indicate the end of the list.

Minerals

Record-8. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file.

The following three records are repeated as many times as number of minerals.

Record-9-1. Mineral record 1

Variable: NAMIN, IKIN, IDISPRE, ISS, M1

Format: A20 (write NAMIN within 'single quotes' shch as 'calcite'), 4I (free)

Remark: Minerals can be entered in any order as long as the minerals at equilibrium precede those under kinetic constraints. The specified minerals consist of reactants and any possible products. Their names must match exactly the names of minerals in

the database. Minerals with identical stoichiometries (i.e. quartz and cristobalite) cannot both be specified at equilibrium, but can be specified under kinetic constraints. Minerals at equilibrium are defined with one record (per mineral). Minerals under kinetic constraints require more records (per mineral).

- NAMIN: name of the mineral phase. It must be consistent with that in the database. Omit NAMIN if no minerals are required. However, the species '*' is always needed to indicate the end of the list.
- IKIN: a flag for the type of mineral: 0 for minerals at equilibrium, and 1 for those under kinetic constraints.
- IDSPRE: a flag for the type of kinetic constraints: 1 for dissolution only, 2 for precipitation only, and 3 for both (mineral can either precipitate or dissolve). Always set IDSPRE = 0 if IKIN = 0 and IDISPRES > 0 if IKIN = 1.
- ISS: an index for a solid solution mineral endmember. All endmembers for a specified phase are given the same ISS value: ISS = 1 for each endmember of the first solid solution, ISS = 2 for each endmember of the second solid solution, and so on (numbers cannot be skipped). Records for each member can appear in any order in the mineral records.
- M1: an index for a mineral that may be precipitated in a dry grid block (liquid saturation < sl1min that is specified in solute.inp file) if there is water flux into the grid block, and/or if the grid block dries out. The mineral with M1 = 1 precipitates first, with M1 = 2 second, and so on. If this flag is set to zero, then the mineral will not be formed in the dry grid block.

If IKIN = 1 and IDSPRE = 1 or 3, Record-9-2 is required to define dissolution rate law parameters

Record-9-2. Mineral record 2

Variable: RKF, IDEP, CK1, CK2, EA, ACFDISS, BCFDISS, CCFDISS
Format: F, I, 6F (all are free format)

- RKF: the coefficient k_{25} in the expression (B.6) given in Appendix B, where k_{25} is the rate constant (in mol/m²/sec) at 25 °C, EA is the activation energy in kJ/mol. The form of the rate law is given in Eq. (B.5).
- IDEP: a flag for rate constant dependence on pH (see Figure B.1 in Appendix B) or multiple mechanisms (see Eq. B.10 in Appendix B). If IDEP = 0, pH dependent rate constants and multiple mechanisms are not considered. If IDEP = 1, Record-9-3 needs to include information on the rate dependence on pH. If IDEP = 2, Record-9-4 and Record-9-5 need to include information on the rate constants contributed from additional mechanisms.
- CK1 and CK2: the exponents η and θ , respectively in in Eq. (B.5).
- EA: the activation energy (KJ/mol).
- ACFDISS, BCFDISS, and CCFDISS: should be set to zero, unless a different form of rate constant dependence with temperature is desired. This alternate form is: $\log(k) = a + b \cdot T + c/T$, where T is absolute temperature in K and

\log is in base 10. To enable this option, RFK must be set to 1.0, EA must be set to zero, CK1 and CK2 can be set to any values, and ACFDISS, BCFDISS, and CCFDISS must be specified as the coefficients a , b , and c , respectively, in the above expression.

If IKIN = 1 and IDSPRE = 2 or 3 Record-9-6 is required to define precipitation rate law parameters.

Record-9-3. Mineral record 3

Variable: PH1, SLOPE1, PH2, SLOPE2
Format: 4F (all are free format)

See Figure B.1 (in Appendix B) for the meaning of these parameters.

Record-9-4. Mineral record 4

Variable: NDIS
Format: F (free format)

NDIS is the number of additional mechanisms contributed to the rate constant (see Eq. B. 10 in Appendix B). An example of the multiple mechanisms can be found in the CO₂ disposal sample problem (Section 8.5).

Record-9-5. Mineral record 5

Variable: NAPRE, RKDSP, EXPDSP
Format: 3F (free format)

Remark: This record must be repeated as many as NDIS times (a maximum of five additional mechanisms can be considered).

RKDS is k_j in Eq. (B. 10) where i is the additional mechanism index.

EADS: is the activation energy (KJ/mol) for each additional mechanism.

NSPDS: is the number of species involved in each mechanism (a maximum of five species can be considered).

NADIS is the name of species involving in the mechanism that must be in the list of primary or secondary species. NADIS and the following variable EXPDSP must be repeated as many as NSPDS times.

EXPDSP is the power term n_j in Eq. (B. 10).

Record-9-6. Mineral record 6

Variable: RKPREC, IDEPREC, CK1PREC, CK2PREC, EAPREC, ACFPREC, BCFPREC, CCFPREC, RNUCL, NPLAW
Format: F, I, 7F, I (all are free formats)

The first 8 input parameters are listed in the same order and have the same functions as those described above for mineral dissolution, except that the parameters apply to mineral precipitation instead of dissolution.

RNUCL: the initial volume fraction ($V_{\text{mineral}}/V_{\text{solid}}$) to be assumed for calculating initial effective surface area if the mineral is not present at the start of a simulation but precipitates as a new reaction product. If zero, RNUCL is assumed to be 10^{-5} .

NPLAW: precipitation law index. NPLAW = 0 for Eq. (B.5 and B.10) in Appendix B; NPLAW = 1 for Eq. (B.8).

Record-9-7. Mineral record 7

This record is only required for a mineral with precipitation.

Variable: SSQK0, SSTK1, SSTK2
Format: 3F (free)

SSQK0: log (Q/K) gap (supersaturation window, see Eq. B.11 in Appendix B). A zero value represents no gap.

SSTK1: temperature (in °C) at which to begin reducing gap.

SSTK2: temperature (in °C) endpoint at which the gap has diminished to nearly zero (1% of original value). The gap decreases exponentially from the first (SSTK1) to the second (SSTK2) temperature value, and SSTK2 must always be greater than SSTK1.

Gaseous species

Record-10. Label

Variable: LABEL
Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-11. Gases

Variable: NAGAS
Format: A20 (write NAGAS within 'single quotes' such as 'co2(g)')
Remark: Repeat Record-11 as many times as number of gaseous species

NAGAS: name of a gaseous species. It must be consistent with that in the chemical thermodynamic database file. Omit NAGAS if no gaseous species are required. However, the species '*' is always needed to indicate the end of the list.

Surface complexes

Record-12. LABEL

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-13. Surface complexes

Variable: NAADS

Format: A20 (write NAADS within 'single quotes')

Remark: Repeat Record-13 as many times as number of surface species

NAADS: name of surface complex. Omit NAADS if no surface complexes are required. However, the species '*' is always needed to indicate the end of the list.

Aqueous species (primary) with Kd and decay

Record-14. LABEL

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-15. Species with Kd and decay

Variable: NAKDD, DECAYC

Format: A20 (write NAADS within 'single quotes'), free

Repeat Record-15 as many times as species with Kd and decay

NAKDD: name of the aqueous primary species with Kd and/or decay. These names must appear in the above mentioned 'primary species record' of the input file.

DECAYC: decay constant (in 1/s). For the species with only Kd adsorption and without decay, set DECAYC equal to zero.

Exchangeable cations

Record-16. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-17. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-18. Data related with exchangeable cations

Variable: NAEXC IMS IEX EKX

Format: A20 I I F (the last three variables are free format)

Remark: Repeat Record-18 as many times as number of exchangeable cations

NAEXC: name of exchangeable cation. Omit NAEXC if no exchangeable cations are required. However, the species '*' is always needed to indicate the end of the list.

IMS: If $IMS = 1$, the cation is used as reference for the exchange reactions (normally Na^+). For the rest of cations IMS must be 0.

IEX: exchange convention type used in the calculations: 1= Gaines-Thomas; 2= Vanselow; 3= Gapon. The value of IEX must be the same for all the exchanged cations.

EKX: exchange coefficient of the cation with respect to the reference cation. If $IMS = 1$, then $EKX = 1.0$.

6.3.2. Initial and boundary water solutions**Record-19. Label**

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-20. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-21. Data related with the number of aqueous solutions

Variable: NIWTYPE NBWTYPE
Format: I I (all are free format)

NIWTYPE: number of types of aqueous solution initially present in the system.
NBWTYPE: number of types of boundary (including pumping/injection at the internal grid blocks) solution.

Data related to aqueous solutions

This part describes the different types of aqueous solutions (initial and boundary). Repeat the following Records 22, 23 and 24 a number of times equal to (NIWTYPE + NBWTYPE), starting with initial solutions, and then boundary solutions.

Record-22. Identification of the solution

Variable: IWTYPE TC2 ITC2
Format: I, F, I (all are free format)

IWTYPE: number of the initial or boundary solution. The value of IWTYPE varies from 1 to NIWTYPE, then starts again with 1 up to NBWTYPE.
TC2: temperature of the solution (°C).
ITC2: set zero for this version

Record-23. Label

Variable: LABEL
Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-24. Data related to the chemical definition of the solution

Variable: NAPRI ICON CGUESS CTOT NADUM ICTOT
Format: A20, I, F, F, A20, I
Remark: Repeat Record-24 as many times as number of primary species

NAPRI: name of the aqueous primary species. The name of the species must coincide with those previously listed as primary species in the definition of the system, although the order may change. Names must be included between 'single quotes' such as 'h+'. The species '*' indicates the end of the list.
ICON: flag indicating the type of constraint controlling the solute content which is given under CTOT:
1 = the concentration of the species is constrained by the total concentration CTOT, except for water which is assumed unity.
2 = the concentration of the species calculated through charge balance.
3 = the activity of the species is fixed during the initialization. In this case, the following two variables: CGUESS = CTOT = the fixed activity. For

example, if the pH of an initial water is fixed at 7, we set CGUESS = CTOT = 10^{-7} for H⁺ activity.

CGUESS: initial guess for the concentration (mol/kg) of the primary species.

CTOT: total dissolved component concentration (mol/kg).

NADUM: is not used in this version, place ' '.

ICTOT: is not used in this version, place zero.

6.3.3. Initial mineral zones

This part describes the different mineral zones initially forming the system.

Record-25. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-26. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-27.

Variable: NMTYPE

Format: I4

NMTYPE: Number of mineral zones forming the system. If mineral is not considered in the system, place NMTYPE = 1.

The following Records 28, 29 and 30 must be repeated NMTYPE times.

Record-28.

Variable: IMTYPE

Format: I4

IMTYPE: number of the mineral zone

Record-29. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-30. Data related to the composition of the mineral zone

Variable: NAMIN VOL IKIN
Format: A20 F I (the last two variables are free format)

NAMIN: name of the mineral present in the system. The name of the mineral must be included among those previously listed in the definition of the system, although the order may change, and it is not needed to repeat the complete list. Names must be included between 'single quotes' such as 'calcite'. The mineral '*' indicates the end of the list of minerals.

VOL: is the initial volume fraction of the mineral, excluding liquid (mineral volume divided by total volume of solids). The sum of VOL's need not add up to 1. The remaining solid volume fraction is considered un-reactive.

IKIN: A flag for the type of mineral: 0 for minerals at equilibrium, and 1 for those under kinetic constraints. When IKIN=1, the following record (Record-30-1) is required.

Record-30-1.

Variable: RAD, AMIN , IMFLG
Format: F, F, I (all are free format)

RAD: radius of mineral grain (in m) used to calculate surface area for initial formation of secondary phase. If RAD = 0, the initial surface area is calculated from RNUCL in Record-9-6.

AMIN: specific reactive surface area. Its unit depends on the following flag IMFLG

IMFLG: A flag for surface area conversion
IMFLG = 0 for cm²/g mineral
IMFLG = 1 for m² rock area/m³ medium
IMFLG = 2 for m²/m³ mineral

6.3.4. Initial gas zones

This part describes the different initial gas zones in the system.

Record-31. Label

Variable: LABEL
Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-32. Label

Variable: LABEL
Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-33.

Variable: NGTYPE
Format: I4

NGTYPE: number of gas zones forming the system. If gaseous species is not considered in the system, place NGTYPE = 1

The following records 34, 35 and 36 must be repeated NGTYPE times.

Record-34.

Variable: IGTYPE
Format: I4

IGTYPE: number of the gas zone

Record-35. Label

Variable: LABEL
Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-36. Data related to the composition of the gas zone

Variable: NAGAS VOLG
Format: A20 F (the last one is free format)

NAGAS: name of the gaseous species present in the system. The name of the gas must be included among those previously listed in the definition of the system, although the order may change, and it is not needed to repeat the complete list. Names must be included between 'single quotes'. The gas '*' indicates the end of the list.

VOLG: partial pressure of the gaseous species (in bar).

6.3.5. Zones for permeability-porosity relationship

Record-37. Label

Variable: LABEL
Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-38. Label

Variable: LABEL
Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-39.

Variable: NPPZON

Format: I4

NPPZON: Number of permeability zones. If permeability change is not considered in the simulation, place NPPZON = 1.

The following records , 40, 41 and 42 must be repeated NPPZON times.

Record-40.

Variable: IPPZON

Format: I4

IPPZON: number of order of the permeability zone

Record-41. Label

Variable: LABEL

Format: A76 (write LABEL within ‘single quotes’)

LABEL: comments which will appear in the output file

Record-42. Data related to zone for permeability-porosity relationship

Variable: ipptyp, apppar, bpppar

Format: I, 2F (All are free format)

Ipptyp: the index for the permeability law. Details on permeability-porosity relationship are described in Appendix F.

Ipptyp = 1: simplified Carman-Kozeny (Eq. F.7 in Appendix F). The parameter values (apppar and bpppar) are not used and may be set to zero or any real number.

Ipptyp = 3: cubic law (Eq. (F.2)). The parameter values (apppar and bpppar) are not used and may be set to zero or any real number.

Ipptyp = 4: modified Cubic Law (Eq. F.3-F.6). The parameters are: (a) *true fracture porosity / fracture-matrix area* (analogous to fracture aperture) (m^3/m^2) and (b) true fracture spacing (m)

Ipptyp = 5: Verma-Pruess permeability-porosity relation (Eq. F.8). The parameters are: (a) the value of “critical” porosity at which permeability goes to zero and (b) a power law exponent

6.3.6. Surface adsorption zones

This part describes the characteristics of the zones with different surface adsorption properties present in the system. The capability of TOUGHREACT for surface complexes has not been tested in the present version. The purpose is to reserve a space for future use.

Record-43. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-44. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-45.

Variable: NDTYPE

Format: I4

NDTYPE: number of surface adsorption zones.

Record-46. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-47. Data related to the adsorption zone

Variable: IDTYPE SUPADS TSS

Format: I4 Free Free

Remark: This record must be repeated NDTYPE times. If NDTYPE is zero omit this. No '*' is required to indicate the end of the list of adsorption zones.

IDTYPE: number of the surface adsorption zone.

SUPADS: specific adsorbent surface of the solid phase per unit volume of solution
($\text{dm}^2 \cdot \text{dm}^{-3}$)

TSS: Total adsorption sites per volume of solution ($\text{mol} \cdot \text{dm}^{-3}$)

6.3.7. Linear Kd zones

This part describes the different linear adsorption Kd zones initially in the system.

Record-48. Label

Variable: LABEL
Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-49. Label

Variable: LABEL
Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-50.

Variable: KDTYPE
Format: I4

KDTYPE: number of Kd zones in the system. If Kd adsorption is not considered in the simulation, place KDTYPE = 1

The following Records 51, 52 and 53 must be repeated KDTYPE times.

Record-51.

Variable: IDTYPE
Format: I4

IDTYPE: number of the Kd zone

Record-52. Label

Variable: LABEL
Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-53. Data related to the Kd zone

Variable: 'NAME', SDEN2, VKD2

Format: A20, F, F (the last two variables are free real number)

NAME : the name of aqueous primary species with Kd, which can be listed in any order. The species spelling must be the same as defined previously.

SDEN2: the solid density (in kg/dm³).

VKD2 is value of Kd (in l/kg which is mass/kg solid divided by mass/l solution).

If SDEN2=0.0, VKD2 automatically represents retardation factor (≥ 1).

6.3.8. Cation exchange zones

This part describes the characteristics of the zones with different cation exchange capacity present in the system.

Record-54. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-55. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-56.

Variable: NXTYPE

Format: I4

NXTYPE: number of cation exchange zones.

Record-57. Label

Variable: LABEL

Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-58. Data related to the cation exchange zone

Record-58 must be repeated NXTYPE times. If NXTYPE is zero omit this card. No '*' is required to indicate the end of the list of cation exchange zones.

Variable: IXTYPE CEC
Format: I F (all are free format)

IXTYPE: number of the cation exchange zone.
CEC: cation exchange capacity (meq/100 g of solid).

6.3.9. End of reading chemical input

This part allows the user to be sure that the chemical data have been entirely read.

Record-59. Label

Variable: LABEL
Format: A76 (write LABEL within 'single quotes')

LABEL: comments which will appear in the output file

Record-60. Label to check the end of chemical data input

Variable: LABEL
Format: A76 (write LABEL within 'single quotes')

LABEL: This label must be 'end'.

6.4. Thermodynamic Data

Aqueous species, minerals, and gases contained in CHEMICAL.INP must be found in this thermodynamic database file. The name of the database file is specified in SOLUTE.INP. The format of the database file is free. For most problems, the database files supplied with TOUGHREACT may be used without addition and modification. If any aqueous species, mineral, and gas are not contained in the supplied database file or one desires to use different thermodynamic data, users must add them to the database file. An example of a chemical database file is given in Figure 6.1. Since the EQ3/6 database is commonly used, the distribution CD provides a utility program for converting EQ3/6 to TOUGHREACT database. The description of the conversion program is given in Appendix J. Appendix J also gives descriptions of other utility programs for switching basis species and regressing logK data.

Record-1. Temperature points

Variable: 'DUMMY', NTEMP, (TEMPC(i), i=1,NTEMP)

Format: A, I, NTEMP(F)

DUMMY: a label used to describe the data for this record.

NTEMP : the number of TEMPC values to read.

TEMPC : temperatures (°C) at which the log(K) data are listed in this file. TEMPC values must be listed in order of increasing temperature. These values are used to constrain log(K) extrapolation within this temperature range. Log(K)'s are not extrapolated outside this temperature range. For example, if the maximum TEMPC is 150 °C but the computed system temperature is 250 °C, log(K)'s will be extrapolated only to 150 °C (i.e. the geochemical speciation will be computed at 150 °C, not 250 °C). Therefore, users must make sure that simulation temperatures are within the range of thermodynamic data temperatures.

Record-2. Basis (primary) species

Variable: NAME, A0, Z

Format: A20, 2F

NAME : chemical formula of aqueous basis species such as 'h+', The maximum length of NAME is A20.

A0 : Debye-Huckel a0 parameter (ion effective or hydrated radius, see Appendix H for details)

Z : the ion electric charge.

This record is repeated as many times as number of primary species. The last line must be: 'null' 0.0 0.0 (where 'null' is the actual string in quotes)

Record-3. Secondary (derived) species

The data for each secondary species is given by 3 sub-records, which are as follows:

Record-3-1.

Variable: 'NAME', A0, Z, NCPS, (STQS(i), 'NAM(i)', i=1,NCPS)

Format: A, 2F, I, NCPS(F, A)

NAME : chemical formula of secondary species. The maximum length of NAME is A20.

A0 : Debye-Huckel a0 parameter (ion effective or hydrated radius)

Z : the ion electric charge.

NCPS : the number of basis species defining the secondary species.

STQS contains the stoichiometric coefficients of component species NAM included in the dissociation reaction of the derived species (negative and positive values for reactants and products, respectively).

Record-3-2.

Variable: 'NAME', (DUMMY(i), i=1,ntemp)

Format: A, ntemp(F)

NAME : chemical formula of secondary species.

DUMMY : contains the dissociation constants ($\log(K)$ in base 10) for the given reaction at each discrete temperature listed in Record-1 above. These data are skipped on input, because all $\log(K)$ values are computed as a function of temperature using the regression coefficients that follow (Record-3-3). The discrete $\log(K)$ values should, however, always be included in the file to provide for an easy reference of the data.

Record-3-3.

Variable: 'NAME', (AKCOES(i), i=1,5)

Format: A, 5(E)

NAME : chemical formula of secondary species.

AKCOES : contains regression coefficients a, b, c, d, and e to calculate $\log(K)$ as a function of temperature (within the range of temperatures listed on the first record of the file) such that $\log(K) = a \cdot \ln(Tk) + b + c \cdot Tk + d/Tk + e/Tk^2$, where Tk is absolute temperature (K), and *log* and *ln* stand for base-10 and natural logarithms, respectively.

Records 3-1, 3-2, and 3-3 are repeated as many times as number of secondary species. The last line must be: 'null' 0.0 0.0 (where 'null' is the actual string in quotes).

Record-4. Minerals

The data for a mineral is given by 3 sub-records, which are as follows:

Record-4-1.

Variable: 'NAME', MOLWT, VMIN, NCPM, (STQM(i), 'NAM(i)', i=1,NCPM)
Format: A, 2F, I, mpri(2F, A)

NAME : chemical formula of a mineral.

MOLWT : molecular weight (g/mol).

VMIN : molar volume (cm³/mole).

NCPM : the number of component species defining the mineral.

STQM : contains the stoichiometric coefficient of basis species NAM in the dissociation (hydrolysis) reaction of the mineral (negative and positive values for reactants and products, respectively).

Record-4-2.

Variable: 'NAME', (DUMMY(i), i=1,ntemp)
Format: A, ntemp(F)

NAME : chemical formula of the mineral.

DUMMY : the dissociation constants (log(K) in base 10) for the given reaction at each discrete temperature listed in the first record of the file. These data are skipped on input, because all log(K) values are computed as a function of temperature using the regression coefficients that follow (below). The discrete log(K) values should, however, always be included in the file to provide for an easy reference of the data.

Record-4-3.

Variable: 'NAME', (AKCOEM(i), i=1,5)
Format: A, 5(E)

NAME : chemical formula of the mineral.

AKCOEM : contains regression coefficients a, b, c, d, and e to calculate log(K) as a function of temperature (within the range of temperatures listed on the first record of the file) such that $\log(K) = a \cdot \ln(Tk) + b + c \cdot Tk + d/Tk + e/Tk^2$.

Records 4-1, 4-2, and 4-3 are repeated as many times as number of minerals. The last line must be: 'null' 0.0 0.0 (where 'null' is the actual string in quotes).

Record-5. Gases

The data for a gas is given by 3 sub-records, which are as follows:

Record-5-1.

Variable: 'NAME', DMOLWT, DMDIAM, NCPG, (STQG(i), 'NAM(i)', i=1, NCPG)
Format: A, 2F, I, NCPG(F, A)

NAME : chemical formula of a gas.
DMOLWT : molecular weight (g/mol)
DMDIAM: molecular diameter (m) used to calculate gas diffusion coefficient (see Eq. (A.1) in Appendix A)
NCPG : the number of basis species defining the gas.
STQG : contains the stoichiometric coefficient of component species NAM in the dissociation reaction of the gas (negative and positive values for reactants and products, respectively).

Record-5-2.

Variable: 'NAME', (DUMMY(i), i=1, ntemp)
Format: A, ntemp(F)

NAME : chemical formula of the gas.
DUMMY : the dissociation constants ($\log(K)$ in base 10) for the given reaction at each discrete temperature listed in the first record of the file. These data are skipped on input, because all $\log(K)$ values are computed as a function of temperature using the regression coefficients that follow (below). The discrete $\log(K)$ values should, however, always be included in the file to provide for an easy reference of the data.

Record-5-3.

Variable: 'NAME', (AKCOEG(i), i=1, 5)
Format: A, 5(E)

NAME : chemical formula of the gas.
AKCOEG : contains regression coefficients a, b, c, d, and e to calculate $\log(K)$ as a function of temperature (within the range of temperatures listed on the first record of the file) such that $\log(K) = a \cdot \ln(T_k) + b + c \cdot T_k + d/T_k + e/T_k^2$.

Records 5-1, 5-2, and 5-3 are repeated as many times as number of gases. The last line must be: 'null' 0.0 0.0 0 (where 'null' is the actual string in quotes).

Record-6. Surface complexes

The capability of TOUGHREACT for surface complexes has not been tested in the present version. Therefore, no data should be entered, except for the termination record: 'null' 0. 0 (where 'null' is the actual string in quotes). The purpose is to reserve a space for future extension and development.

7. Anticipated Error Messages

All execution stops built into TOUGHREACT are accompanied by a message indicating why the execution was aborted. These messages are written to file runlog.out. Other error messages do not lead to a program interruption. Only messages related to the reactive transport part of the program are reviewed below. Error messages originating from fluid and heat flow calculations are the same as for TOUGH2 V2 (Pruess et al., 1999).

7.1. From Routine: INIT (reads the CHEMICAL.INP file)

Most of these messages are self explanatory and refer to exceeded array dimensions or other errors encountered when reading the chemical.inp file. Array dimension problems can be corrected by reducing the problem size or changing array dimensions in the source file PARAMETE.INC and recompiling the program. Some examples are given as follows:

Error: maximum number of component species (MPRI) was exceeded. Current max=(MPRI)

Execution stop: yes. Self explanatory.

Error: maximum number of minerals (MMIN) was exceeded. Current max= (MMIN)

Execution stop: yes. Self explanatory.

error reading aqueous species of the system

Execution stop: yes. Self explanatory.

error reading minerals of the system

Execution stop: yes. Self explanatory.

error reading gases of the system

Execution stop: yes. Self explanatory.

error reading initial water zone=___ (iwtype)

Execution stop: yes. Self explanatory.

error reading initial mineral zone= ____ (imtype)

Execution stop: yes. Self explanatory.

error reading initial gas zone= ____ (imtype)

Execution stop: yes. Self explanatory.

7.2. From Routine: NRINIT (initial Newton-Raphson iterations)

*ERROR (convergence problem in initialization of water composition)
Please adjust convergence criteria regarding chemical iteration
and initial guess of concentration of primary species*

Execution stop: yes. Self explanatory. This error results in calling routine chdump for troubleshooting (i.e. the last chemical speciation data are output in the *chdump.out* file). This error occurs during the initial geochemical speciation of waters specified in CHEMICAL.INP (no minerals, before the first time step). Check the *chdump.out* file for clues, and also check that water temperatures specified in CHEMICAL.INP data are not too different than the initial condition of temperature specified in the FLOW.INP file.

7.3. From Routine: READTHERM (reads thermodynamic database file)

All these messages occur while reading the thermodynamic database and are self explanatory. These indicate improperly-formatted records in the database file. All errors result in a program execution stop. Some example are :

*Error reading temperature data: stop
Error reading primary species: stop
Error reading secondary species: stop (followed by the species name)
Error reading minerals: stop (followed by the mineral name)
Error reading gases: stop (followed by the gas name)
Error reading adsorbed species: stop (followed by the species name)
Error in opening database file: stop*

7.4. From Routine: READSOLU (reads the file SOLUTE.INP)

There are currently no specific error messages generated while reading the file SOLUTE.INP. The unit number of this file is 31. System error messages relating to this I/O number originate while reading this file. Make sure the fixed formats of this file are respected.

7.5. From Routine: CR_CP (kinetic data calculations)

error in data option for mineral (kinetic)= _____

Execution stop: yes. This message occurs if the flag IDEP for any of the kinetic minerals is not set to either 0 or 1. With this program version, IDEP must always be zero (this flag is specified in the mineral section of the CHEMICAL.INP file).

7.6. From Routine: NEWTONEQ (Newton-Raphson iterations after 1st time step)

ERROR: chemistry did not converge at node _____ (routine NEWTONEQ)

Species: ____ Error= ____ Error limit= ____ relative

Node temperature (C): ____

Program execution was not aborted. Check results!

Execution stop: only if this error occurs at more than fifty grid blocks at any given time step. This error also calls routine *chdump* for troubleshooting (i.e. the last chemistry calculation data are output in the *chdump.out* file). This error occurs during the block-by-block geochemical speciation computations after the first time step (complete system, with minerals and gases if any). Check the *chdump.out* file for clues on why convergence was not reached. You may need to increase the loop limit (MAXITCH) and/or tolerance (TOLCH) in the SOLUTE.INP file. If boiling occurs, you may try increasing STIMIN or decreasing STIMAX (specified in SOLUTE.INP). Chemical convergence may also fail because of errors during transport, resulting in erroneous system compositions that cannot yield a solution to geochemical speciation calculations. In this case, the time step may be decreased and/or the Courant number option enabled (RCOUR in SOLUTE.INP input file). Depending on the type of problem, chemical speciation in closely spaced grid blocks can be skipped by setting D1MAX > 0 (last resort).

Error: Negative concentration for species ____

Execution stop: no. Self explanatory. A concentration may temporarily become negative during the chemical Newton-Raphson iterations, but should not remain negative. This error may indicate problems to come. It is rarely encountered.

7.7. From Routine: LUDCMP (linear equation solver)

This routine is called during the Newton-Raphson iterations to compute geochemical speciation.

Singular Matrix in Chemical Solver, STOP

Execution stop: yes. Self explanatory. This indicates an ill-defined chemical system. This error results in calling *chdump* to output the last geochemical speciation data in the *chdump.out* file. A phase-rule violation or inclusion of minerals (at equilibrium) with identical stoichiometries in the simulation will cause this error. In some cases, divergence and over/underflows during Newton-Raphson iterations (sometimes related to transport problems) may cause this error even though a true singularity has not occurred. Check the *chdump.out* file for clues on why the error happened.

8. Sample Problems

In this section we present applications of TOUGHREACT to problems in geothermal reservoir behavior, groundwater quality, nuclear waste isolation, supergene copper enrichment, and geologic disposal of greenhouse gases. The test problems serve as checks and benchmarks to verify proper code installation. The input files can be used as templates to facilitate preparation of input data for new problems. To assist with checking on code performance, we provide printouts of portions of the output files generated for each of the sample problems. Simulations of sample problem presented here were run on Pentium 4 PC machines (1.7G). These EXE files were generated from COMPAQ Visual Fortran compiler version 6.6, which are also provided in the distribution CD.

8.1. Aqueous Transport with Adsorption (Linear Kd) and Decay (EOS9)

A 1-D homogeneous fully water-saturated porous medium is considered (Figure 8.1.1), using the following parameters: a porosity of 0.1, a pore velocity v of 0.1 m/day, a solid density of 2600 kg/m³, a distribution coefficient Kd of 0.042735 l/kg, which corresponds to a retardation factor R of 2 (Equation C.8 in Appendix C), and a half-life $t_{1/2}$ of 20 days. The flow system is a cylindrical, horizontal porous medium with cross-sectional area of 1 m² and 12 m length, divided into 60 grid blocks of 0.2 m thickness. Parameters for water flow are specified in file flow.inp (Fig. 8.1.2). Water chemical compositions are assigned through data in files solute.inp (Figure 8.1.3) and chemical.inp (Fig. 8.1.4). In chemical.inp, the data (1 1) following the keyword 'INITIAL AND BOUNDARY WATER TYPES' specify that one initial water composition will be read, as well as one boundary water composition. The data entered in solute.inp under "default values of chemical zone codes for nodes" attach the first (and only) initial water type to all grid blocks in the problem, as well as attaching the first (only) boundary water composition to all injection grid blocks. Injection occurs only in block F = 1, and with the boundary water chemical composition.

Figure 8.1.1. . Simplified conceptual model for 1-D transport with linear Kd and decay.

The EOS9 flow module is used. Part of the concentration output file is given in Figure 8.1.5. The complete input and output files are given in the distribution CD (subdirectory: treat/sample-problems/P1_EOS9_kd-decay).

A total of four species are simulated in a single run. Species 1 is not subject to adsorption ($R = 1$) and decay ($t_{1/2} = \text{infinite}$), and is denoted by 'na⁺' in chemical input file 'chemical.inp'. Species 2 has a $R = 2$ and a $t_{1/2} = \text{infinite}$, and is denoted by 'skdd1' in the chemical input file 'chemical.inp'. Species 3 has a $R = 1$ and a $t_{1/2} = 20$ days, and is denoted by 'skdd2' in the input file. Species 4 has a $R = 2$ and a $t_{1/2} = 20$ days, and is denoted by 'skdd3' in the input file. Species skdd1, skdd2, and skdd3 are artificial tracer species. The species names must appear in the primary species block of the thermodynamic database. Initial concentrations for all four species are set equal to a very small value of 10^{-10} mol/l (practically zero, because TOUGHREACT takes log10 calculation for concentrations in order to avoid convergence problems). The inlet concentrations are set equal to 10^{-4} mol/l for all four species. An analytical solution for this problem is given in Javandel et al. (1984). In the numerical simulation, we give a diffusion coefficient of zero. Dispersion is not considered in this code. However, the upstream weighting scheme used in the code results in a numerical dispersivity $\alpha_n = \Delta x/2 = 0.1$ m (where Δx is the grid size, 0.2 is used in the simulation). In the analytical calculations, we use a dispersion coefficient $D = \alpha_n v = 0.01$ m²/day to account for the numerical dispersion in the code. The numerical results together with analytical solution are presented in Figure 8.1.6.

Figure 8.1.6. Relative concentrations at 50 days for 1-D aqueous solute transport with adsorption (linear Kd) and decay (concentrations are normalized to the inlet concentration 10^{-4} mol/l).

8.2. Water Quality in the Aquia Aquifer, Maryland (EOS9)

NaHCO_3 type waters in coastal plain aquifers of the eastern United States have been related to freshening of the aquifer (Chapelle and Knobel, 1983). These investigators depict major cation patterns as a function of flow length in the Aquia aquifer (Maryland). The water quality in this aquifer shows zonal bands with changes in concentrations of major cations that have been attributed to cation exchange and calcite dissolution/precipitation.

The observed water quality pattern had been previously simulated with PHREEQM by Appelo (1994). In the present TOUGHREACT simulation, hydrological conditions considered and all data used are the same as Appelo (1994). The aim is to validate our model applicability to field-scale ambient problems. Figure 8.2.1 shows a schematic cross section along a flow path. The aquifer is bounded to the east by a change in facies. The prepumping hydraulic head distribution suggests a confined aquifer in the upstream half and gradual loss of water in the downstream part of the aquifer (Chapelle and Drummond, 1983). Leakage probably occurs via Pleistocene channels that cut through the confining beds. The hydrological conditions have been modeled assuming a one-dimensional flow tube with recharge at $x = 0$, and with seepage into the confining layers evenly distributed over the second half of the flow tube.

Figure 8.2.1. Schematic cross section of the Aquia aquifer (Maryland) adapted from Appelo (1994). Recharge occurs in the outcrop of the formation; discharge is assumed to take place evenly in the downstream half. (1 foot equals 0.3048 m; 1 mile equals 1.609 km)

It was assumed that the initial water quality was brackish as a result of mixing of seawater with fresh water during deposition of the overlying Marlboro clay, which is a brackish water clay.

The recharge water quality is presumed to be unchanged from that analyzed in the upstream reaches of the aquifer. The initial and recharge water compositions are presented in Table 8.2.1. These data are inferred from observations and paleohydrochemical conditions. The detailed analysis and discussion are given by Appelo (1994). To obtain recharge water quality in the first 10 miles (16 km) of the flow path, the exchange capacity for the first 10 miles was set to zero.

Table 8.2.1. Initial and recharge water composition (concentrations are given in mmol/l) for modeling the water quality patterns in the Aquia aquifer. X⁻ represents cation exchange sites. Data are from Appelo (1994).

	pH	Na ⁺	K ⁺	Mg ²⁺	Ca ²⁺	Cl ⁻	HCO ₃ ⁻	SO ₄ ²⁻	X ⁻
Initial	6.80	87.4	1.9	9.92	4.38	101.8	15.5	0.27	200
Recharg	7.57	0.1	0.05	0.0	1.40	0.1	2.8	0.0	

The EOS9 flow module is used. The flow and solute transport input files are similar to the previous example. Here we only present the chemical input file in Figure 8.2.2. The complete input and output files are given in the distribution CD (subdirectory: treat/sample-problems/P2_EOS9_Aquia-aquifer). The thermodynamic data used for aqueous species and mineral (calcite) can be found in the database file thermXu4.dat. Part of output file for aqueous chemical concentrations is given in Figures 8.2.3. Parameters for water flow are specified in file flow.inp. A pore velocity of 2.42 mile/ka (1.2347×10^{-10} m/s) was used in the upper part of the aquifer. A porosity of 0.3 was used throughout. A dispersivity of 2.0 miles (3.2 km) was used by Appelo (1994). No dispersion is allowed in TOUGHREACT. We treated the dispersion in a similar way as diffusion by letting diffusion coefficient $D = \alpha v = 3.951 \times 10^{-7}$ m²/s, then place this value in file solute.inp and a tortuosity of one in flow.inp.

Water chemical compositions are assigned through data in files solute.inp and chemical.inp. In chemical.inp, the data (1 1) following the keyword 'INITIAL AND BOUNDARY WATER TYPES' specify that one initial water composition will be read, as well as one boundary water composition. The data entered in solute.inp under "default values of chemical zone codes for nodes" attach the first (and only) initial water type to all grid blocks in the problem, as well as attaching the first (only) boundary (recharge) water composition to all

injection grid blocks. Recharge occurs only in block F = 1, and with the boundary water chemical composition. Cation exchange reactions considered and their selectivities are listed in Table 8.2.2 (from Appelo, 1993). The Gaines-Thomas convention (Appelo, 1993) was used for cation exchange. In this convention, selectivities are calculated by using the equivalent fraction of the exchanged cations for the activity of the exchanged cations. It should be pointed out that selectivity is a relative concept. Na⁺ was chosen as the reference. Therefore, Na⁺ selectivity is equal to one. According to this definition, the lower the selectivity, the higher the exchange capacity. A divalent cation, in general, is more strongly exchanged than a monovalent cation. Usually, Ca²⁺ has a higher affinity for the exchange complex, usually in the following exchange order: Ca²⁺ > Mg²⁺ > K⁺ > Na⁺ (Appelo, 1993). Selectivity of H⁺ is very sensitive for simulation results, because it affects pH, in turn calcite dissolution and availability of Ca²⁺. The original H⁺ selectivity, 1.3092×10⁻⁶ was adjusted to, 3.1×10⁻⁶, in order to obtain a better pH fit with the observations (Figure 8.2.3).

Table 8.2.2. List of cation exchange reactions considered for modeling the water quality patterns in the Aquia aquifer. The cation selectivity listed is based on Appelo (1994).

Cation exchange:	Selectivity (in terms of Na ⁺)
Na ⁺ + 0.5Ca-X ₂ = 0.5Ca ²⁺ + Na-X	0.3981
Na ⁺ + 0.5Mg-X ₂ = 0.5Mg ²⁺ + Na-X	0.5012
Na ⁺ + K-X = K ⁺ + Na-X	0.1995
Na ⁺ + H-X = H ⁺ + Na-X	1.3092×10 ⁻⁶

The results after a simulation time of 144 ka are compared with observations for major cations and alkalinity (Figure 8.2.4). The agreement between numerical results and observations is reasonably satisfactory. The fit for Mg^{2+} can be further improved by adjusting Mg^{2+} selectivity. The sequential appearance of Mg^{2+} and K^+ is attributed to chromatographic separation and can be varied in the model only by varying the Mg^{2+}/K^+ selectivity. An apparent dip in alkalinity is observed just before Na^+ concentrations increase, which is matched by the simulation. The upstream increase of Ca^{2+} concentrations in the region where K^+ and Mg^{2+} are peaking indicates an increased concentration of $Ca-X_2$ (X represents cation exchange sites). The increase occurred during flushing of Na^+ and is due to dissolution of calcite. The increase of Na^+ and alkalinity at the downstream end agrees with earlier conclusions about the development of $NaHCO_3$ water quality in a freshening aquifer (Chapelle and Knobel, 1983).

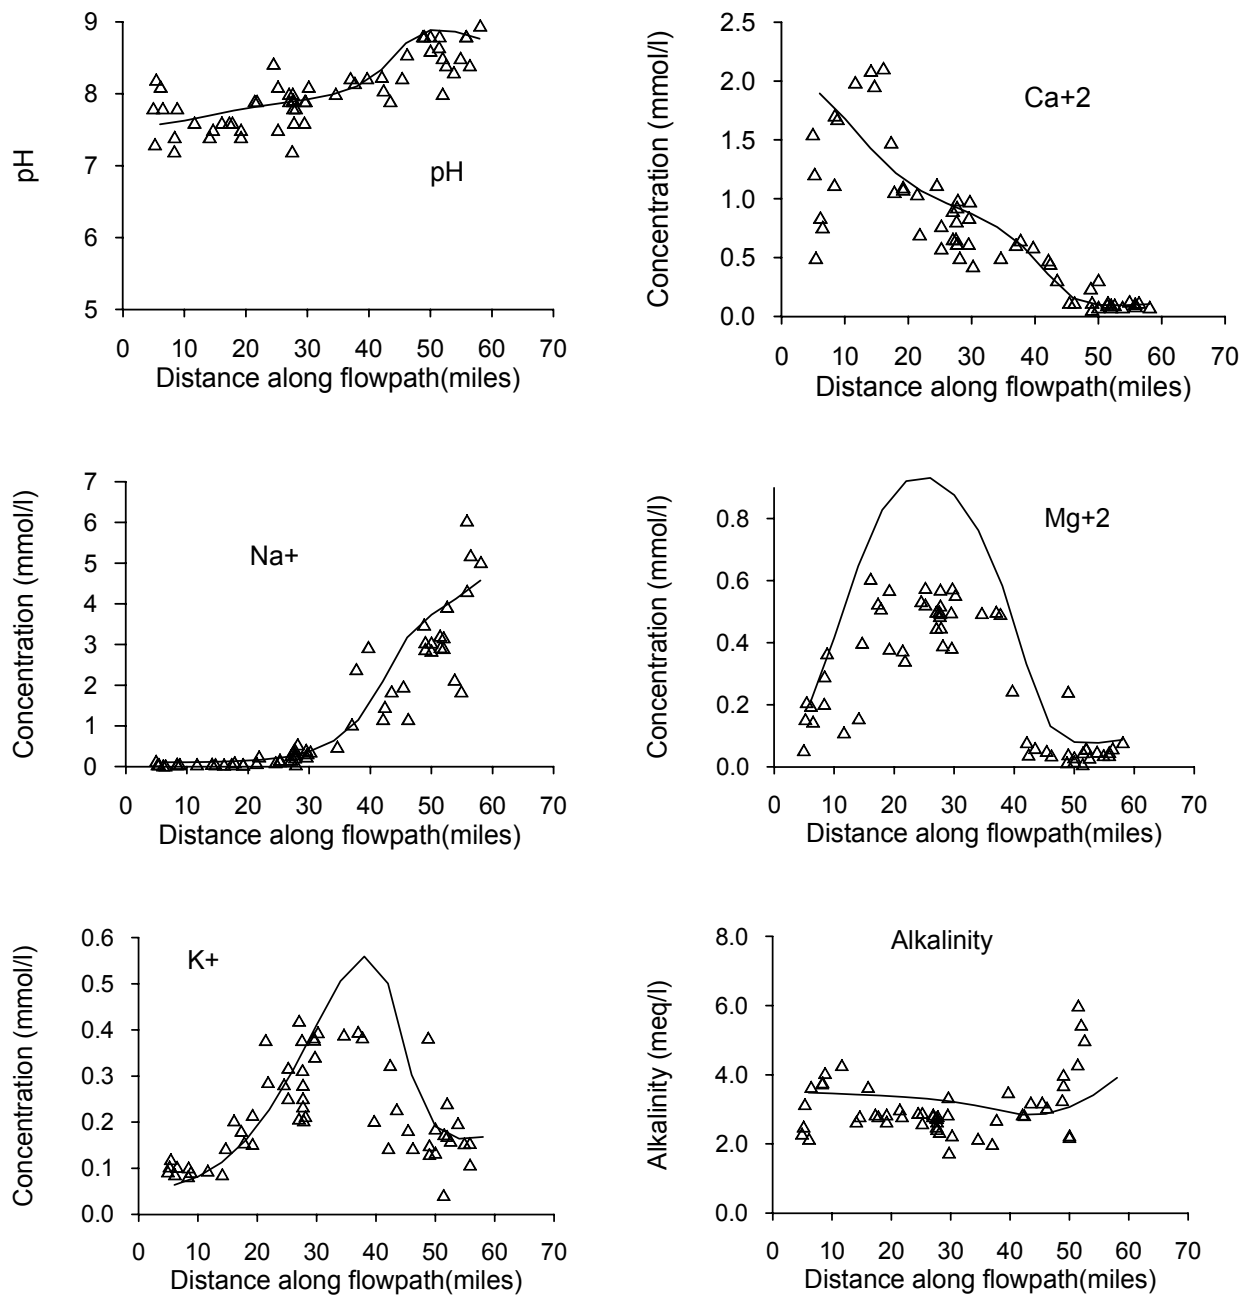

Figure 8.2.4. Concentrations of Na⁺, K⁺, Mg²⁺, Ca²⁺, alkalinity and pH along a flow path in the Aquia aquifer (Maryland). Symbols indicate observations that are provided by Appelo (1994) and originally from Chapelle and Knobel (1983); solid lines represent simulated concentrations using TOUGHREACT.

8.3. Infiltration and Calcite Deposition at Yucca Mountain, Nevada (EOS3)

8.3.1. Problem statement

Yucca Mountain in southern Nevada (USA) is being investigated as a possible site for an underground nuclear waste repository. The semiarid environment and a thick (500 to 700 m) unsaturated zone (UZ) are considered to be favorable for long-term isolation of radioactive waste (Montazer and Wilson, 1984). The percolation flux in the UZ is an important parameter addressed in site characterization and hydrological modeling of Yucca Mountain, because it controls seepage into drifts that may contact waste packages. Hydrogenic calcite deposits in fractures and lithophysal cavities at Yucca Mountain were studied to estimate past percolation fluxes (Carlos, 1995; Vaniman and Chipera, 1996; Paces et al., 1998; Marshall et al., 1998; Marshall, 1999; Fabryka-Martin, 2000). These deposits provide evidence of water flow in the past and may improve the understanding of current and future UZ percolation rates, because direct measurements of infiltration fluxes over thousands of years are not possible.

An objective of these previous studies was to investigate the relationship between percolation flux and measured calcite abundances. The U.S. Geological Survey determined calcite abundances from a deep surface-based borehole (WT-24) (Fabryka-Martin, 2000) by measuring the CO₂ given off by heating of the rock. Geochronology work performed by the Geological Survey (Paces et al., 1998; Neymark et al., 2001) indicates that this calcite formed over approximately 10 million years. Hydrogenic mineral coatings in the UZ are non-uniformly distributed and located almost entirely on fracture footwalls and cavity floors, in contrast to saturated environments, in which vein and cavity deposits usually coat all surfaces (Paces et al., 1998).

Here, we present some results of a reaction-transport numerical model for calcite deposition under different infiltration conditions using TOUGHREACT. More details on problem setup and results are given in Xu et al. (2003a). The reactive transport model here considers a complete set of hydrological and geochemical processes, including the following essential factors affecting calcite precipitation: (1) infiltration, (2) the ambient geothermal gradient, (3) gaseous CO₂ diffusive transport and partitioning in liquid and gas phases, (4) fracture-matrix interaction for water flow and chemical constituents (dual permeability), and (5) water-rock interaction. In

addition, any effects of water-rock interaction (e.g., pH modification) also affects the calcite solubility and hence its abundance in each rock unit. The dual permeability model allows us to address not only the abundances of calcite with depth, but also their relative abundances in fractures and in the rock matrix as a function of the hydrological/geochemical processes.

8.3.2. Calcite precipitation mechanisms

Precipitation, along with wind-blown dust, carries much of the calcium to the surface (Vaniman et al., 2001). In the soil zone, strong evapotranspiration along with some water-rock interaction and root-zone biological processes leads to saturation with respect to calcite. The depth to reach calcite equilibrium depends on climate and infiltration variations over time and episodic water flow, as well as on near-surface biogeochemical conditions. During more typical smaller infiltration events, calcite may reach equilibrium close to the surface. However, large infiltration pulses of calcite under-saturated water could dissolve near-surface calcite and reach equilibrium at a greater depth. Because we are primarily interested in calcite deposition in a deep geological unit, the Topopah Spring welded tuff (TSw) where the potential repository is located, uncertainties in the infiltrating water composition near the surface are not significant because calcite reaches saturation well above this unit. In addition, the constant infiltration rate and steady-state water flow conditions over geological time used in our simulations are also justified by evidence that calcite growth in the UZ has remained approximately constant over at least the past 8 million years, as indicated by radiocarbon, $^{230}\text{Th}/\text{U}$, and U-Pb ages (Paces et al., 1998).

The primary driving force for calcite precipitation from percolating waters in the UZ is its decreasing solubility with increasing temperature. Therefore, consideration of the ambient geothermal gradient is very important for calcite precipitation. The temperature distribution is a function of the crustal heat flow and the effect of infiltration, which has been evaluated in Sonnenthal and Bodvarsson (1998). The modeled temperature distributions in borehole WT-24 are discussed later. Pore waters extracted from deep locations of the Yucca Mountain rock matrix are close to equilibrium with respect to calcite (Fabryka-Martin, 2000), and no measurements of aqueous concentrations are available from fractures because they generally have low liquid saturations. Previous models for calcite precipitation, under conditions of local equilibrium (Marshall et al., 1999), have indicated that increased infiltration-percolation fluxes result in greater abundances of calcite precipitated over time. These models have not considered,

however, effects such as water-rock interaction, changes to the geothermal gradient, and fracture-matrix interaction. They have also assumed a fixed partial pressure of CO₂.

The Ca concentration and CO₂ partial pressure in percolating water are major controlling factors for the abundance of calcite and its stability. This is a result of the decreasing solubility of CO₂ gas in water with increasing temperature, which in turn causes the following degassing process: $\text{HCO}_3^- + \text{H}^+ \rightarrow \text{CO}_2 (\text{g}) + \text{H}_2\text{O}$. Gaseous CO₂ is also redistributed by gas phase diffusive transport. Degassing increases the pH, and then contributes to calcite precipitation: $\text{Ca}^{2+} + \text{HCO}_3^- \rightarrow \text{CaCO}_3 (\text{calcite}) + \text{H}^+$. Water and gas flow between fractures and the adjacent matrix governs the resulting calcite distribution within each medium. Calcite precipitation is also affected by other factors such as the dissolution and precipitation of aluminosilicate minerals (mainly through modifying the pH and the CO₂ partial pressure).

8.3.3. Hydrogeological and geochemical conditions

Hydrogeological Conditions

The Yucca Mountain UZ consists of layers of welded and non-welded volcanic tuffs. The welded and non-welded tuffs have vastly different hydrologic properties. The welded units are characterized by relatively low porosity, low matrix permeability, and high fracture density, whereas the nonwelded tuffs have higher matrix porosity and permeability, and lower fracture density (Liu et al., 1998; Sonnenthal and Bodvarsson, 1999). Montazer and Wilson (1984) developed a conceptual model for the UZ at Yucca Mountain that identified five main hydrogeological units based on the degree of welding and on the associated relationship to fracture intensity. This conceptual model has formed the basis for modeling flow in the UZ at Yucca Mountain. A schematic East-West cross-section through Yucca Mountain illustrating the major hydrogeological units in the UZ at Yucca Mountain is shown in Figure 8.3.1. Table 8.3.1 provides a description of the units, each of which is further divided into a number of model layers with different hydrogeological and geochemical properties (Ahlers and Liu, 2000; Sonnenthal and Spycher, 2001; Spycher et al., 2003a). The Calico Hills nonwelded (CHn) unit is comprised of zeolitic and vitric nonwelded tuffs underlying the basal vitrophyre of the Topopah Spring Tuff. Below the CHn are the Crater Flat undifferentiated (CFu) units, consisting of the lower Bullfrog and Tram Tuffs of the Crater Flat Group. The hydrogeological units below the TSw were not considered in the geochemical transport simulations, so details regarding these units are not given

in Table 8.3.1. This is based on: (1) the lateral flow that may occur in these units, (2) they have a more complex mineral assemblage (zeolites, glass, and clays) which has a less well-constrained effect on calcite reactions, and (3) we are primarily interested in calcite deposition within the TSw unit, where the potential repository is located (TSw4 and TSw5 model layers in Table 8.3.1). The exclusion of the underlying hydrogeological units does not affect the results in the TSw unit because flow is predominantly gravity driven, and upward chemical diffusion is subordinate to downward advective transport.

Figure 8.3.1. Schematic East-West cross-section through Yucca Mountain depicting the major hydrogeological units in the unsaturated zone and the approximate location of the potential repository horizon.

Table 8.3.1. Hydrogeologic units, model layers, and hydrogeological properties for the Yucca Mountain Unsaturated Zone Flow and Transport Model as given by the property calibration model (Ahlers and Liu, 2000).

Hydrogeologic unit	Description	Model layer	Fracture		Matrix	
			Permeability (m ²)	Porosity	Permeability (m ²)	Porosity
TCw: Tiva Canyon Welded unit	Moderately to densely welded portions of the Tiva Canyon Tuff of the Paintbrush Group	TCw1	2.41×10^{-12}	3.7×10^{-2}	3.86×10^{-15}	0.253

		PTn4	4.67×10^{-13}	1.5×10^{-2}	7.86×10^{-14}	0.411
		PTn5	7.03×10^{-13}	7.9×10^{-3}	7.00×10^{-14}	0.499
		PTn6	4.44×10^{-13}	4.6×10^{-3}	2.21×10^{-13}	0.492
TSw: Topopah Spring welded unit	Moderately to densely welded portions of the Topopah Spring Tuff down to and including the densely welded basal vitrophyre	TSw1	3.21×10^{-11}	7.1×10^{-3}	6.32×10^{-17}	0.053
		TSw2	3.56×10^{-11}	1.2×10^{-2}	5.83×10^{-16}	0.157
		TSw3	3.86×10^{-11}	8.4×10^{-3}	3.08×10^{-17}	0.154
		TSw4	1.70×10^{-11}	1.0×10^{-2}	4.07×10^{-18}	0.110
		TSw5	4.51×10^{-11}	1.5×10^{-2}	3.04×10^{-17}	0.131
		TSw6	7.01×10^{-11}	2.0×10^{-2}	5.71×10^{-18}	0.112
		TSw7	7.01×10^{-11}	2.0×10^{-2}	4.49×10^{-18}	0.094
		TSw8	5.92×10^{-13}	1.6×10^{-2}	4.53×10^{-18}	0.037
		TSw9	4.57×10^{-13}	5.9×10^{-3}	5.46×10^{-17}	0.173

A one-dimensional vertical column corresponding to the location of a deep borehole (WT-24) was chosen for modeling calcite deposition because measured calcite abundances (by the U.S. Geological Survey, and reported by Fabryka-Martin, 2000) were available for comparison. The model grid, hydrogeological parameters and flow conditions were adopted from the hydrological property calibration work performed by Ahlers and Liu (2000).

Geochemical Model

Initial mineral abundances, potential secondary minerals, reactive surface areas, kinetic and thermodynamic data were taken from the modeling work of coupled thermal, hydrological, and chemical (THC) processes for the potential high-level nuclear waste repository at Yucca Mountain (Sonnenthal and Spycher, 2001; Spycher et al., 2003a). Minerals considered in the simulations are calcite, gypsum, goethite, tridymite, cristobalite- α , quartz, amorphous silica, hematite, fluorite, albite, K-feldspar, anorthite, Ca-smectite, Mg-smectite, Na-smectite, illite, kaolinite, opal-CT, stellerite, heulandite, mordenite, clinoptilolite, and glass. This full assemblage of minerals and the corresponding aqueous species are hereafter termed the extended-case geochemical system, because it has more complexities and uncertainties in terms of thermodynamics and kinetics of mineral solid solutions (clays, zeolites and feldspars), effects on pH, and the partial pressure of CO₂. A simpler set of minerals and aqueous species (base-case geochemical system) disregards all aluminosilicates, Fe- and Mg-bearing minerals.

Calcite and gypsum dissolution and precipitation were assumed to take place under geochemical equilibrium, whereas dissolution and precipitation of the other minerals was treated under kinetic constraints. Initial mineral abundances were derived from X-ray diffraction measurements on cores and studies of fracture surfaces (Carey et al., 1998; S. Levy, unpublished data). Potential secondary minerals (i.e., those allowed to precipitate but which may not necessarily form) were determined from field and experimental observations of water-rock interaction and from equilibrium geochemical model calculations. Reactive surface areas of minerals on fracture walls were calculated from the fracture-matrix interface area/volume ratio, the fracture porosity, and the derived mineral volume fractions. These areas were based on the fracture densities, fracture porosities, and mean fracture diameter. Mineral surface areas in the rock matrix were calculated using the geometric area of a cubic array of truncated spheres that make up the framework of the rock and reductions to those areas owing to the presence of alteration phases such as clays and zeolites. Full details are given in Sonnenthal and Spycher (2001).

Initial pore water chemical concentrations were based on analyses of ultracentrifuged water (L. DeLoach, unpublished data) and chemical speciation calculations (Sonnenthal and Spycher, 2001; Spycher et al., 2003a). Except for perched water that lies well below the potential repository horizon, water has not been observed in fractures in the UZ. Therefore, the initial composition of water in the fractures was assumed to be the same as the matrix pore water (Table

8.3.2). The same water composition, re-equilibrated at the temperature of the top model boundary, was assumed for infiltrating water. Oxidizing conditions were considered for this water, because the fracture permeability of the rock is high and the system is unsaturated (air phase is everywhere present). The CO₂ gas partial pressures used for initial and top boundary conditions of the gas transport are in equilibrium with the corresponding aqueous chemical composition. An elevated gas partial pressure (relative to an atmospheric value of 0.344×10^{-3} bar) at the upper boundary can be attributed to soil-zone CO₂ production.

Table 8.3.2. Water and gas chemistry used for initial and boundary conditions of the reaction-transport simulations (Sonnenenthal and Spycher 2001).

Component	Concentration	Unit
Ca ²⁺	101	mg/L
Mg ²⁺	17	mg/L
Na ⁺	61.3	mg/L
K ⁺	8	mg/L
SiO ₂ (aq)	70.5	mg/L

HCO ₃ ⁻	200	mg/L
Cl ⁻	117	mg/L
SO ₄ ²⁻	116	mg/L
F ⁻	0.86	mg/L
Fe ³⁺	6.46×10^{-8}	mg/L
PH	8.32 (at 25 °C) 7.75 (at 17 °C)	
PCO ₂	2.726×10^{-3} at 17 °C	bar

Simulation Setup

Simulations were performed using three infiltration rates, a base-case rate of 5.92 mm/yr (Ahlers and Liu, 2000), and bounding rates of 2 mm/yr and 20 mm/yr. The corresponding steady-state water flow conditions were used for geochemical transport simulations. Steady-state temperature distributions corresponding to the same three infiltration rates were obtained using a top temperature of 15.6°C at the land surface and a bottom temperature of 28°C at the water table (Figure 8.3.5). For the three infiltration rates, the same water and gas chemistry was used for the top boundary condition. The EOS3 flow module was used for these simulations.

For the reactive transport simulations of calcite precipitation, a simulation time of 10 million years was selected, based on the following inferences: (1) calcite growth has remained approximately constant over the past 8 million years, as indicated by radiocarbon, $^{230}\text{Th}/\text{U}$, and U-Pb ages (Paces et al., 1998) (2) the tuff is 12.7 million years old (Paces et al., 1998), and (3) all dated surfaces indicated by ages of outer mineral surfaces are young compared to the age of the tuffs. Infiltration rates and temperatures were held constant throughout the simulation, and therefore the results can only be considered to reflect the average conditions over this period of time.

In this manual, we only present results with a base-case infiltration rate of 5.92 mm/yr. More results are given in Xu et al. (2003a). The corresponding input and output files are given in the distribution CD (subdirectory: `tract/sample-problems/P3_EOS3-YM-calcite`). To shorten the simulation time for installation purpose, the simulation time in the PARAM input block of `flow.inp` is specified as 3.15576E09 s (100 years). For simulation of ten million years, users can reset this variable to 3.15576E13. Parts of output files for fluid flow, aqueous chemical concentrations, and changes of mineral abundances are given in Figures 8.3.2, 8.3.3 and 8.3.4.

Figure 8.3.2. Part of file flow.out for problem no. 3 (calcite and infiltration).

Figure 8.3.5. Modeled temperature profiles in borehole WT-24 as a function of depth for three infiltration rates.

8.3.4. Results and discussion

The simulated total (fracture plus matrix) calcite abundances in the WT-24 column obtained using the three different infiltration rates, together with USGS measured data, are presented in Figure 8.3.6. Generally, the results obtained using the base-case infiltration rate (5.92 mm/yr) agree better with the measured WT-24 mineral abundances than those obtained using the other infiltration rates, especially for the PTn unit.

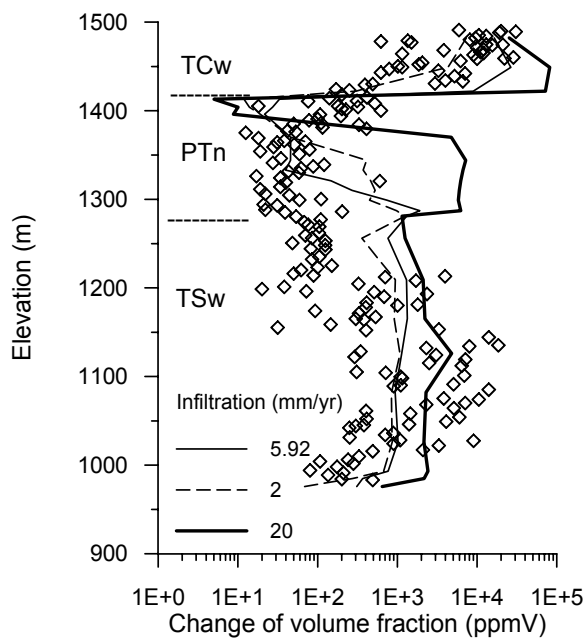

Figure 8.3.6. Simulated total (fracture plus matrix) calcite abundances (volume fraction) in the WT-24 column for different infiltration rates after 10 million years (Extended geochemical system). Diamonds represent bulk rock calcite abundances measured by the U.S. Geological Survey (Fabryka-Martin, 2000).

The simulated calcite abundances in the basal PTn layer for the three infiltration simulations are higher than that measured in WT-24. This is a result of an increase in the temperature gradient (Figure 8.3.5) resulting in a concomitant decrease in calcite solubility. The relatively larger calcite abundances in the bottom layer of the PTn have been observed at other locations such as in another deep borehole USW G-2 (Carey et al., 1998). The lower measured

calcite abundances may also be a result of lateral flow that is not captured in the one-dimensional simulations.

Results for the welded TSw unit (of the most interest to the Yucca Mountain Project) generally fall in the wide range of measured calcite data. Calcite deposition values obtained from the highest infiltration rate (20 mm/yr) are closer to the high bound of measured values. Those values from the base-case (5.92 mm/yr) fall in the middle of the TSw measured data range. This may imply that the 20-mm/yr percolation rate is the high bound for the WT-24 location; whereas the base infiltration (5.92 mm/yr) from the flow property calibration (used for the flow model) may be close to the long-term mean infiltration rate for this location. More results are presented in Xu et al. (2003a)

8.4. Heat Test Problem (EOS4)

This test problem of a large-scale *in-situ* thermal test at Yucca Mountain (Nevada) provides a complex 2-D example of coupled thermal, hydrological, and chemical (THC) processes in unsaturated fractured rock. The model setup incorporates many aspects of the capabilities of both TOUGH2 and TOUGHREACT, including time-dependent heat generation, dual-permeability, vapor pressure lowering (EOS4), numerous aqueous, gaseous, and mineral species, CO₂ diffusion (P- and T-dependent), and coupling of permeability and capillary pressure to porosity changes.

8.4.1. Background

The Drift Scale Test (DST) is the second underground thermal test to be carried out in the Exploratory Studies Facility (ESF) at Yucca Mountain, Nevada. The purpose of the test was to evaluate the coupled thermal, hydrological, chemical, and mechanical processes that take place in unsaturated fractured tuff over a range of temperatures (approximately 25°C to 200°C). Briefly, the DST consists of an approximately 50 m long drift that is 5 m in diameter. Nine electrical floor canister heaters were placed in this drift (the Heated Drift) to simulate nuclear-waste-bearing containers. Electrical heaters were also placed in a series of horizontal boreholes (wing heaters) drilled perpendicular outward from the central axis of the Heated Drift. These heaters were emplaced to simulate the effect of adjacent emplacement drifts. The DST heaters were activated on December 3, 1997, with a planned period of 4 years of heating, followed by 4 years of cooling. After just over 4 years, the heaters were switched off on January 14, 2002, and since that time the test area has been slowly cooling.

The first predictive model for THC processes in the DST was begun just prior to the initiation of heating in late 1997 with the final predictive report completed several months after the test had begun (Sonnenthal et al. 1998; Xu et al., 2001). The 2-D numerical grid, thermal and hydrological properties for the THC model were based on the original TH model developed for the DST (Birkholzer and Tsang, 1997; 1998). Model development, results, and data shown in this test problem are based on Spycher et al. (2003b), and Sonnenthal et al. (in prep. for a special issue of the International Journal of Rock Mechanics and Mining Sciences).

8.4.2. Conceptual model for THC processes

The evolution of the chemical regime in the unsaturated zone surrounding a heat source is closely related to the spatial distribution of temperature and the transport of water and vapor. An important aspect of the unsaturated fractured tuff at Yucca Mountain is that the highly permeable fractures are nearly dry, whereas the low permeability and porosity rock matrix has a water saturation of about 90 percent. Thus, heating of the rock induces boiling of the matrix pore water, transport of water vapor into fractures, and condensation along fracture walls. The numerical model for reaction-transport processes in the fractured welded tuffs must account for the different rates of transport in fractures, compared to a much less permeable rock matrix. Transport rates greater than the rate of equilibration via diffusion leads to disequilibrium between waters in fractures and matrix. Because the system is unsaturated, and undergoes boiling, the transport of gaseous species, especially CO₂, is an important consideration. The model must also capture the differences in initial mineralogy in fractures and matrix and their evolution.

In order to handle separate yet interacting processes in fractures and matrix, the dual permeability method has been adopted, such that each grid block is divided into matrix and fracture continua, characterized by their own pressure, temperature, liquid saturation, water and gas chemistry, and mineralogy. In the dual-permeability model, the fracture continuum is considered as co-located but interacting with the matrix continuum, in terms of the flow of heat, water, and vapor through advection, diffusion, and conduction (for heat). The aqueous and gaseous species are transported via advection and molecular diffusion between the fractures and matrix. Each continuum has its own well-defined initial physical and chemical properties.

8.4.3. Drift scale test 2-D numerical grid

The two-dimensional dual-permeability numerical grid for the DST represents a vertical cross section through the Heated Drift at a distance approximately 30 m from the bulkhead, separating the Heated Drift from the Access Drift (Figure 8.4.1a). The mesh consists of 4,490 grid blocks, including fracture and matrix (Figure 8.4.1a and b). The top boundary is approximately 99 m above the drift center, with the bottom boundary at approximately 157 m below the center. The DST includes a plane of linear wing heaters on each side of the drift that are given small grid blocks in the model. Small grid blocks are also employed adjacent to the wing heaters and drift

wall to capture the strong gradients in temperature and liquid saturation in these regions (Figure 8.4.1b). Radial mesh blocks in the drift interior were removed from the original mesh and replaced near the drift base by Cartesian grid blocks to represent the concrete invert (Figure 8.4.1b). The Heated Drift grid block is connected directly to the Heater Test Alcove grid block. The connection area and distance were adjusted so that heat loss from the drift resulted in roughly similar crown temperatures to the maximum observed values. In the approximate location of the observation drift, the grid block volumes were increased to a large value to represent connection to the atmosphere. The distances from the drift center grid block and the connecting elements were modified to represent the true distance, so that heat could be applied to the drift center to approximate the effect of the electrical canister heaters.

Figure 8.4.1a. Three-dimensional schematic diagram of the DST showing perspective view of 2-D numerical mesh for DST THC model simulations (mesh extends in all directions from area shown).

NOTE: Inner (violet diamonds closer to drift) and outer wing heater (red squares) indicate grid block coordinates. Heat was applied to the drift center. Green squares indicate grid block locations for the concrete invert.

Figure 8.4.1b. Enlarged view of the numerical mesh showing the locations of grid blocks representing the heated drift, wing heaters, and concrete invert heater power

In the Heated Drift, heat was applied solely to the drift-center grid block, which is connected to all surrounding grid blocks. The wing heaters are split into inner and outer zones, with more power applied to the outer zone to approximate the presence of an adjacent parallel drift. The positions of grid blocks representing heaters are shown in Figure 8.4.1b. The heating schedule was based on step-wise averages of the 10-day incremented power data. A 9-month initial period is set to the ambient temperature, corresponding approximately to the time that was required to set up the test. Intentional power reductions were directly accounted from the power data. Estimates were made of the duration of the longer (approximately greater than 1/2 day) temporary power outages. Table 8.4.1 gives the step-wise averaged power data implemented in the model simulations in the GENER file. Each time in Table 8.4.1 represents the initiation of a specific period of heating or power loss that continues until the succeeding time. The simulation can be run for the full period of heating plus a 4-year period of cooling (shown by the hypothetical end time at the base of Table 8.4.1). Depending on the speed of floating point calculations on a particular computer, the full simulation could take up to a few days or longer. The complexity of this heating schedule provides a good example of stepwise heat generation in TOUGH2/TOUGHREACT.

8.4.4. Hydrological and thermal parameters

Values of hydrological and thermal input data are listed in Table 8.4.2. The fracture tortuosity (0.7) is based on models of *in situ* testing data. This value was further modified for fracture-fracture connections by multiplication of the tortuosity by the fracture porosity of the

bulk rock. This operation yields a better approximation for the fracture-to-fracture interconnection area (only for calculation of diffusive fluxes; the entire grid block connection area is used for calculating advective fluxes, because the bulk fracture permeability is used for flow calculations). The capillary pressure in both fractures and matrix must reach some maximum, finite value upon complete dryout (zero liquid saturation). For fractures and matrix in the Tptpmn and Tptpll lithostratigraphic units (model units tsw34 and tsw35, respectively), the limit is set by the calculated slope of the P_{cap} versus liquid saturation curve at a liquid saturation value equal to $S_r + \epsilon$. For these units, ϵ values for the matrix yield maximum P_{cap} values of 10^8 Pa (Table 8.4.2); for fractures, ϵ is set to 0.01 (maximum P_{cap} values around 10^3 – 10^4 Pa). These specific implementations of the van Genuchten equations are invoked by setting the MOPR(5) parameter to “2”, in addition to the specific values given in the ROCKS block.

tortuosity	t	0.7	0.7	0.7
epsilon (for max P_{cap})	ϵ	0.01	0.01	0.01

NOTE: ¹ Fracture thermal properties are derived using matrix properties.

* Bulk conductivities converted from grain conductivity values and lithophysal porosities, using $K_{bulk} = K_{grain} (1 - \phi_{lith}) + \phi_{lith} K_{air}$, with $K_{air} = 0.028$ (W/m-K) (see Spycher et al., 2003b).

The thermal conductivities of fracture and matrix grid blocks are calculated assuming a linear interpolation between dry and wet conductivities as a function of liquid saturation. These are the thermal conductivities for the solid + fluid system. For fractures, thermal conductivities are multiplied by the fracture porosity to account for the correct fracture-to-fracture connection area in calculations of heat conduction (i.e., this is needed because full grid block areas are input into the model). Fracture thermal conductivities are also reduced by a factor of 10 to account for the limited spatial continuity and connectivity between fracture grid blocks. The volume of the fracture continuum is, however, only a small fraction of the matrix continuum. Therefore heat conduction occurs primarily through the matrix continuum and, as a result, the model is not sensitive to the amount of heat conduction in fractures.

8.4.5. Geochemical input data

Thermodynamic data and kinetic data are provided in the thermok1.01.dat and the chemical.inp files, respectively. Equilibrium and kinetic mineral-water reactions are treated in this test problem. Different representations for reactive surface areas of minerals in fractures and in the porous rock matrix are provided in the chemical.inp file. In most cases, the chemical and physical properties of minerals that form solid solutions are approximated by their individual endmember compositions and properties. An ideal solid-solution model was implemented for smectite (Na, Ca, and Mg endmembers), with each endmember's activity equaling its mole

fraction. Treating the smectite as a solid solution, results in individual smectite endmembers either all dissolving or all precipitating, providing a better physical representation of dissolution/precipitation processes. Feldspar solid solutions are not considered because albite (Na-feldspar) and anorthite (Ca-feldspar) are generally strongly undersaturated in the simulations, and thus their dissolution rates are governed primarily by the kinetic rate constant rather than the saturation index. Coupling of permeability to mineral precipitation for fractures is given as a function of the hydraulic aperture and fracture porosity for each rock type (see Appendix F). For the rock matrix it is given as a relation to porosity, using a simplified form of the Kozeny-Carman equation. Coupling of capillary pressure to porosity and permeability is performed using Leverett scaling and “turned on” by setting the MOPR(6) parameter in the flow.inp file to “1”.

8.4.6. Initial and boundary conditions: Hydrological and thermal

The top and bottom boundaries were set to constant temperature, pressure, and liquid saturation, based on steady-state values obtained from simulations of a 1-D column extending from the land surface to the water table. The top boundary of the 2-D model extends 150 m above and below the drift center, but does not reach either the land surface or the water table. Under these conditions, the percolation flux at the top boundary is approximately 0.5 mm/yr. The bottom boundary condition is open to gas and to liquid flow. The side boundaries of the domain are located 81.5 m away from the drift center on each side (outside of the test influence area) and are no-flux for mass and heat. The air pressure and temperature in the observation drift are set to constant values. The Heated Drift wall is open to advection and conduction of heat and mass (e.g., air, water vapor, and CO₂). The INCON file provides the steady-state thermohydrological conditions in EOS3 format. Vapor-pressure lowering (EOS4) is implemented by setting MOP(19) = 2, and the simulation can be run using either EOS module.

8.4.7. Initial and boundary conditions: Geochemical

Aqueous and gaseous species concentrations in the rock were initially set to uniform values, based on the measured pore water composition and calculated equilibrium values for CO₂ and some aqueous species. The Heater Alcove and Observation Drift CO₂ concentrations were fixed to approximately that of the atmosphere. The Heated Drift CO₂ concentration was initially set to the same value as that in the Observation Drift, but was allowed to exchange CO₂ with the

Heater Test Alcove and with the surrounding rock. All initial geochemical conditions are provided in the chemical.inp and solute.inp files. Both the top and bottom boundary conditions are open to gas and aqueous species transport. The top and bottom boundaries were also set so that no mineral reactions take place (and therefore no changes in aqueous species concentrations occur as a result of mineral-water reactions). Their volumes were set to extremely large values, so that they act essentially as constant concentration boundaries. The side boundaries are no-flux for gas and aqueous-species transport.

8.4.8. Simulation parameters

The maximum simulation time for this test problem is set in the flow.inp file to 2.75 years (0.75 preheating period plus 2 years of heating), although the GENER file includes the full 8.65 year periods of preheating, heating, and cooling. The maximum time step is set to one day, so that errors due to the non-sequential iteration method, in particular related to gas phase CO₂ diffusion and rapid reaction rates, are reduced.

The corresponding input and some output files are given in the distribution CD (subdirectory: treat/sample-problems/P4_EOS4_heat-test). To shorten the simulation time for installation purpose, the simulation time step variable, MCYC, in the PARAM input block of flow.inp is specified as 99. For the full simulation, users can reset MCYC to 9999. In TOUGHREACT, if MCYC = 9999, the simulation time is not controlled by MCYC, and is only controlled by TIMAX in Record PARAM.2 (see section 6.1). Parts of output files for fluid flow, aqueous chemical concentrations, and changes of mineral abundances are given in Figures 8.4.2, 8.4.3 and 8.4.4.

Figure 8.4.4. Part of file tec_min.dat for problem no. 4, giving changes in mineral abundances (in volume fraction, positive values indicate precipitation and negative dissolution) after $t = 0.237909$.

8.4.9. Model results and comparisons to measured data

Gas-Phase CO₂ Evolution

The concentration of CO₂ in the gas phase is a function of temperature, pressure, aqueous-phase chemistry, mineral-water reactions, and advective and diffusive transport. Simulation results are compared to concentrations measured in gas samples taken from boreholes during the heating phase of the DST. The modeled evolution of CO₂ has been validated by comparison to over 4 years of measurements from the Drift Scale Test. Simulated CO₂ concentrations in the fracture gas phase are shown after 3 years of heating in Figure 8.4.5. The results show the general outward migration of elevated CO₂ concentrations as the boiling front moves outward. The peak in CO₂ concentrations is centered at approximately the 60°C isotherm, and at higher temperatures the concentrations generally decline as a result of degassing and transport with water vapor to cooler regions.

Figure 8.4.5. Modeled CO₂ concentrations in fractures after 3 years of heating. Note locations of numbered boreholes collared in the Observation Drift (circular region at left).

Comparisons of modeled CO₂ concentrations to measurements performed on gas samples from boreholes (shown in Figure 8.4.5) are presented in Figure 8.4.6. Samples were collected from zones a few meters (borehole interval 76-3) to about 15 meters away from the Heated Drift (borehole interval 74-3). Measured concentrations were corrected for water vapor condensation that took place as part of the procedure for gas sampling. Zones closest to the heaters (interval 76-3) exhibit narrower and earlier peaks in concentration compared to zones further out in the rock (interval 74-3). Simulated and measured concentrations are close in magnitude and in their trends. There is little difference between fracture and matrix concentrations, because of rapid equilibration by advection and diffusion of gas species and their local equilibration with pore water.

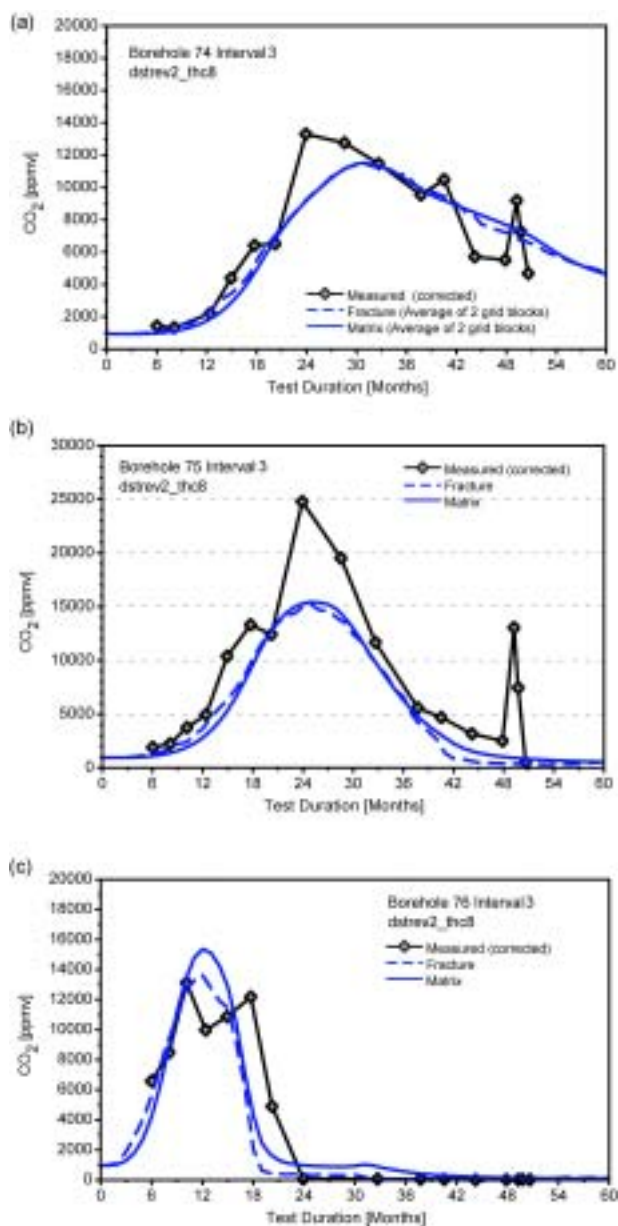

Figure 8.4.6. Modeled CO₂ concentrations in fractures and matrix compared to measured values from boreholes (corrected for vapor condensation) (a) Borehole interval 74-3 (average of bounding grid blocks); (b) Borehole interval 75-3; (c) Borehole interval 76-3.

Aqueous Species Evolution

The evolution of aqueous species in waters collected in the DST exhibit small reductions in pH (from about pH 8 in the pore water to about 6-8 in condensate waters. The drop in pH is related to the local increases in CO₂ concentrations. Figure 8.4.7 shows an example of the initial

drop in pH during vapor condensation, followed by increasing pH as the zone is further heated and CO₂ is diluted by water vapor.

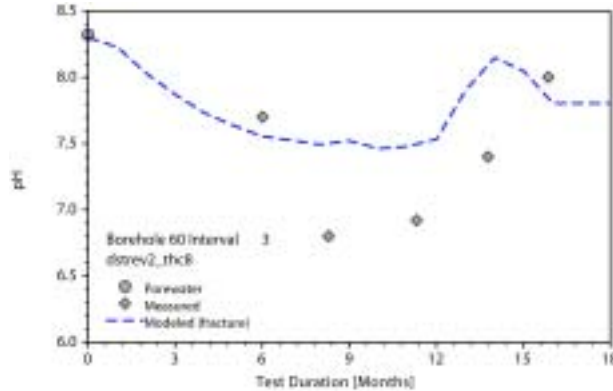

Figure 8.4.7. Measured and modeled pH (in fractures) for samples collected from borehole interval 60-3, located below the heaters. Data provided by L. DeLoach.

Simulated and measured concentrations of conservative species in the fractures, such as chloride, are much lower than in the initial matrix pore water, indicating that fracture-matrix interaction has been negligible. However, reactive species, such as silica and potassium show significant effects of reaction with fracture-lining silicate minerals.

Mineral Precipitation/Dissolution

Model predictions, followed by analyses of *in-situ* sidewall core samples, showed that amorphous silica, calcite and lesser amounts of gypsum are the dominant precipitating phases expected in the boiling regions. The greatest amount of mineral precipitation is predicted to be above the heaters where reflux of water condensed in fractures dissolves fracture-lining minerals and is boiled. Simulations and measurements of amorphous silica and calcite, along with locations of observed mineralization are shown in Figures 8.4.8 and 8.4.9. Amorphous silica forms only where strong evaporation by boiling takes place. Calcite also forms in the boiling zones, however calcite that is originally present in fractures dissolves in the lower pH waters that formed in condensation zones around the boiling zone and in the drainage zones below the heaters.

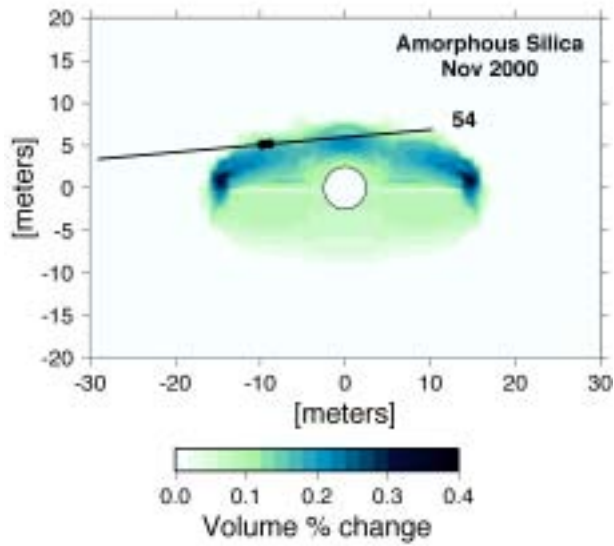

Figure 8.4.8. Volume percent change in amorphous silica abundance in fractures. Filled circle indicates sidewall core sample locations where it was observed.

Figure 8.4.9. Volume percent change in calcite abundance in fractures. Filled circle indicates sidewall core sample locations where it was observed.

8.5. CO₂ Disposal in Deep Saline Aquifers (ECO₂)

8.5.1. Problem statement

The feasibility of storing CO₂ in deep formations has been discussed in the technical literature over the last decade. Studies include an evaluation of the feasibility of CO₂ aquifer storage in The Netherlands (Lohuis, 1993) and in the Alberta Basin, Canada (Gunter et al., 1993; Bachu et al., 1994; Law and Bachu 1996; Gunter et al., 1996 and 1997). Furthermore, large-scale CO₂ disposal in an aquifer is already being practiced in the Norwegian sector of the North Sea (Korbol and Kaddour, 1995).

Carbon dioxide is retained in geologic formations in three ways (Hitchon, 1996). First, CO₂ can be trapped as a gas or supercritical fluid under a low-permeability caprock. This process, commonly called hydrodynamic trapping, will likely be, in the short term, the most important mechanism of retention. Second, CO₂ can dissolve into the groundwater, referred to as a solubility trapping. The dissolution of CO₂ in groundwater increases the acidity of water and affects the solubilities of minerals composing the host rock matrix. Third, CO₂ can react directly or indirectly with minerals and organic matter in the geologic formation leading to the precipitation of secondary carbonates and the solubilization of organic matter. The latter process, so-called “mineral trapping”, is attractive because it could immobilize CO₂ for long time scales, and prevent its easy return to the atmosphere. The interaction of CO₂ with alkaline aluminosilicate minerals will also result in the formation of dissolved alkali carbonates and bicarbonates, thereby enhancing “solubility trapping”.

Numerical modeling of geochemical processes is a necessary tool for investigating the long-term consequences of CO₂ disposal in deep formations, because alteration of the predominant host rock aluminosilicate minerals is very slow and is not experimentally accessible under ambient deep-aquifer conditions. Johnson et al. (2001) simulated CO₂ injection at Statoil’s North-Sea Sleipner facility and analyzed the coupled process mechanisms that lead to hydrodynamic, solubility, and mineral trapping, and to quantify the relative effectiveness of the distinct sequestration processes as a function of key reservoir properties. White et al. (2001) applied reactive chemical transport modeling to simulate mineral sequestration of CO₂ for saline reservoirs on the Colorado Plateau. McPherson and Lichtner (2001) used a sedimentary basin

model, including multiphase flow of CO₂, groundwater, and brine, to evaluate resident times in possible aquifer storage sites and migration patterns and rates away from such sites in the Powder River Basin of Wyoming. Xu et al. (2004a) performed batch geochemical modeling for three different formation mineralogies in the presence of CO₂ at high pressure. The modeling included (1) redox processes that could be important in deep subsurface environments, (2) the presence of organic matter, (3) the kinetics of chemical interactions between the host rock minerals and the aqueous phase, and (4) CO₂ solubility dependence on pressure, temperature and salinity of the system (see Eq. B.12 through B.15 in Appendix B).

During large-scale injection of CO₂ into deep formations, geochemical processes are strongly affected by physical processes such as multiphase fluid flow and solute transport. Fluid pressures will rise as CO₂ displaces formation water in which it partly dissolves. The dissolution of primary and precipitation of secondary minerals change formation porosity and permeability, and could alter fluid flow patterns. All coupled hydrologic and chemical processes affect the feasibility of CO₂ injection and storage in deep formations. Uncoupled batch geochemical modeling and flow simulation are inadequate to describe the complex subsurface physical and chemical interactions expected to occur. A systematic process-based understanding of the coupled physical and chemical phenomena is required.

8.5.2. Definition of test problem

The response of deep formations to CO₂ injection will depend on many factors, including formation permeability and porosity, the presence of heterogeneities such as faults and layers of high or low permeability, the physical and chemical characteristics of the brines, and the nature of the mineral phases that are present. A great deal of specific and detailed information will be required to assess the feasibility of disposing of CO₂ in a brine formation at any particular site, and to develop engineering designs for CO₂ disposal systems. Before moving into site-specific investigations, general features and issues relating to brine formation disposal of CO₂ should be explored. This can be done by investigating deep brine systems that abstract site-specific features and thereby attempt to represent characteristics that are common to many such systems.

A basic issue in geologic disposal of CO₂ is the physical and chemical behavior in the vicinity of a CO₂ injection well. Previous numerical studies have investigated simple models of one- and two-dimensional radial flow to examine the displacement of formation waters by

injected CO₂ (Pruess and Garcia, 2002; Pruess et al., 2003). These studies have provided initial insight into issues regarding volumetric sweep, CO₂ storage capacity, and pressurization processes that would arise from large-scale CO₂ injection. Exploratory studies of geochemical effects have also been conducted, using a zero-dimensional batch reaction approach to model the chemical reactions that would take place when different mineral assemblages are exposed to CO₂ at high pressures in the presence of brine (Perkins and Gunter, 1996; Gunter et al., 1997; Xu et al., 2004a). The present study combines the simple 1-D radial model previously investigated by Pruess et al. (2003) with the batch chemical reaction model of Xu et al. (2004a), in a first attempt to model the coupled processes of fluid flow and chemical reactions near a CO₂ injection well.

Geologic formation

The setup of the present problem is similar to that of Xu et al. (2003b), except using the following (1) a porosity of 0.3 not 0.1, (2) a temperature of 75°C (at about 2000 m depth) instead of 75°C, (3) improved mineralogical composition, and kinetic rate law and parameters.

The geologic formation is assumed to be infinite-acting and homogeneous with a thickness of 100 m, containing a 1 M NaCl brine at a constant temperature of 75°C. A 1-D radial model is used. This simplification does not consider non-uniform sweep that may occur due to formation heterogeneities, or to buoyancy forces that would tend to drive CO₂ towards the top of the aquifer. In future studies we plan to examine such multidimensional flow effects. Some justification for a 1-D approach can be derived from the slow rates and long time scales of geochemical changes, which will cause processes to play out over time, which will make the distribution of CO₂ more uniform. Initially, injected CO₂ will tend to accumulate and spread out near the top of permeable intervals, partially dissolving in the aqueous phase. CO₂ dissolution causes the aqueous-phase density to increase by a few percent. This will give rise to buoyant convection where waters enriched in CO₂ will tend to migrate downward (Weir et al., 1995; Garcia, 2001). The process of CO₂ dissolution and subsequent aqueous phase convection will tend to mix aqueous CO₂ in the vertical direction. The time scale for significant convective mixing is likely to be slow (of the order of hundreds of years or more; J. Ennis-King, private communication, 2001), and may be roughly comparable to time scales for significant geochemical interactions of CO₂.

The well field is modeled as a circular region of 10,000 m radius, at the center of which CO₂ is injected uniformly at a constant rate of 100 kg/s (\approx 8,640 tonnes per day), This injection rate is approximately equivalent to that generated by a 300 MW coal-fired power plant (Hitchon, 1996). A 1-D radial grid was used with a spacing gradually increasing away from the well. The CO₂ injection was assumed to continue for a period of 100 years. The fluid flow and geochemical transport simulation was run for a period of 10,000 years.

Table 8.5.1. Hydrogeologic parameters for the radial fluid flow problem.

Aquifer thickness	100 m
Permeability	10^{-13} m^2
Porosity	0.30
Compressibility	$4.5 \times 10^{-10} \text{ Pa}^{-1}$
Temperature	$75 \text{ }^\circ\text{C}$
Pressure	200 bar
Salinity	0.06 (mass fraction)
CO ₂ injection rate	100 kg/s
Relative permeability	
Liquid (van Genuchten, 1980):	
$k_{rl} = \sqrt{S^*} \left\{ 1 - \left(1 - [S^*]^{1/m} \right)^m \right\}^2$	$S^* = (S_l - S_{lr}) / (1 - S_{lr})$
irreducible water saturation exponent	$S_{lr} = 0.30$ $m = 0.457$
Gas (Corey, 1954):	
$k_{rg} = (1 - \hat{S})^2 (1 - \hat{S}^2)$	$\hat{S} = \frac{(S_l - S_{lr})}{(S_l - S_{lr} - S_{gr})}$
irreducible gas saturation	$S_{gr} = 0.05$
Capillary pressure	
van Genuchten (1980)	
$P_{cap} = -P_0 \left([S^*]^{-1/m} - 1 \right)^{1-m}$	$S^* = (S_l - S_{lr}) / (1 - S_{lr})$
irreducible water saturation exponent	$S_{lr} = 0.00$ $m = 0.457$
strength coefficient	$P_0 = 19.61 \text{ kPa}$

Geochemical system

A proxy for a sediment from the United States Gulf Coast modified from that originally presented by Apps (1996) was used for the present reactive geochemical transport simulations. The mineralogy is similar to that commonly encountered in sedimentary basins. Apps (1996) presented a batch geochemical simulation of the evolution of Gulf Coast sediments as a basis for interpreting the chemical processes relating to the deep injection disposal of hazardous and industrial wastes.

The initial mineral abundances used in the present reactive geochemical transport modeling (Table 8.5.2), are refined from the batch geochemical modeling study by Xu et al. (2004a). The specification of formation mineralogy is determined in part by the availability of data. Most studies related to the Tertiary Gulf Coast sediments are concentrated in the state of Texas. The principal reservoir-quality sandstones within that region are respectively, the Frio, the Vicksberg and the Wilcox formations, all of which are found within the lower Tertiary. Of the three formations, the Frio was chosen as a representative candidate for the sequestration of supercritical carbon dioxide. It is the shallowest of the three formations, but over much of its areal extent, it is located at depths between 5,000 and 20,000 ft, depths sufficient to ensure adequate CO₂ densities for effective storage.

Calcite was assumed to react with aqueous species at local equilibrium because its reaction rate is typically quite rapid. Dissolution and precipitation of other minerals are kinetically-controlled. Kinetic rates are a product of the rate constant and reactive surface area (Eq. B.5 in Appendix B). Multiple mechanisms (including neutral, acid and base) are used for dissolution of minerals (Eqs. B.9 and B.10 in Appendix B). Kinetic parameters: rate constant (k_{25}), the activation energy (E_a), and the power term (n) for each mechanism are listed in Table 8.5.2. At any pH the total rate is the sum of the rates via each mechanism. Most of these parameters were taken from Palandri and Kharaka (2004) who compiled and fitted many experimental data reported by a large number of investigators. Parameters for illite were set to those of smectite. Acid mechanism parameters for siderite, ankerite, and dawsonite were set to those of dolomite. Neutral mechanism parameters for siderite were taken from Steefel (2001). Neutral parameters for ankerite and dawsonite are set to those of siderite.

Precipitation rate data do not exist for most minerals. Several aspects regarding precipitation are different from dissolution, including nucleation, crystal growth and Ostwald

ripening processes, as well as the calculation of the reactive surface area (Steefel and van Capellen, 1990). These processes for mineral precipitation are not considered in the current problem. We simply used parameters for neutral mechanism in Table 8.5.2 for precipitation of the corresponding minerals. Notice that different sets of parameters for precipitation can be specified in the chemical input file of TOUGHREACT code.

The evolution of surface area in natural geologic media is very complex, especially for multi-mineralic systems, and is not quantitatively understood at present. Mineral reactive surface areas (the third column of Table 8.5.2) were taken from Sonnenthal and Spycher (2001), which were calculated using a cubic array of truncated spheres that make up the framework of the rock. For clay minerals kaolinite, illite, and smectite, increased surface areas were used due to edges in these sheet silicate minerals (Nagy, 1995). A reactive surface area calculated from grain size may be a poor estimate of the hydrologically accessible mineral surface area. To account this effect, surface areas listed in Table 8.5.2 were reduced by one order of magnitude in the present simulations. The magnitudes of surface areas are highly uncertain and cover a wide range of values. Sensitivity regarding the kinetic rate constants and reactive surface areas should be addressed in the future.

Table 8.5.2. List of initial mineral volume fractions, possible secondary mineral phases, and their kinetic properties used in the simulation. Notice that: (1) all rate constants are listed for dissolution; (2) A is the reactive surface area (Eq. B.5 in appendix B), k_{25} is the kinetic constant at 25 °C, E_a activation energy, and n is the power (Eq. B.9); (3) the power terms n for both acid and base mechanisms are with respect to H^+ , (4) for pyrite, the neutral mechanism has a n with respect to $O_2(aq)$, the acid mechanism has two species involved: one n with respect to H^+ and another n with respect to Fe^{3+} (see Eq. B.10); (5) dolomite, Ca-smectite and pyrite were included in the list of possible secondary mineral phases in the input but they were not formed during the simulation.

Mineral	Vol.% Of solid	A (cm ² /g)	Parameters for kinetic rate law

Prior to CO₂ injection, a simulation of water-rock interaction was performed to obtain a nearly equilibrated water chemistry using a pure 1.0 M solution of sodium chloride reacting with the primary minerals listed in Table 8.5.2 at a temperature of 75 °C. The resulting water chemistry was used for the initial condition of reactive geochemical transport simulations under CO₂ injection.

The ECO2 fluid property module was used for this CO₂ disposal problem. As mentioned above, the reactive transport simulation was performed for a total time period of 10,000 years. To demonstrate the RESTART feature, we performed a series of two TOUGHREACT runs. The first run was performed until 100 years. The input and major output files for the first run are given in the distribution CD (subdirectory: `treact/sample-problems/P5_ECO2-1Dradial`). Parts of output files for fluid flow, aqueous chemical concentrations, and changes of mineral abundances are given in Figures 8.5.1, 8.5.2 and 8.5.3. For the continuation run (restart) to 10,000 yr, we create a new subdirectory `~/P5_ECO2-1Dradial/restart`, into which we copy the input files (`flow.inp`, `solute.inp`, `chemical.inp`, `thermXu4.dat`), the CO₂ property file (`CO2TAB`), and the files `SAVE` and `savechem` from the first run. File `SAVE` is renamed `INCON`, `savechem` is renamed `inchem`, and the following minor changes are made in `flow.inp`: delete the `INCON` input block, and change the simulation time from `3.15576E09` (100 years) to `3.15576E11` (10,000 years) in the `PARAM` input block. Now we can perform the restart run. Major output files from the restart run are also in subdirectory: `~/P5_ECO2-1Dradial/restart`.

A different feature for ECO2 module (and also EOS2) from other modules is that partial pressures of CO₂ gas are calculated from fluid flow calculations and then feed to geochemistry. While, if we consider CO₂ for reactions with EOS3 and EOS4 modules, CO₂ is assumed to be a trace gas and transported with bulk gas phase by advection and diffusion. In EOS 9, CO₂ is also assumed to be a trace gas but transported only by diffusion because bulk gas phase is not considered in the EOS9. For the ECO2 (or EOS2), if CO₂ partial pressure in block 'INITIAL gas ZONES' of `chemical.inp` (see the file `chemical.inp` in the distribution CD) is greater than zero, this partial pressure is specified for the background partial pressure (regions not flooded with the injected CO₂). If this value is set to zero, no background CO₂ partial pressure buffer is allowed.

8.5.3. Results and discussion

Figure 8.5.4 shows water saturations along the radial distance (gas CO_2 saturations are complementary to water saturations, or $S_g = 1 - S_l$). Water saturations are lower close to the CO_2 injection well. In the first 15 m water is completely displaced by CO_2 gas at 100 years.

Figure 8.5.4. Water saturations at different times for the 1-D radial flow problem.

Significant ankerite and dawsonite precipitates due to CO₂ injection and dissolution of aluminosilicate minerals. Minor siderite and very slight magnetite precipitation occurs. No dolomite precipitation is observed in the simulation. Calcite dissolves rather than precipitates in the injected CO₂ plume region, but calcite precipitation occurs in background region due to the constant CO₂ partial pressure buffer specified in the input. The cumulative sequestration of CO₂ by carbonate precipitation is given in Figure 8.5.6. More results on mineral alteration and on aqueous concentrations are given in the files, co2d_min.dat and co2d_conc.dat in the distribution CD.

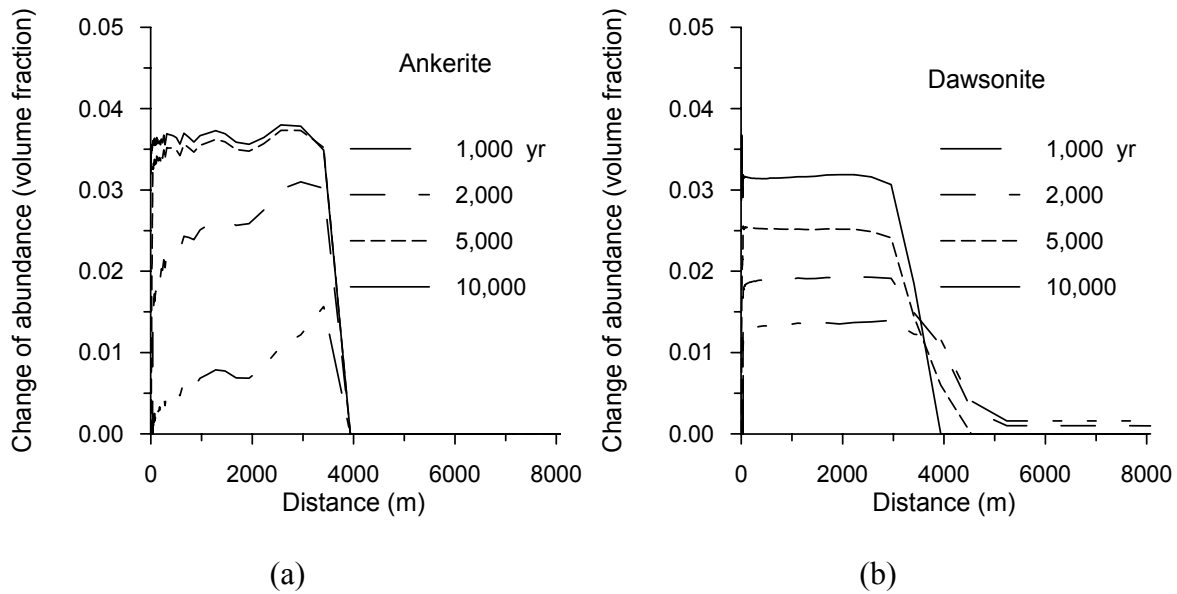

Figure 8.5.5. Change of mineral abundance (negative values indicate dissolution and positive precipitation) after different times for the 1-D radial flow problem.

Figure 8.5.6. Cumulative CO₂ sequestration by carbonate precipitation after different times. The positive values in the background region ($x > 4000$ m) are due to calcite precipitation.

8.6. Supergene Copper Enrichment (EOS9)

8.6.1. Problem statement

This simulation problem was published in Xu et al. (2001). Supergene copper enrichment (SCE) involves hydrochemical differentiation by near-surface weathering processes in which water transports metals from a source region or leached zone (Brimhall et al., 1985; Brimhall and Dietrich, 1987; Ague and Brimhall, 1989) to an enrichment blanket zone where they are reprecipitated as secondary ore compounds conserving mass (Figure 8.6.1). The schematic system shown in Figure 8.6.1 captures, in a simplified manner, conditions of desertification in Northern Chile that led to oxidation and chemical enrichment of copper deposits at certain times in the past (of order 15 Ma) when a decline of the ground water table exposed sulfides to unsaturated conditions (Brimhall et al., 1985; Brimhall and Dietrich, 1987; Alpers and Brimhall, 1989; Ague and Brimhall, 1989).

Figure 8.6.1. A schematic representation of a supergene copper enrichment system according to Ague and Brimhall (1989).

Oxidative weathering of pyrite (FeS_2) and chalcopyrite (CuFeS_2) causes acidification and mobilization of metals in the oxidizing zone and intense alteration of primary minerals, with subsequent formation of enriched secondary copper bearing sulfide mineral deposits (enrichment blanket) in the reducing conditions below the water table. Such oxidative weathering-driven

processes have produced some of the world's largest copper deposits (Ague and Brimhall, 1989). The present investigation on geochemical transport in SCE systems is not specific to any field site, but the geochemistry for this work was based on field and laboratory studies of SCE systems as carried out by Brimhall et al. (1985), and Ague and Brimhall (1989). The coupled modeling study is intended to provide a better understanding of the complex interplay of oxygen diffusion, sulfide mineral oxidation, subsequent intense alteration of primary minerals and reprecipitation of secondary minerals. The SCE processes typically took place in a fractured porous medium such as at the El Salvador mine, Chile (Mote et al., 2001). To gain better insight into the processes involved, we first considered a problem in a one-dimensional unsaturated-saturated porous medium. A simple porous medium description may be applicable in regions with highly fractured rocks. Then we considered the case of SCE processes in a variably saturated fractured rock system using the "multiple interacting continua" (MINC) method. Here we only present the case of SCE processes in a variably saturated fractured rock. The simple porous medium case is given in Xu et al. (2001)

8.6.2. Problem setup

The method of "multiple interacting continua" (MINC) is used to resolve "global" flow and diffusion of chemicals in the fractured rock and its interaction with "local" exchange between fracture and matrix rock. This method was developed by Pruess and Narasimhan (1985) for fluid and heat flow in fractured porous media. The extension of the MINC method to reactive geochemical transport is described in detail by Xu and Pruess (2001b). It is well-known that in the case of reactive chemistry diffusive fluxes may be controlled by reactions occurring near (within millimeters) the fracture walls. The resolution of concentration gradients in matrix blocks is achieved by appropriate subgridding. The MINC concept is based on the notion that changes in fluid pressures and chemical concentrations propagate rapidly through the fracture system, while invading the tight matrix blocks only slowly. Therefore, changes in matrix conditions will be (locally) controlled by the distance from the fractures and can then be modeled by means of one-dimensional strings of nested grid blocks (Figure 8.6.2).

In general it is not necessary to consider explicitly subgrids in all the matrix blocks separately. Within a certain subdomain (corresponding to a finite difference grid block), all fractures will be lumped into continuum # 1, all matrix material within a certain distance from the

fractures will be lumped into continuum # 2, matrix material at larger distance becomes continuum # 3, and so on. Quantitatively, the subgridding is specified by means of a set of volume fractions $VOL(j)$, $j = 1, \dots, J$, into which the "primary" porous medium grid blocks are partitioned. The information on fracturing (spacing, number of sets, shape of matrix blocks) required for this is provided by a "proximity function" $PROX(x)$ which expresses, for a given domain V_0 , the total fraction of matrix material within a distance x from the fractures (Pruess and Karasaki, 1982). If only two continua are specified (one for fractures, one for matrix), the MINC approach reduces to the conventional double-porosity or dual permeability methods.

We consider an idealized fractured porous medium with two perpendicular sets of plane, parallel, vertical fractures of equal aperture and spacing. Because of symmetry only one column of matrix blocks needs to be modeled. Figure 8.6.2 shows an areal view of a rock matrix column that is surrounded by vertical fractures with a spacing of 0.5 m, with subgridding of the matrix according to the MINC method. Subgrid 1 represents the fracture domain which is defined to include 50 percent by volume of wall rock. Subgrids 2 through 7 represent the rock matrix. In the vertical direction, a total of 10 model layers are used with a thickness of 2 m. A net rainwater infiltration rate of 0.015 m yr^{-1} over the entire area was applied to the fractures. Water pressure is held constant at 2 bar at the bottom ($z = -20 \text{ m}$), so that the water table is located at a depth of approximately 10 m. In addition to global water flow and chemical transport in the fracture network, our model considers flow and transport between fractures and matrix, as well as vertical matrix-matrix water flow and chemical transport. The steady-state water saturations obtained without chemical reactions are used as initial conditions for the calculation of reactive geochemical transport. Hydrological parameters for the fracture and matrix are listed in Table 8.6.1.

Figure 8.6.2 Subgridding of a rock matrix in the method of "multiple interacting continua" (MINC). The figure represents an areal view of a rock matrix column that is surrounded by vertical fractures.

Table 8.6.1. Hydrological parameters used for supergene copper enrichment in the fractured rock

Parameter	Matrix	Fracture
Permeability (m ²)	10 ⁻¹⁶	10 ⁻¹²
Fracture domain volume fraction, v *		0.01
Fracture spacing (m)		0.5
Porosity	0.08	0.5
Relative permeability and capillary pressure (van Genuchten, 1980):		
λ	0.457	0.457
S _{lr}	0.1	0.05
S _{ls}	1.0	1.0
P ₀ (pa)	2.17×10 ⁵	6.2×10 ³

* $v = V_f / (V_f + V_m)$ where V_f and V_m are fracture and matrix domain volumes.

The geochemical transport simulation considers unsaturated-saturated liquid phase flow and diffusive supply of oxygen to the protore. The domain modeled is initially filled entirely with a protore mineral assemblage as listed in Table 8.6.2. The dissolution of the primary minerals is considered to be kinetically-controlled. The kinetic rate constants and specific surface areas used are also given in Table 8.6.2. Precipitation of secondary minerals (Table 8.6.2 with initial $V_f = 0$

where V_f is mineral volume fraction) is represented using the same expression as dissolution. To simplify the description of precipitation kinetics, in the present study all secondary minerals are assigned the same kinetic constant ($2.0 \times 10^{-10} \text{ mol m}^{-2} \text{ s}^{-1}$) and reactive surface areas (0.1 m^2 per dm^3 bulk medium). Because the rate constants assumed for precipitation reactions are larger than those for dissolution of primary minerals, formation of secondary minerals occurs effectively at conditions close to local equilibrium. The kinetic rate of sulfide mineral oxidation can be strongly influenced by catalytic effects of bacteria (Singer and Stumm, 1970; Olson, 1991; Nordstrom and Alpers, 1997), which are not considered in the present study. Estimates of field oxidation rate cover a wide range of values (Nordstrom and Alpers, 1997). The rate determining process is often transport of oxygen or other reactants to the reaction site. This is the process we are investigating in this work. Heat generation by pyrite oxidation may change temperature, but this effect is not considered in our simulations. Calculations are carried out at a constant temperature of $25 \text{ }^\circ\text{C}$. Thermodynamic data used in the simulations were taken from the EQ3/6 V8.2b database (Wolery, 1992) which were derived using SUPCRT92 (Johnson et al., 1992).

Table 8.6.2. Initial protore mineral volume fractions (V_f) and possible secondary mineral phases ($V_f = 0.0$) considered in the supergene copper enrichment problem. Kinetic data of primary minerals are based on Ague and Brimhall (1989) and Gérard and others (1997).

Oxygen is treated as an ideal gas, and its interaction with the aqueous solution is assumed at equilibrium. The oxygen partial pressure at the land surface boundary is assumed to be constant at 0.2 bar. A dilute oxidizing water equilibrated with an oxygen partial pressure of 0.2 bar is initially placed in the unsaturated zone, while a reducing water is assumed for the saturated zone. The infiltration water composition is the same as the initial unsaturated water. The aqueous complexation is assumed at equilibrium, even though some aqueous redox pairs such as sulfite and sulfide species may not be at equilibrium (Stumm and Morgan, 1981). Whether a particular reaction should be described as governed by the local equilibrium approximation (LEA) or by kinetic rates depends not only on the reaction itself but also on the rates of hydrodynamic transport processes (Domenico and Schwarz, 1990). The LEA is applicable when the characteristic time for transport of reactants is longer than the time required to reach chemical

equilibrium. In the present simulations for reactive geochemical transport, the choice of equilibrium depends mainly on kinetic rate, infiltration rate, oxygen availability, and space discretization.

The EOS9 flow module was used for this ambient mineral deposition problem. The input and output files for the problem are given in the distribution CD (subdirectory: `tract/sample-problems/P6_EOS9_copper`). To shorten the simulation time for installation purpose, the time in the PARAM input block of `flow.inp` is specified as $3.15576E08$ (s, or 10 years). Users can reset this variable to their desired time. Parts of output files for fluid flow, aqueous chemical concentrations, and changes of mineral abundances are given in Figures 8.6.3, 8.6.4 and 8.6.5.

We also include a 1-D supergene enrichment problem in a new subdirectory `~/P6_EOS9-copper/1-D`. Details on the specification of the 1-D problem is given in Xu et al. (2001). A quasi-stationary state (QSS, Lichtner, 1988) is applied by setting the last two variables $TOLDC = 1.0E-4$ and $TOLDR = 1.0E-4$ in `Record_6` (Data related to convergence criteria) of input file `solute.inp`. $TOLDC$ and $TOLDR$ are relative changes in concentrations and dissolution (and/or precipitation) rates between two consecutive time steps. The chemical QSS can be reached only after fluid flow steady-state is reached. The flow steady-state can be recognized by setting variable $MOPR(4) = 1$ in the REACT input block of `flow.inp` file. If $TOLDC$ and $TOLDR$ are set to zero, or $MOPR(4)$ is set to two, the QSS option is not used. Over extended time periods, changes in porosity and permeability due to mineral dissolution and precipitation can cause changes in fluid flow. However, by neglecting such changes, a QSS could be obtained for the reactive system, which provides a tremendous simplification of the computational problem and makes it possible to consider the difficult redox geochemistry in great detail. Although we do not allow porosity change to affect fluid flow, we monitor it during the simulation based on changes in mineral abundances. The QSS option can also applied to the above 2-D copper problem for a longer time simulation.

8.7. Caprock Alteration (EOS2)

8.7.1. Problem statement

This problem was published in Xu and Pruess (2001a). The interaction between hydrothermal fluids and the rocks through which they migrate alters the earlier formed primary minerals and leads to the formation of secondary minerals, resulting in changes in physical and chemical properties of the system. Here, we consider the following processes: (1) detailed fracture-matrix interaction for fluid, heat and chemical constituents; (2) gas phase participation in multiphase fluid flow and geochemical reactions; (3) the kinetics of fluid-rock chemical interaction, and (4) heat effects on thermophysical and chemical properties and processes, which include water and CO₂ partitioning between liquid and gas phases, temperature-dependent phase density and viscosity, and thermodynamic chemical equilibrium and kinetic rate constants. The range of problems concerning the interaction of hydrothermal fluids with rocks is very broad. We confine our attention to the evolution of geothermal fields associated with magmatic activity, such as are encountered in the Long Valley Caldera (LVC), California (Sorey, 1985; White and Peterson, 1991; and Sorey et al., 1998) and in the Taupo Volcanic Zone, New Zealand (White and Christenson, 1998). In the hydrothermal fluids in these areas, water vapor and CO₂ are the dominant gas phase constituents. The present study uses, as an example, water and gas chemistry data from the hydrothermal system in the LVC (Sorey, 1985; White and Peterson, 1991; and Flexser, 1991). The flow system studied in this paper is intended to capture realistic features of hydrothermal systems such as the LVC.

8.7.2. Problem setup

The Long Valley Caldera (LVC) is a 450 km² elliptical depression located along the eastern front of the Sierra Nevada in east-central California (Sorey, 1985; White and Peterson, 1991; and Sorey et al., 1998). Many hot springs in and around LVC occur along north to northwest trending normal faults, and are derived from hydrothermal reservoirs. Hot water is transported upward along fault systems into shallow aquifers (Sorey, 1985; White and Peterson, 1991). In these aquifers, the hydrothermal fluids mix with varying proportions of cold meteoric

water before discharging in hot springs. The present LVC hydrothermal system has been active for perhaps 40, 000 years (Flexser, 1991).

For the sake of simplification and interpretation of results, we consider an idealized fractured rock with a set of plane, parallel vertical fracture zones (faults) of equal aperture (0.1 m) and spacing (3.5 m). Because of the symmetry of this fractured rock, only one column of matrix blocks needs to be modeled (Figure 8.7.1). We simulated a vertical column extending from the atmosphere (top boundary) through the fracture-matrix system to the hydrothermal reservoir (bottom boundary). The depth of the hydrothermal reservoir varies from site to site. For example, according to the data presented in White and Peterson (1991) for the LVC, the reservoir depth varies from several tens of meters to near 1000 meters. In this study, we use a single depth of 280 m for simplicity. A 1-m-thick vertical slice is modeled, where a total depth of 280 m is discretized into 56 layers of 5 m thickness. The fracture is considered as one model grid zone. The rock matrix is further discretized into 6 grid zones with permeability decreasing away from the fracture (Table 8.7.1). A thermal conductivity of 2.1 W/m°C, a specific heat of 920 J/kg°C, and an aqueous chemical diffusion coefficient of 1×10^{-10} m²/s are used. Other parameters for the fracture and matrix are listed in Table 8.7.1. The top atmosphere and bottom hydrothermal reservoir boundaries are modeled as constant pressure boundaries with properties shown in Figure 8.7.1. At a depth of 88.4 m the rising hot water mixes with shallow cold meteoric water. The cold water (11 °C) recharge is assumed to occur only in the fracture grid block at a rate of 3×10^{-5} kg/s, and is treated as a source term for fluid, heat and chemical constituents, the concentrations of which are given in Table 8.7.2. The bottom reservoir is assigned the same thermophysical properties as the fracture zone.

Cl ⁻	8.31x10 ⁻³	1.61x10 ⁻⁴
pH	6.6	6.8
T (°C)	225	11

The aqueous phase chemical composition is based on data reported by White and Peterson (1991). The concentrations of major chemical species in samples at various wells are in general similar, and we arbitrarily choose data from well RDO-8 (Table 8.7.2) for our simulation. CO₂ is the dominant gaseous species in the hydrothermal system, and its partial pressures range from 1 to 9 bar (1 bar \equiv 10⁵ Pa). We use an intermediate partial pressure value of approximately 4 bars. The cold recharge water chemical composition is taken from Sorey (1985) for cold Big Springs of LVC (Table 7) that is assumed to be representative of the shallow aquifer meteoric water. The initial fracture-matrix system is assumed to be liquid-water saturated.

The caprock mineral composition is highly variable in geothermal reservoirs. For the purpose of our study, we chose an initial rock mineral assemblage as listed in Table 8.7.3 throughout the column, which is based on the studies carried out by Steefel and Lasaga (1994) and White and Christenson (1998). The dissolution of the primary minerals proceeds subject to kinetic controls. The precipitation of secondary minerals (also given in Table 8.7.3) is represented using the same kinetic expression as that for dissolution. However, several aspects regarding precipitation are different, including nucleation, crystal growth and Ostwald ripening processes, as well as the calculation of the reactive surface area (Steefel and van Capellen, 1990). To simplify the description of precipitation kinetics, a constant reactive surface area of 0.01 m² per dm³ (cubic decimeter) medium is used for the entire simulation time. Kinetic rates of precipitation depend on the activities of reactants supplied by dissolution.

Table 8.7.3. Initial caprock mineral volume fractions (with $V_f > 0$ where V_f is mineral volume fraction) and secondary mineral phases ($V_f = 0.0$) formed in the simulation. The kinetic rate law used is given in Eq. B.5 (in Appendix B) using two exponential parameters μ and n set equal to one (first order kinetics). Rate constants are calculated from Eq. B.6, and kinetic constant at 25°C (k_{25}) and activation energy (E_a) are taken from Steefel and Lasaga (1994), and Johnson et al. (1998).

Mineral	Chemical composition	Volume (%)	Surface area (m ² /dm ³ medium)	k_{25} (moles m ⁻² s ⁻¹)	E_a (KJ/mol)

The simulation is run for 1000 years. Initially, we limit the simulation to only fluid and heat flow until a steady-state is attained. Then we simulate chemical transport and fluid-rock interactions using the steady-state fluid and heat flow as the initial condition. Modeling the transport of a chemically reactive multi-component fluid is computationally intensive, and requires that a balance be struck between fluid and chemical complexity and calculation time. The described two-step approach can significantly save on computational time and give a detailed description of geochemical evolution of the system. In addition, the interpretation of results is easier when flow is decoupled from reactive transport. Despite our use of a two-step approach, our model is fully capable of simulating both flow and reactive transport at the same time. Although we only consider an idealized fractured rock, generally any fracture geometry can be considered by our model. Furthermore, we should point out that CO₂ consumed by mineral precipitation such as calcite is assumed not to affect its partial pressure and then fluid flow. If at the bottom boundary (geothermal reservoir) the partial pressure remains constant as in the case

simulated in this paper, this assumption is justified. A 1-D vertical column is tested first with the bottom and top boundary conditions as shown in Figure 8.7.1. The effect of CO₂ consumed by calcite precipitation on fluid flow is negligible in this kinetically-controlled chemical system. Most calcite precipitation occurs close to the bottom reservoir. CO₂ consumed by calcite precipitation is replenished by enhanced physical transport processes from the reservoir.

The EOS2 flow module was used for this problem. The input and output files for the problem are given in the distribution CD (subdirectory: `treact/sample-problems/P7_EOS2-LVC`). To shorten the simulation time for installation purpose, the time in the PARAM input block of `flow.inp` is specified as 3.15576E08 (s, or 10 years). Users can reset this variable to their desired time.

8.7.3. Results

Contour plots of steady-state liquid water saturation and temperature are presented in Figure 8.7.2. Some results for changes of mineral abundances are given in Figures 8.7.3 and 8.7.4. More results can be found in Xu and Pruess (2001a).

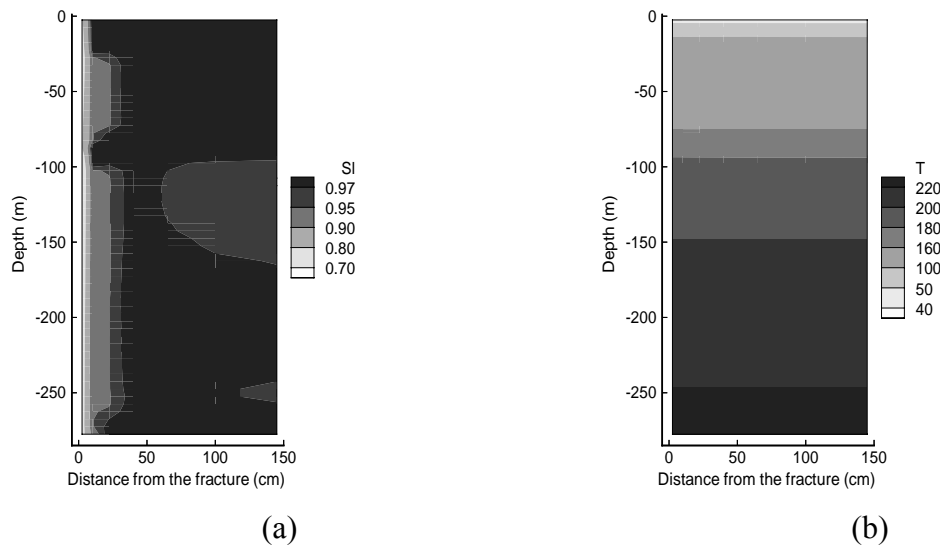

Figure 8.7.2. Liquid saturation (a) and temperature (b, in °C) in the fracture-matrix system. This and subsequent contour plots extend to a distance of 145 cm, which is the distance between the center of the fracture zone, and the nodal point at the center of the innermost matrix grid block. The overall size of the model domain is 175 cm (sum of all grid spacings; see Table 8.7.1).

Figure 8.7.3. Change of primary mineral abundance (in volume fraction) after 1000 years. The inflection points in the figures result from (1) grid discretization and (2) highly non-linear nature of heterogeneous reactions. The space discretization in our simulation is not fine enough to give an accurate definition of mineral abundances near inflection points.

Figure 8.7.4. Change of mineral abundance (secondary phases, in volume fraction) and porosity after 1000 years.

8.8. Injection Well Scaling and Acidizing at Tiwi Field, Philippines (EOS1)

8.8.1. Problem statement

Nag-67 is one of the hot brine injectors located to the South-east of the Tiwi production field, Philippines. The well was completed in March 1987 as a deviated hole with a 9 5/8" casing shoe set at 917 m MD (Measured Depth), and the top of a 7" production liner at 878 m MD with the shoe at 2114 m MD (1873 m TVD - Total Vertical Depth). The injectivity of the well decreased significantly with time. The drop in injection capacity was attributed to scaling inside the wellbore as early as October 1992; the liner was found reduced in diameter to 5" at the depth of 1651 m.

Records of injection history (Figure 8.8.1) and fluid chemistry for Nag-67 were reviewed to determine the nature of the deposited scale and to estimate the amount and location of the deposits. The well was acidized in January 1989 primarily to clear the near-wellbore formation of drilling mud damage and to improve its injectivity. Injection capacity of the well after the stimulation was 126 kg/s at a wellhead pressure of 1.38 MPa. In 1996, the well was found to accept only 38 kg/s at an injection wellhead pressure of about 1 MPa. In 1999, an injectivity test indicated that the capacity of the well had dropped to 17 kg/s at an injection wellhead pressure of 1.31 MPa. In March 2000, the recorded injection rate in Nag-67 suddenly decreased to 3.8 kg/s.

In January 2001, the scale inside the Nag-67 wellbore was drilled-out and the scale deposited in the near-well formation was dissolved by acid. Measurements after the scale drillout indicated that the capacity of the injector went up to 25.2 kg/s, and another test after the acid stimulation showed a further increase to 113.4 kg/s. These results strongly suggested that the decline in injectivity of the well was caused primarily by scale deposition in the near-well formation. Based on the chemistry of the brine injected and analysis of deposited scale, it was determined that most of the scale in Nag -67 was amorphous silica.

The silica concentration and pH of the brine being supplied to the Nag-67 injector were monitored between 1989 and 2000. Complete brine analyses were also available for every year except 1999 and were used to characterize the saturation state of the brine with respect to other minerals. From this historical chemical record, the degree of amorphous silica saturation in each analyzed water sample was determined.

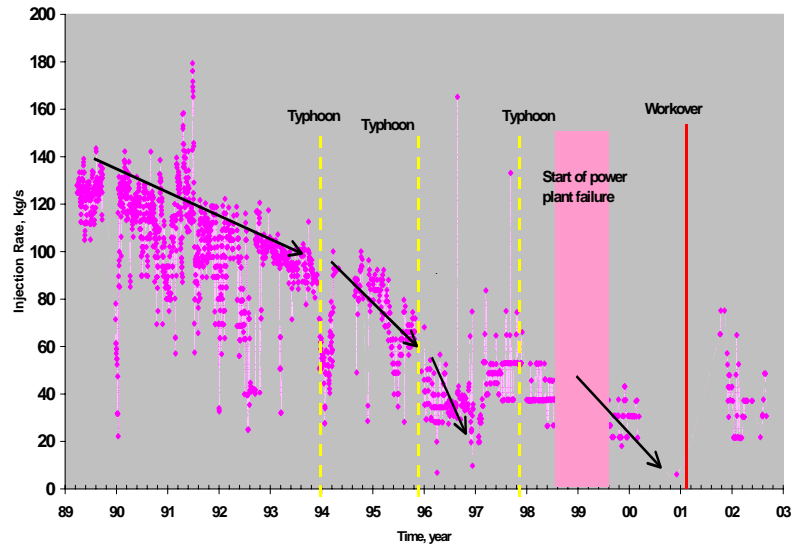

Figure 8.8.1. Historical injection rates (kg/s) in Nag-67.

The estimated amount of silica (in the formation) dissolved by acid stimulation was calculated by assuming that the acid dissolved a stoichiometrically equivalent amount of silica. The silica scale volume calculated in this way was only 1.4 m³. The dissolution of this seemingly small amount of amorphous silica, nevertheless increased the injection capacity of the well to near original capacity. Therefore, it would appear that in the present case, a significant part of the injectivity loss was related to silica deposition in the formation close to the wellbore, as opposed to in the wellbore itself.

To understand the scaling process and loss of injectivity in hot brine injectors, Ontoy et al. (2003) identified factors that cause the deposition of amorphous silica in the near-well formation and the extent of their effect using TOUGHREACT. These factors include the silica concentration in the hot brine injectate, the temperature of the injectate, the flowrate of the injectate, the pH of the injectate, and the temperature and pressure conditions of the reservoir in the vicinity of the injector.

Xu et al. (2004b) conducted a large number of numerical simulations to reproduce the loss of injectivity and its recovery by acid injection. A porosity-permeability relationship (Verma and Pruess, 1988; see Eq. F.8 in Appendix F) was calibrated by comparing predicted injection indexes with field observed data. Here we give brief description of the work of Xu et al. (2004b).

8.8.2. Problem setup

Grid and fluid flow parameters

A 120 m thick reservoir formation at the bottommost permeable zone of the injection well (Nag-67) was modeled. A simple one-dimensional radial flow model was used, consisting of 50 radial blocks with logarithmically increasing radii (Figure 8.8.2). The 50 blocks represent a distance of 1000 m from the wall of the drilled open hole. A fracture porosity of 1% (ratio of fracture volume over the total formation volume) was assumed. The initial bulk permeability has been estimated at $8.5 \times 10^{-14} \text{ m}^2$, to be consistent with the observed initial injectivity index of the well. Conductive heat exchange with rocks of low permeability above and below this zone is an important process. The confining layers are modeled as semi-infinite half spaces, and heat exchange is treated with a semi-analytical technique due to Vinsome and Westerveld (1980).

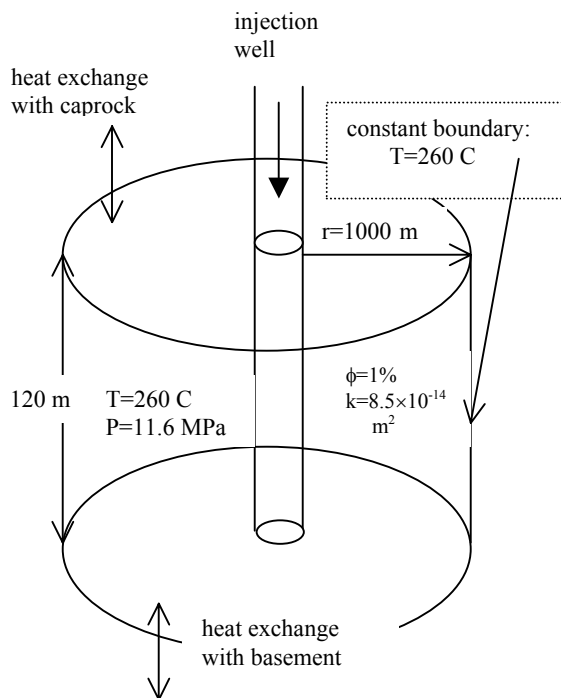

Figure 8.8.2. Simplified conceptual model for injection well Nag-67.

Only the fracture network is considered in the flow simulation, with the assumption that the fluid exchange with the surrounding low permeability matrix is insignificant. To allow for chemical reaction with the rock, a 50% porosity was assigned to the blocks, and the total volume was accordingly doubled. The simulation zone was therefore “compressed” into a 2.4 m thick layer with 50% pore volume and 50% rock volume. A fracture permeability of $4.3 \times 10^{-12} \text{ m}^2$ was used in the simulation (corresponding to a bulk fracture permeability value of $8.5 \times 10^{-14} \text{ m}^2$ for the whole formation thickness with 1% fracture porosity). For consistent purpose, bulk fracture porosity and permeability are reported here.

Initial reservoir temperature and pressure were assumed as 260°C and 11.6 MPa, respectively. The injection history of the well was used to define the amount of injected mass versus time (Figure 8.8.1): 50% of the total injection rate in Nag-67 was used because spinner surveys showed that the bottommost permeable zone accepted about 50% of the injectate. A constant injection temperature of 160°C was used because measured temperature fluctuations were generally small and with a relatively flat average trend (Figure 8.8.3).

Figure 8.8.3. Measured temperature of the injected water.

Geochemical data

The types and initial abundances of primary minerals were determined from the reported Nag-67 alteration mineralogy at the 1798-1920 m MD permeable zone (propylitic/phyllitic rock). Secondary minerals were also determined from field observations (Table 8.8.1).

Table 8.8.1. List of minerals and aqueous species considered in the simulations

Mineral	Mineral Precipitation /Dissolution	Mineral Initial Volume fraction	Primary Aqueous Components
Primary:			
albite-low	Kinetic	0.18	H ₂ O
anorthite	Kinetic	0.02	H ⁺
illite	Kinetic	0.05	Ca ⁺²
quartz	Kinetic	0.14	Mg ⁺²
muscovite	Kinetic	0.16	Na ⁺
clinochlore-7a	Kinetic	0.08	Cl ⁻
clinozoisite	Kinetic	0.01	SiO _{2(aq)}
calcite	Equilibrium	0.13	HCO ₃ ⁻
			SO ₄ ⁻²
Secondary:			
amorphous silica	Kinetic		K ⁺
microcline	Kinetic		AlO ₂ ⁻
kaolinite	Kinetic		
anhydrite	Equilibrium		

The composition of the injected brine was provided from historical analytical data. The formation water was reconstituted from the known brine composition as follows. First, the brine was diluted to yield saturation with quartz at the observed reservoir temperature of 260°C (thus reversing the concentrative effect of flashing). The resulting water was then equilibrated with minerals identified in the well mineralogy log (calculating the aluminum concentration using equilibrium with microcline, sodium using albite, pH using calcite, calcium using clinozoisite, and magnesium using clinochlore). Calcite and anhydrite were assumed to react at equilibrium because their reaction rate is typically quite rapid. Other minerals were set to react under kinetic constraints (Table 8.8.1). Thermodynamic and kinetic data for amorphous silica were taken from Carroll et al. (1998), and Gunnarsson and Arnorsson (2000). For other minerals, thermodynamic and kinetic data were taken from various other literature sources.

For all minerals except amorphous silica, input surface areas were estimated from the geometry of the modeled fracture (around 130 m²/m³ medium). For amorphous silica, a large

surface area was estimated ($10^7 \text{ cm}^2/\text{g}$) from Parks (1990, Fig. 16). Such a large value takes into account the very small size of amorphous silica particles in solution. Silica concentrations of 705 and 710 ppm were used, within the range of observed silica concentrations (Figure 8.8.4).

Figure 8.8.4. The history of silica concentration of the injected water.

Parameters ϕ_c and n in Eq. (F. 8) in Appendix F were calibrated by comparing simulated injection indexes with measured data. The injection index is defined as

$$\Pi = \frac{\text{Flowrate}}{P_b - P_i}$$

where P_b is the borehole pressure and P_i is the initial reservoir pressure (116 bar). A total of 18 simulations were performed using the silica concentrations and values of parameters ϕ_c and n as listed in Table 8.8.2. The simulated time of injection was approximately 12 years, corresponding to the time from the initial acidization of the well in January, 1989 to the time of the well workover in January, 2001.

Table 8.8.2. List of simulations using different injection silica concentrations and values of parameters ϕ_c and n .

Silica concentration (ppm)	ϕ_c (%)	n	Simulation number
705	0.88	9	1
		11	2
		13	3

8.8.3. Results and discussion

The injection indexes can be reproduced by different sets of parameter combinations in the porosity-permeability relationship, Eq. (F.8) in Appendix F. For an injection silica concentration of 705 ppm, reasonable fits are obtained for the following combinations of ϕ_c and n values: (1) $\phi_c = 0.88\%$ and $n = 13$, (2) $\phi_c = 0.9\%$ and $n = 11$, (3) $\phi_c = 0.92\%$ and $n = 10$, and (4) $\phi_c = 0.94\%$ and $n = 6$. Here results obtained with only two sets of ϕ_c and n values are presented in Figure 8.8.5. More results can be found in Xu et al. (2004b). A smaller critical porosity ϕ_c

requires a larger power term n . For a silica concentration of 710 ppm, the matching parameter combinations are (1) $\phi_c = 0.9\%$ and $n = 5$, and (2) $\phi_c = 0.92\%$ and $n = 4$. The simulated results show that small decreases in porosity result in steep reductions in permeability. This is consistent with a permeability experiment of Moore et al. (1983) in which a heated aqueous fluid was passed down a temperature gradient through Westerly Granite. The experiment showed a reduction in permeability of 96% with an 8% reduction of the initial porosity over a two-week period.

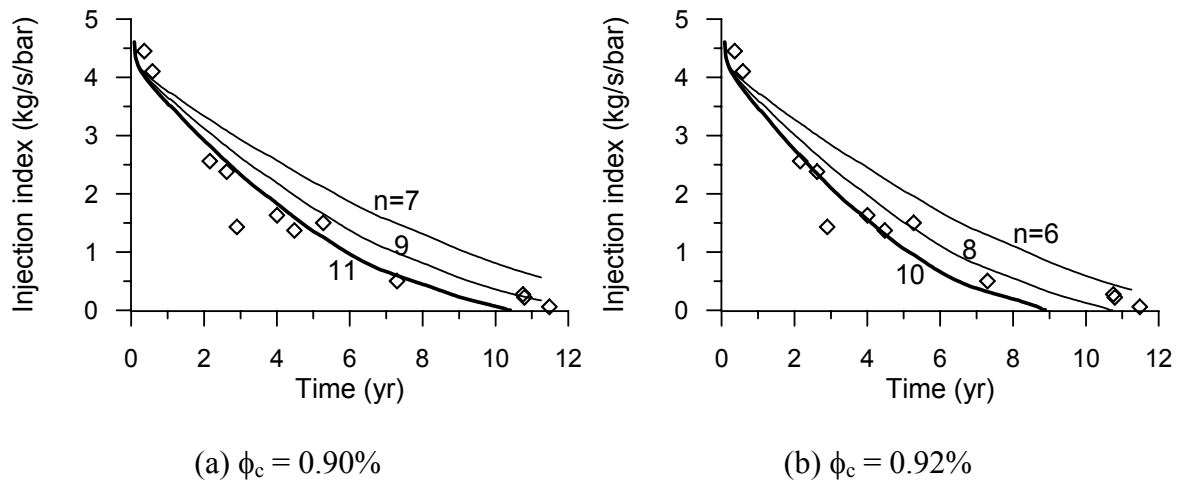

Figure 8.8.5. Simulated injection indexes using an injection silica concentration of 705 ppm, together with measured data.

An injection silica concentration of 705 ppm results in a total amorphous silica precipitation of 5.9 m^3 in the reservoir formation, while a silica concentration of 710 ppm results in 19.5 m^3 . The estimated amount of amorphous silica in the formation dissolved by acid is about 1.4 m^3 . Therefore, an injection silica concentration of 705 ppm could be a reasonable number for capturing total silica precipitation.

Further reviews of Figure 8.8.5 show that the simulated injection indexes reach zero at earlier times than observed. Figure 8.8.3 indicates that after January 1996 (seven years after the simulation start) temperatures increase significantly above 160°C . We then performed an additional simulation using an injection temperature of 161°C for the later time period. Other parameters for the additional simulation are an injection silica concentration of 705 ppm, $\phi_c = 0.92\%$ and $n = 10$. Results of the additional simulation are presented in Figure 8.8.6, showing that

the match of injection indexes to observations for the later period was improved. The higher temperature results in some early precipitated silica dissolving at later time. At the end of the simulation, a total of 2 m³ of amorphous silica remains in the formation, which is close to the actual amount of 1.4 m³ estimated to be dissolved by acid.

Figure 8.8.6. Simulated injection indexes using an injection temperature of 161°C for the later time period, together with measured data (silica concentration = 705 ppm, $\phi_c = 0.92\%$, and $n = 10$).

Significant reductions in porosity and permeability occur within a 10 m radius of the well (Figure 8.8.7). The pattern of permeability change as a logarithmic scale is similar to porosity change as a linear scale. The porosity reduction is mainly due to precipitation of amorphous silica (Figure 8.8.8). Some albite-low precipitation is also obtained. Minor illite precipitation and calcite dissolution occur in the simulations.

(a) Porosity

(b) Permeability

Figure 8.8.7. Distribution of porosity and permeability along the well radius for the simulation shown in Figure 8.8.6.

Figure 8.8.8. Precipitation of Amorphous silica along the well radius for the simulation shown in Figure 8.8.6.

For only one simulation corresponding to Figure 8.8.6, input and output files are given in the distribution CD (subdirectory: `tract/sample-problems/P8_EOS1-scaling`). To shorten the simulation time for installation purpose, the time in the PARAM input block of `flow.inp` is specified as $3.5478e+07$ (s, 1/10 of the entire simulation time and slightly longer than 1 year). Users can reset this variable to their desired time. Parts of output files for fluid flow, aqueous chemical concentrations, and changes of mineral abundances are given in Figures 8.8.9, 8.8.10 and 8.8.11.

Figure 8.8.11. Part of file sca_min.dat for problem no. 8 after $t = 1$ yr (unit of permeability is m^2 ; mineral abundances are expressed as changes in volume fraction, positive values indicate precipitation and negative dissolution)).

Other simulations can be achieved by modifying ϕ_c and n values in file chemical.inp (under key word 'Permeability-Porosity Zones'). As mentioned before, only the fracture network is considered in the simulation. To allow for chemical reaction with the rock, a 50% porosity was assigned to the blocks (with 50% pore volume and 50% rock volume). Therefore, an intrinsic porosity of 0.46 (in file chemical.inp) corresponds to bulk $\phi_c = 0.46 \times 2\% = 0.92\%$.

After the first phase of simulations of injectivity loss due to silica scaling, a simulation of acidization for the injectivity recovery was performed. For the actual acidization, a 5 wt% (about 2.5 mol/kg) HF acid was injected for five hours at an average rate of 18.2 kg/s. In the recovery simulation, a HF concentration of 1.25 mol/kg was used to account for some dilution by wellbore and formation waters. The predicted amount of amorphous silica dissolved by acid was also consistent with the estimated amount. Detailed results are given in Xu et al. (2004b).

8.8.4. Summary

A review of historical injection records, fluid chemistry data, and analyses of scale materials suggest silica scaling at Nag-67 occurred mainly in the rock formation immediately adjacent to the wellbore. Silica scaling (precipitation) decreases porosity, in turn permeability and injectivity. A reactive transport numerical model, including the porosity-permeability relationship of Verma and Pruess was used to simulate injection loss and recovery. The porosity-permeability

relationship involves two parameters: a “critical” porosity ϕ_c (which is the value of porosity at which permeability goes to zero) and a power term n (Eq. F.8). A number of simulations were performed using different combinations of values of ϕ_c and n under two different injection silica concentrations.

Significant precipitation of amorphous silica, and reductions of porosity and permeability occur within a 10 m radius from the well. The pattern of log10 scale of permeability is similar to linear scale of porosity. The simulated injection indexes were compared to measured data for each simulation. A good match was obtained using different parameter combinations; a smaller critical porosity ϕ_c requires a larger power term n . The porosity-permeability relationship is well suited for capturing the steep loss of injectivity at Nag-67. A steep reduction in permeability with a small decrease in porosity is consistent with a published permeability experiment. Taking an injection silica concentration of 705 ppm, within the range of observed values, results in a total amorphous silica precipitation of 2 m³ in the reservoir formation, close to the amount of 1.4 m³ estimated from the quantity of acid used to recover injectivity.

9. Concluding Remarks

We have documented a comprehensive computer program for non-isothermal multiphase fluid flow and geochemical transport. The gas phase is considered active for multiphase fluid flow, species transport, and chemical reactions. Our model is applicable to porous media as well as to fractured rocks. An integral finite difference (IFD) technique is employed for space discretization. The IFD can deal with irregular grids, does not require reference to a global system of coordinates, and includes classical dual-continua, multiple interacting continua, and multi-region models for heterogeneous and fractured rocks as special cases. Non-isothermal effects are considered, including water-vapor phase change and air partitioning between the liquid and gas phases, temperature-dependence of thermophysical properties such as phase density and viscosity, and chemical properties such as thermodynamic and kinetic parameters. Chemical reactions considered under the local equilibrium assumption include aqueous complexation, acid-base, redox, gas dissolution/exsolution, cation exchange, and surface complexation. Mineral dissolution/precipitation can proceed either subject to local equilibrium or kinetic conditions.

TOUGHREACT is applicable to one-, two-, or three-dimensional geologic domains with physical and chemical heterogeneity. TOUGHREACT can be applied to a wide range of subsurface conditions. Temperature can range from 0 to 300 °C, limited at present by available geochemical databases such as EQ3/6 (Wolery, 1992). Pressures can be from 1 bar (atmospheric pressure) to several hundred bars (at several thousand meter depth). Water saturation can range from completely dry to fully water saturated. The model can deal with ionic strength from diluted to saline waters with up to 6 mol/kg H₂O for NaCl dominant solution.

TOUGHREACT applications have been demonstrated for a variety of reactive fluid and geochemical transport systems, including (1) contaminant transport with linear K_d adsorption and decay, (2) natural groundwater quality evolution under ambient conditions, (3) assessment of nuclear waste disposal sites, (4) sedimentary diagenesis and CO₂ disposal in deep formations, (5) mineral deposition such as supergene copper enrichment, and (6) mineral alteration and silica scaling in hydrothermal systems under natural and production conditions. Additional applications will be explored in the future.

Acknowledgement. We are grateful to Carl Steefel and Keni Zhang for a review of the manuscript and suggestions for improvement. We thank to Tom Wolery for allowing us to use the EQ3/6 database. The development of TOUGHREACT was initiated with funding from the Laboratory Directed Research and Development Program of the Ernest Orlando Lawrence Berkeley National Laboratory. Subsequent development was supported by several DOE program offices. Documentation and public release of the code were funded by the Assistant Secretary for Energy Efficiency and Renewable Energy, Office of Geothermal Technologies, of the U.S. Department of Energy, under Contract No. DE-AC03-76SF00098. For sample problem no. 4 (Yucca Mountain heat test), geochemical data from the Drift Scale Test discussed in this report were reported by Laura DeLoach (aqueous species), Schon Levy (mineralogy), and Mark Conrad (CO₂). Sumit Mukhopadhyay and Jens Birkholzer developed the initial TH grid. John Apps worked on initial development of the thermodynamic database and Sonia Salah worked on a refinement of the kinetic database. This sample problem (problem no. 4) and also problem no. 3 are based on work supported by the Director, Office of Civilian Radioactive Waste Management, U.S. Department of Energy, through Memorandum Purchase Order QA-B004220RB3X between Bechtel SAIC Company, LLC and the Ernest Orlando Lawrence Berkeley National Laboratory (Berkeley Lab).

Appendix A. Mathematical Equations for Flow and Transport

All flow and transport equations have the same structure, and can be derived from the principle of mass (or energy) conservation. Table A.1 summarizes these equations and Table A.2 gives the meaning of symbols used. The fluid and heat flow model has been discussed in detail by Pruess (1987 and 1991) and Pruess et al. (1999). Aqueous species are subject to transport in the liquid phase as well as to local chemical interactions with the solid and gaseous phases. Chemical transport equations are written in terms of total dissolved concentrations of chemical components that are concentrations of their basis species plus their associated aqueous secondary species (Yeh and Tripathi, 1991; Steefel and Lasaga, 1994; Walter et al., 1994). Advection and diffusion processes are considered for chemical transport, and diffusion coefficients are assumed to be the same for all species.

Table A.1. Governing equations for fluid and heat flow, and chemical transport. Symbol meanings are given in Table A.2. Take EOS3 and EOS4 flow modules as example. For EOS2 and ECO2, component ‘Air’ in the table should be replaced with ‘CO₂’. For EOS1, equation for air is not required. For EOS9, equation for air and heat are not required (only Richard equation).

General governing equations:	$\frac{\partial M_{\kappa}}{\partial t} = -\nabla F_{\kappa} + q_{\kappa}$	
Water: $M_w = \phi(S_l \rho_l X_{wl} + S_g \rho_g X_{wg})$	$F_w = X_{wl} \rho_l \mathbf{u}_l + X_{wg} \rho_g \mathbf{u}_g$	$q_w = q_{wl} + q_{wg}$
Air: $M_c = \phi(S_l \rho_l X_{cl} + S_g \rho_g X_{cg})$	$F_c = X_{cl} \rho_l \mathbf{u}_l + X_{cg} \rho_g \mathbf{u}_g$	
	$q_c = q_{cl} + q_{cg} + q_{cr}$	
Heat: $M_h = \phi(S_l \rho_l U_l + S_g \rho_g U_g) + (1 - \phi) \rho_s U_s$	$F_h = \sum_{\beta=l,g} h_{\beta} \rho_{\beta} \mathbf{u}_{\beta} - \lambda \nabla T$	q_h
	where $\mathbf{u}_{\beta} = -k \frac{k_{r\beta}}{\mu_{\beta}} (\nabla P_{\beta} - \rho_{\beta} \mathbf{g}) \quad \beta = l, g$ (Darcy's Law)	
Chemical components in the liquid phase ($j = 1, 2, \dots, N_l$):		
$M_j = \phi S_l C_{jl}$	$F_j = \mathbf{u}_l C_{jl} - (\tau \phi S_l D_l) \nabla C_{jl}$	$q_j = q_{jl} + q_{js} + q_{jg}$
	$\tau_{\beta} = \phi^{1/3} S_{\beta}^{7/3}$	(Millington and Quirk, 1961)

Table A.2. Symbols used in Table A.1.

C	component concentration, mol L ⁻¹	ρ	density, kg m ⁻³
D	diffusion coefficient, m ² s ⁻¹	μ	viscosity, kg m ⁻¹ s ⁻¹
F	mass flux, kg m ⁻² s ⁻¹ (*)	λ	heat conductivity, W m ⁻¹ K ⁻¹
k	permeability, m ²		
k _r	relative permeability	Subscripts:	
g	gravitational acceleration, m s ⁻²	c	air
M	mass accumulation, kg m ⁻³	g	gas phase
N	number of chemical components	h	heat
p	pressure, Pa	j	aqueous chemical component
q	source/sink	l	liquid phase
S	saturation	r	reaction
T	temperature, °C	s	solid phase
U	internal energy, J kg ⁻¹	w	water
u	Darcy velocity, m s ⁻¹	κ	governing equation index
X	mass fraction	β	phase index
φ	porosity	τ	medium tortuosity

(*) For chemical transport and reaction calculations, molar units are used instead of kg.

The primary governing equations given in Table A.1 must be complemented with constitutive relationships that express all parameters as functions of thermophysical and chemical variables. These expressions for non-isothermal multiphase flow are given by Pruess et al. (1999). The expressions for chemical reactions are given in Appendix B.

Gas diffusion coefficients are computed as a function of temperature and pressure. Assuming ideal gas behavior, the tracer diffusion coefficient of a gaseous species is expressed as a function of temperature and pressure as follows (Lasaga, 1998):

$$D = \frac{RT}{3\sqrt{2}\pi P N_A d_m^2} \sqrt{\frac{8RT}{\pi M}} \quad (\text{A. 1})$$

where:

- D = diffusion coefficient (m²/s)
- R = molar gas constant (8.31451 m²kg s⁻²mol⁻¹ K⁻¹)
- T = temperature in Kelvin units
- π = 3.1415926536
- P = pressure (kg m⁻¹ s⁻²)
- N_A = Avogadro's number (6.0221367 x 10²³ molecules/mol)
- D_m = molecular diameter (m)
- M = molecular weight (kg/mol)

Appendix B. Mathematical Formulation of Chemical Reactions

For representing a geochemical system, it is convenient to select a subset of N_C aqueous species as basis species (or component or primary species). All other species are called secondary species that include aqueous complexes, precipitated (mineral) and gaseous species (Reed, 1982; Yeh and Tripathi, 1991; Steefel and Lasaga, 1994). The number of secondary species must be equal to the number of independent reactions. Any of the secondary species can be represented as a linear combination of the set of basis species such as

$$S_i = \sum_{j=1}^{N_C} v_{ij} S_j \quad i = 1, \dots, N_R \quad (\text{B.1})$$

where S represent chemical species, j is the basis species index, i is the secondary species index, N_R is the number of reactions (or secondary species), and v_{ij} is the stoichiometric coefficient of j -th basis species in the i -th reaction.

Aqueous complexation. These reactions are assumed to be at local equilibrium. By making use of the mass action equation to the dissociation of the i -th aqueous complex (Equation B.1), concentrations of aqueous complexes can be expressed as functions of the concentrations of basis species:

$$c_i = K_i^{-1} \gamma_i^{-1} \prod_{j=1}^{N_C} c_j^{v_{ij}} \gamma_j^{v_{ij}} \quad (\text{B.2})$$

where c_i is molal concentration of the i -th aqueous complex, and c_j is molal concentration of the j -th basis species, γ_i and γ_j are thermodynamic activity coefficients (details on calculation of activity coefficients are given in Appendix H), and K_i is the equilibrium constant.

Equilibrium mineral dissolution/precipitation. The mineral saturation ratio can be expressed as

$$\Omega_m = X_m^{-1} \lambda_m^{-1} K_m^{-1} \prod_{j=1}^{N_C} c_j^{v_{mj}} \gamma_j^{v_{mj}} \quad m = 1 \dots N_P \quad (\text{B.3})$$

where m is the equilibrium mineral index, X_m is the mole fraction of the m -th mineral phase, λ_m is its thermodynamic activity coefficient (for pure mineral phases X_m and λ_m are taken equal to one), and K_m is the corresponding equilibrium constant. At equilibrium, we have

$$SI_m = \log_{10} \Omega_m = 0 \quad (\text{B.4})$$

where SI_m is called the mineral saturation index. The treatment for mineral solid solutions is given in Appendix I.

Kinetic mineral dissolution/precipitation. Kinetic rates could be functions of non-basis species as well. Usually the species appearing in rate laws happen to be basis species. In this model, we use a rate expression given by Lasaga et al. (1994):

$$r_n = f(c_1, c_2, \dots, c_{N_C}) = \pm k_n A_n \left[1 - \Omega_n^\theta \right]^\eta \quad n = 1 \dots N_q \quad (\text{B.5})$$

where positive values of r_n indicate dissolution, and negative values precipitation, k_n is the rate constant (moles per unit mineral surface area and unit time) which is temperature dependent, A_n is the specific reactive surface area per kg H₂O (details on A_n calculations are given in Appendix G), Ω_n is the kinetic mineral saturation ratio defined as in (B.3). The parameters θ and η must be determined from experiments; usually, but not always, they are taken equal to one. The temperature dependence of the reaction rate constant can be expressed reasonably well via an Arrhenius equation (Lasaga, 1984; Steefel and Lasaga, 1994). Since many rate constants are reported at 25°C, it is convenient to approximate rate constant dependency as a function of temperature, thus

$$k = k_{25} \exp \left[\frac{-E_a}{R} \left(\frac{1}{T} - \frac{1}{298.15} \right) \right] \quad (\text{B.6})$$

where E_a is the activation energy, k_{25} is the rate constant at 25°C, R is gas constant, T is absolute temperature.

Carroll et al. (1998) noted that the rates of amorphous silica precipitation based on Rimstidt and Barnes (1980) are about three orders of magnitude lower than those observed in geothermal systems. Carroll et al. (1998) presented experimental data on amorphous silica precipitation for more complex geothermal fluids at higher degrees of supersaturation, and also for a near-saturation simple fluid chemistry. Under conditions far from equilibrium, the rate law for amorphous silica precipitation has been expressed as:

$$r = kA(\Omega)^\theta \quad (\text{B. 7})$$

This rate does not tend to zero as Ω goes to one, and therefore, a modification was made to this law so that it tends to zero as Ω approaches one

$$r = kA \left[(\Omega)^\theta - \frac{1}{\Omega^{2\theta}} \right] \quad (\text{B. 8})$$

The pH dependence of mineral precipitation and dissolution rates is calculated using the following expressions:

$$\begin{aligned} k_{adj} &= k (10^{-pH_c}/10^{-pH_1})^{slope1} && \text{if } pH_c < pH_1 \\ k_{adj} &= k (10^{-pH_c}/10^{-pH_2})^{-slope2} && \text{if } pH_c > pH_2 \end{aligned}$$

where k_{adj} is the rate adjusted for pH, k is the original rate (Equation B.5), pH_c is the current (calculated) pH, pH_1 is the pH below which the rate is adjusted by *slope1* and pH_2 is the pH above which the rate is adjusted by *slope2*. Parameters *slope1* and *slope2* are the absolute values (both positive numbers) of the $\log(k)$ versus pH slopes below pH_1 and above pH_2 , respectively (Figure B.1). Between these two pH values, the rate is assumed to remain independent of pH.

Figure B.1. Variation of reaction rate with pH. Slopes shown are for the dissolution of silicate and aluminosilicate minerals (After Drever, 1997).

The kinetic rate constant k in Eqs. (B.5) and (B.6) only considers the most well-studied mechanism in pure H_2O (neutral pH). Dissolution and precipitation of minerals are often catalyzed by H^+ (acid mechanism) and OH^- (base mechanism). For many minerals, the kinetic rate constant k includes each of these three mechanisms (Lasaga et al., 1994; Palandri and Kharaka, 2004), or

$$k = k_{25}^{nu} \exp\left[\frac{-E_a^{nu}}{R} \left(\frac{1}{T} - \frac{1}{298.15}\right)\right] + k_{25}^H \exp\left[\frac{-E_a^H}{R} \left(\frac{1}{T} - \frac{1}{298.15}\right)\right] a_H^{n_H} + k_{25}^{OH} \exp\left[\frac{-E_a^{OH}}{R} \left(\frac{1}{T} - \frac{1}{298.15}\right)\right] a_{OH}^{n_{OH}} \quad (B.9)$$

where superscripts or subscripts nu, H, and OH indicate neutral, acid and base mechanisms, respectively; a is the activity of the species; and n is power term (constant). Notices that parameters θ and η (see Eq. B.5) are assumed the same for each mechanism. The rate constant k can be also dependent on other species such as Al^{3+} and Fe^{3+} . Two or more species may involved

in one mechanism. A general form of species dependent rate constants (extension of Eq. B.9) is coded in TOUGHREACT, or,

$$k = k_{25}^{\text{nu}} \exp\left[\frac{-E_a^{\text{nu}}}{R}\left(\frac{1}{T} - \frac{1}{298.15}\right)\right] + \sum_i k_{25}^i \exp\left[\frac{-E_a^i}{R}\left(\frac{1}{T} - \frac{1}{298.15}\right)\right] \prod_j a_{ij}^{\text{nu}_{ij}} \quad (\text{B.10})$$

where superscripts or subscripts i is the additional mechanism index, and j is species index involved in one mechanism that can be primary or secondary species. TOUGHREACT considers up to five additional mechanisms and up to five species involved in each mechanism. An application of multiple mechanisms (Eq. B.10) can be found in the CO₂ disposal sample problem (Section 8.5).

The precipitation of a mineral can be suppressed up to a given, positive saturation index value, $\log(\Omega)_w$. Within this "supersaturation window", the mineral is not allowed to precipitate. The mineral precipitates if its saturation index $\log(\Omega) \geq \log(\Omega)_w$, and dissolves if $\log(\Omega) < 0$. The size of the window can be set to decrease exponentially with temperature as follows:

$$\log(\Omega)_{w,T} = \log(\Omega)_{w,T^0} \exp(-4.61(T-T^0)/(T_1-T^0)) \quad (\text{B.11})$$

where $\log(\Omega)_{w,T}$ is the window at the current temperature T and $\log(\Omega)_{w,T^0}$ is the initial (input) window at temperature T^0 . T_1 is the temperature at which the window is one hundredth the size of the initial window (thus the temperature at which the effect of the window essentially disappears, see Figure B.2). Values of $\log(\Omega)_{w,T^0}$, T_0 , and T_1 are provided as input parameters.

Figure B.2. Supersaturation window dependence on temperature.

Gas dissolution/exsolution. Reactions involving aqueous and gaseous phases are usually assumed to be at equilibrium. According to the Mass-Action Law, one has:

$$p_f \Gamma_f K_f = \prod_{j=1}^{N_c} c_j^{v_{fj}} \gamma_j^{v_{fj}} \quad (\text{B.12})$$

where subscript f is gas index, p is the partial pressure (in bar), Γ is the gas fugacity coefficient. For low pressures (in the range of atmospheric pressure), the gaseous phase is assumed to behave like an ideal mixture, and the fugacity coefficient Γ is assumed equal to one. At higher temperatures and pressures, such as boiling conditions in hydrothermal systems and CO_2 disposal in deep aquifers, the assumption of ideal gas and ideal mixing behavior is not valid, and the fugacity coefficients should be corrected according to temperatures and pressures (Spycher and Reed, 1988). For example, for the $\text{H}_2\text{O}-\text{CO}_2$ mixtures in boiling conditions, we assume that H_2O and CO_2 are real gases, but their mixing is ideal. According to Spycher and Reed (1988), the fugacity coefficients can be calculated from

$$\ln \Gamma = \left(\frac{a}{T^2} + \frac{b}{T} + c \right) P + \left(\frac{d}{T^2} + \frac{e}{T} + f \right) \frac{P^2}{2} \quad (\text{B.13})$$

where P is the total gas pressure (vapor and CO₂), T is absolute temperature, and a, b, c, d, e, and f are constants fitted from experimental data. For P-T ranges, 50-350 °C, up to 500 bars, the fitted constants have the following values: a = -1430.87, b = 3.598, c = -2.27376×10⁻³, d = 3.47644, e = -1.04247×10⁻², and f = 8.36271×10⁻⁶. Examples of equilibrium calculations between aqueous and gas phases show that ideal mixing of real gases is an adequate approximation in the above-mentioned P-T ranges (Spycher and Reed, 1988).

For low ionic strength solution, CO₂(aq) activity coefficient γ can be assumed equal to one. For high ionic strength sodium chloride solution, γ should be corrected (salting out effect). Here we use an activity coefficient expression of Drummond (1981) for the neutral CO₂(aq) species:

$$\ln \gamma = \left(C + FT + \frac{G}{T} \right) I - (E + HT) \left(\frac{I}{I+1} \right) \quad (\text{B.14})$$

where T is the absolute temperature, I is ionic strength (or sodium chloride molality), C, F, G, E, and H are constants (C=-1.0312, F=0.0012806, G=255.9, E=0.4445, and H=-0.001606). This expression was previously used in geochemical modeling codes EQ3/6 (Wolery, 1992). The ionic strength I is defined by

$$I = \frac{1}{2} \sum_i c_i z_i^2 \quad (\text{B.15})$$

where the summation is over all aqueous species, and c_i and z_i are concentration (mol/kg H₂O) and electrical charge of species i.

Cation exchange. Cation exchange takes place when free cations in solution exchange with interlayer cations. This process can be described as an equilibrium reaction between an

exchangeable cation and an exchange site. The equilibrium constant is usually known as the exchange coefficient because its value depends on the ionic strength of the solution. A general expression for cation exchange reactions according to the Gaines-Thomas convention is (Appelo and Postma, 1993):

where v_i and v_j are the stoichiometric coefficients (equal to their charges) of dissolved and interlayer cations, respectively; S_i and S_j denote dissolved cationic species and $(X_{v_i} - S_i)$ and $(X_{v_j} - S_j)$ represent exchange sites or exchange interlayer cations. The equilibrium equation for cation exchange is obtained from the Mass Action Law:

$$K_{ij}^* = \frac{\overline{w}_i^{-1/v_i} \cdot a_j^{1/v_j}}{\overline{w}_j^{-1/v_j} \cdot a_i^{1/v_i}} \quad (\text{B.17})$$

where K_{ij}^* is the exchange coefficient or selectivity, a_j is the activity of the j -th dissolved species and \overline{w}_i is the activity of the i -th exchanged species. Activities of dissolved cations are related to concentrations as given in Appendix H. Activities of interlayer cations are approximated by their equivalent fractions of the number of exchange sites. Thus, the activity of the interlayer cation \overline{w}_i is assumed to be equal to its equivalent fraction β_i , and is calculated as:

$$\overline{w}_i \cong \beta_i = \frac{w_i}{\sum_{i=1}^{N_w} w_i} \quad (\text{B.18})$$

where w_i is the concentration of the i -th interlayer cation and N_w is the total number of such interlayer cations. The sum of concentrations of surface sites or interlayer cations is the so-called cation exchange capacity (CEC). Substituting (B.18) into (B.17) yields the general equation for cation exchange:

$$K_{ij}^* = \frac{\beta_i^{1/v_i} \cdot (c_j \gamma_j)^{1/v_j}}{\beta_j^{1/v_j} \cdot (c_i \gamma_i)^{1/v_i}} \quad (\text{B.19})$$

where the activity of each dissolved species a_i has been expressed as the product of its concentration c_i time its activity coefficients γ_i . From this equation, the equivalent fraction of the j -th interlayer cation can be expressed as

$$\beta_j = (K_{ij}^*)^{-v_j} c_j \gamma_j \left(\frac{\beta_i}{c_i \gamma_i} \right)^{v_j/v_i} \quad j = 1, 2, \dots, N_w \quad (\text{B.20})$$

From the definition of equivalent fraction, one has:

$$\sum_{j=1}^{N_w} \beta_j = 1 \quad (\text{B.21})$$

Substituting Equation B.20 into B.21 results in:

$$\sum_{j=1}^{N_w} (K_{ij}^*)^{-v_j} c_j \gamma_j \left(\frac{\beta_i}{c_i \gamma_i} \right)^{v_j/v_i} = 1 \quad (\text{B.22})$$

which for given dissolved concentrations c_j can be solved for the single unknown β_i . This equation is quadratic when cation exchange involves only homovalent and divalent cations. However, when cation exchange involves also trivalent cations a cubic equation is obtained. Once

the equivalent fraction β_i is known the rest of exchange fractions can be calculated from Equation B.18. The concentration of the i -th exchanged cation w_j (in moles per liter of fluid) can be obtained from the i -th equivalent fraction according to Equation B.18 through:

$$w_j = \beta_j \text{CEC } \rho_s z_j \frac{(1 - \phi)}{100\phi} \quad (\text{B.23})$$

where CEC is the cation exchange capacity (usually measured as the number of milli equivalents of cations per 100 gram of solid), ϕ is the porosity, ρ_s is the density of the solids (kg of solids per dm^3 of solids) and z_j is the cation charge.

Three cation exchange conventions, Gaines-Thomas, Vanselow and Gapon (Appelo and Postma, 1993), are implemented in TOUGHREACT.

Appendix C. Solution Method for Solute Transport Equations

Most chemical species are only subject to transport in the liquid phase. A few species can be transported in both liquid and gas phases such as O₂ and CO₂. We first derive the numerical formulation of reactive transport in the liquid phase. This will then be extended to transport in the gas phases for some gaseous species.

C.1. Transport in the Liquid Phase

In the sequential iteration approach (SIA), the mass transport equations and chemical reaction equations are considered as two relatively independent subsystems. They are solved separately in a sequential manner following an iterative procedure. If reactions taking place in the liquid phase are assumed to be at local equilibrium, mass transport equations can be written in terms of total dissolved component concentrations. By lumping all mass accumulation terms due to mass transfer between aqueous and solid phases including precipitated (kinetics and equilibrium), exchanged and sorbed species, and by using Equation (4.1) (in Chapter 4), we can write equations for multi-component chemical transport in the liquid phase as

$$\frac{\Delta t}{V_n} \sum_m A_{nm} \left[u_{nm}^{k+1} C_{nm}^{(j),k+1,s+1/2} + D_{nm} \frac{C_m^{(j),k+1,s+1/2} - C_n^{(j),k+1,s+1/2}}{d_{nm}} \right] = \Delta M_n^{(j),k+1} - q_n^{(j),k+1} \Delta t - R_n^{(j),k+1,s} \Delta t \quad j = 1, 2, \dots, N_C \quad (C.1)$$

where n labels the grid block, j labels the chemical component, N_C is the total number of chemical components, l labels liquid phase (for simplicity, the liquid phase index l is neglected), k labels the number of the time step, s labels the number of the transport-chemistry iteration (details are given later), u_{nm} is the liquid volumetric flux or Darcy's velocity (m/s), D_{nm} is the effective diffusion coefficient (including effects of porosity, phase saturation, tortuosity and weighting factors between the two grid blocks), d_{nm} is the nodal distance, $R_n^{(j),k+1}$ are the overall chemical reaction source/sink terms.

The concentrations in the advective and diffusive flux terms of Equation (C.1) can be evaluated by

$$\begin{aligned}
C_{nm}^{(j),k+1,s+1/2} &= \theta \left[\varepsilon_{nm} C_n^{(j),k+1,s+1/2} + (1 - \varepsilon_{nm}) C_m^{(j),k+1,s+1/2} \right] \\
&\quad (1 - \theta) \left[\varepsilon_{nm} C_n^{(j),k} + (1 - \varepsilon_{nm}) C_m^{(j),k} \right] \\
C_n^{(j),k+1,s+1/2} &= \theta C_n^{(j),k+1,s+1/2} + (1 - \theta) C_n^{(j),k} \\
C_m^{(j),k+1,s+1/2} &= \theta C_m^{(j),k+1,s+1/2} + (1 - \theta) C_m^{(j),k}
\end{aligned} \tag{C.2}$$

where θ is the time weighting factor, with values in the range from 0 to 1; $\theta = 1$ indicates full implicit; and

$$\varepsilon_{nm} = \begin{cases} 0 & \text{if } u_{nm} \geq 0 \text{ inflow} \\ 1 & \text{if } u_{nm} < 0 \text{ outflow} \end{cases}$$

Fully upstream weighting is used for advective flux calculations. The mass accumulation terms can be evaluated as

$$\Delta M_n^{(j),k+1} = S_{l,n}^{k+1} \phi_n^{k+1} C_n^{(j),k+1,s+1/2} - S_{l,n}^k \phi_n^k C_n^{(j),k} \tag{C.3}$$

By substituting Equations (C.2) and (C.3) into (C.1), and then rearranging them in terms of unknowns, $C^{(j),k+1,s+1/2}$ (total dissolved component concentrations), one has

$$\begin{aligned}
& \left[S_{l,n}^{k+1} \phi_n^{k+1} + \frac{\theta \Delta t}{V_n} \sum_m A_{nm} \left(-u_{nm}^{k+1} \varepsilon_{nm} + \frac{D_{nm}}{d_{nm}} \right) \right] C_n^{(j),k+1,s+1/2} + \\
& \frac{\theta \Delta t}{V_n} \sum_m A_{nm} \left[u_{nm}^{k+1} (\varepsilon_{nm} - 1) - \frac{D_{nm}}{d_{nm}} \right] C_m^{(j),k+1,s+1/2} = \\
& \frac{(1-\theta) \Delta t}{V_n} \sum_m A_{nm} \left(u_{nm}^{k+1} \varepsilon_{nm} - \frac{D_{nm}}{d_{nm}} \right) C_n^{(j),k} - \\
& \frac{(1-\theta) \Delta t}{V_n} \sum_m A_{nm} \left[u_{nm}^{k+1} (\varepsilon_{nm} - 1) + \frac{D_{nm}}{d_{nm}} \right] C_m^{(j),k} \\
& S_{l,n}^k \phi_n^k C_n^{(j),k} + q_n^{(j)k+1} \Delta t + R_n^{(j),k+1,s} \Delta t \quad j = 1, 2, \dots, N_C
\end{aligned} \tag{C.4}$$

For the sequential iteration approach, the iteration index s is essential. A new transport-chemistry iteration consists of two parts, transport part denoted by, $s+1/2$, (it should be noted that $1/2$ does not mean $\Delta t/2$), and chemistry part denoted by, $s+1$. Equation (C.4) for each chemical component j is linear if $R^{(j),s}$ is known, and has the same structure as the non-reacting (conservative) solute transport equation. The chemical reaction source/sink term $R^{(j),s}$ represents mass transfer of component j between aqueous and solid phases. The values of these source/sink terms at the new transport iteration, $s+1/2$, are evaluated at the previous chemistry iteration, s . The resulting new values of $C^{(j),s+1/2}$, obtained by solving transport Equations (C.1), are substituted into chemical reaction subroutines and one can compute new values of $R^{(j),s+1}$. Transport and chemical reaction equations are solved iteratively until prescribed convergence criteria are satisfied. The essence of this sequential iteration approach is therefore the sequential solution of two independent sets of equations: the transport equations and the chemical equations. The transport equations are solved on a component by component basis, whereas the chemical equations are solved on a grid block basis. These two sets of equations are coupled by updating chemical source/sink terms.

For kinetic mineral dissolution-precipitation, the terms $R^{(j)}$ can be calculated directly from kinetic expressions. For equilibrium, these terms can be obtained indirectly from component mass

balance equations. The solution of chemical equilibrium system and calculation of the source/sink terms $R^{(j)}$ are presented in Appendix D. From the chemistry point of view, equilibrium mineral dissolution-precipitation does not appear in an explicit rate expression. To avoid confusion, we write the last term in Equation (C.4) as

$$R_n^{(j),k+1,s} \Delta t = -\Delta P_n^{(j),k+1,s} \quad (C.5)$$

where $\Delta P_n^{(j),k+1,s}$ means mass transfer of component j from the aqueous phase to the mineral phase at iteration s , grid block n and time step $k+1$ (or called mass accumulation in mineral phases; negative values indicate mass transfer from the mineral phase to the aqueous phase)

Returning to Equation (C.4), we can see that the coefficient matrix is the same for all chemical components as long as diffusion coefficients are the same for all aqueous species. The matrix depends on space and time discretization, and flow conditions. The equations for different components only differ in right-hand side terms.

The mathematical treatment of adding K_d linear adsorption and first-order decay effects in the model follows the work by Oldenburg and Pruess (1995, EOS7R), but no gas phase partitioning is considered. The mass accumulation term for any species (for simplification, the species index is not appeared in the following equations) with K_d adsorption on the solid matrix is

$$M = \phi S_l C + (1 - \phi) \rho_s C K_d \quad (C.6)$$

where ϕ is porosity, S_l is the liquid saturation, C is the aqueous concentration (mol/l), ρ_s is the solid density (kg/dm³), K_d is the distribution coefficient (l/kg = mass/kg solid divided by mass/l solution) and is species-dependent. The accumulation term also can be written in terms of retardation factor

$$M = \phi S_1 RC \quad (C.7)$$

and

$$R = 1 + \frac{(1 - \phi)\rho_s}{\phi S_1} K_d \quad (C.8)$$

The input can be optionally by K_d and R depending on user convenience and data availability.

The first-order decay of a species is handled by the discretized equation (Oldenburg and Pruess, 1995)

$$M_n^{k+1}(1 + \lambda\Delta t) - M_n^k = \frac{\Delta t}{V_n} \left(\sum_m A_{nm} F_{nm}^{k+1} + V_n q_n^{k+1} \right) \quad (C.9)$$

where λ is decay constant (1/s) which is species-dependent, subscript n labels grid block, superscript k labels time step, subscript m labels the grid block connected to grid block n , Δt is time step size, M_n is the average mass per unit volume, surface integrals are approximated as a discrete sum of averages over surface segments A_{nm} , F_{nm} is the average mass flux over the surface segment A_{nm} between volume elements V_n and V_m , q is the average value of source/sink term per unit volume and unit time.

C.2. Transport in the Gas Phase

Gaseous species concentrations can be related to partial pressures by

$$C^g = \frac{10^2}{RT} P^g \quad (C.10)$$

where C^g are gaseous species concentrations (in mol/l), P^g is the gaseous species partial pressure (in bar), R is the gas constant ($8.314 \text{ J}\cdot\text{mol}^{-1}\cdot\text{K}^{-1}$) and T is the absolute temperature. By following

the same principle used for transport in liquid phase and by considering Equation (C.10), the numerical formulation of gaseous transport in the gas phases can be expressed as

$$\begin{aligned}
& \left[\frac{10^2}{RT} S_{g,n}^{k+1} \phi_n^{k+1} + \frac{\Delta t}{V_n} \sum_m A_{nm} \frac{10^2}{RT} \left(-\mathbf{u}_{nm}^{g,k+1} \boldsymbol{\varepsilon}_{nm}^g + \frac{D_{nm}^g}{d_{nm}} \right) \right] \mathbf{P}_n^{g,(j),k+1,s+1/2} + \\
& \frac{\Delta t}{V_n} \sum_m A_{nm} \frac{10^2}{RT} \left[\mathbf{u}_{nm}^{g,k+1} (\boldsymbol{\varepsilon}_{nm}^g - 1) - \frac{D_{nm}^g}{d_{nm}} \right] \mathbf{P}_m^{g,(j),k+1,s+1/2} = \\
& \frac{10^2}{RT} S_{g,n}^k \phi_n^k \mathbf{P}_n^{g,(j),k} + \mathbf{q}_n^{(j)k+1} \Delta t + \mathbf{R}_n^{(j),k+1,s} \Delta t \quad j = 1, 2, \dots, N_g
\end{aligned} \tag{C.11}$$

where N_g is number of gaseous species (in most cases, only a few species can be present in the gas phase such as O_2 and CO_2 that are significant for reactive chemistry). The structure of Equations (C.11) is the same as that of (C.4) for transport only in liquid phase. The same solution method can be applied for solving Equations (C.11).

Appendix D. Solution Method for Mixed Equilibrium-Kinetics Chemical System

We assumed that aqueous complexation and gas dissolution/exsolution proceed according to local equilibrium, while mineral dissolution/precipitation are subject to equilibrium and/or kinetic conditions. Only pure mineral phases are considered. Gas dissolution/exsolution is included in the model and treated in a similar way as equilibrium mineral dissolution/precipitation. The formulation is based on mass balances in terms of basis species as used by Parkhurst et al. (1980) and Reed (1982) for the equilibrium chemical system. The kinetic rate expressions for mineral dissolution/precipitation are included in the equations along with the mass balances of basis species (Xu et al., 1999b). At time zero (initial), the total concentrations of basis species j in the system are assumed to be known, and are given by

$$T_j^0 = c_j^0 + \sum_{k=1}^{N_x} v_{kj} c_k^0 + \sum_{m=1}^{N_p} v_{mj} c_m^0 + \sum_{n=1}^{N_q} v_{nj} c_n^0 \quad j = 1, \dots, N_C \quad (D.1)$$

where superscript 0 represents time zero; c are concentrations (chemical reactions are always solved per kg of water, and concentration units used here are mol/kg which is close enough to mol/l when its density is close to 1 kg/l); subscripts j , k , m , and n are the indices of basis species, aqueous complexes, minerals at equilibrium and minerals under kinetic constraints, respectively; N_C , N_x , N_p , and N_q are the number of the corresponding species and minerals; v_{kj} , v_{mj} , and v_{nj} are stoichiometric coefficients of the basis species in the aqueous complexes, equilibrium and kinetic minerals, respectively. After a time step Δt_r , the total concentration of basis species j is given by

$$T_j = c_j + \sum_{k=1}^{N_x} v_{kj} c_k + \sum_{m=1}^{N_p} v_{mj} c_m + \sum_{n=1}^{N_q} v_{nj} (c_n^0 - r_n \Delta t_r) \quad j = 1, \dots, N_C \quad (D.2)$$

where r is the kinetic dissolution rate (negative for precipitation, units used here are moles per kg water per time). For a closed system, according to mass conservation, we have

$$T_j^0 = T_j \quad (D.3)$$

The set of nonlinear chemical reactions is solved by the Newton-Raphson iterative method. The use of this method requires lumping all the terms in the right-hand side in a single term (or residual function which is zero in the limit of convergence), and we denote this term by F_j^c

$$F_j^c = T_j - T_j^0 = 0 \quad (D.4)$$

By substituting Equations. (D.1) and (D.2) into (D.4), we obtain

$$F_j^c = c_j + \sum_{k=1}^{N_x} v_{kj} c_k + \sum_{m=1}^{N_p} v_{mj} c_m - \sum_{n=1}^{N_q} v_{nj} r_n \Delta t_r - U_j^0 = 0 \quad j = 1, \dots, N_C \quad (D.5)$$

where

$$U_j^0 = c_j^0 + \sum_{k=1}^{N_x} v_{kj} c_k^0 + \sum_{m=1}^{N_p} v_{mj} c_m^0 \quad (D.5a)$$

According to mass action equations, concentrations of aqueous complexes c_k can be expressed as functions of concentrations of the basis species c_j (Equation B.2 in Appendix B). Kinetic rates r_n are functions of c_j (Equation (B.5)). No explicit expressions relate equilibrium mineral concentrations c_m , to c_j . Therefore, N_p additional mass action equations (one per mineral) are needed, which are provided by Equation (B.4). At equilibrium we have the residual functions F_m^p

$$F_m^p = SI_m = 0 \quad m = 1, \dots, N_p \quad (D.6)$$

where SI_m is the m -th equilibrium mineral saturation index which is a function of c_j (see Equations B.3 and B.4 in Appendix B). N_C equations in (D.5) and N_p in (D.6) constitute a complete set of

equations needed for N_C+N_P primary variables, $(c_1, c_2, \dots, c_{N_C}, c_1, c_2, \dots, c_{N_P})$. Denoting the set of primary variables collectively as X_i ($i=1, 2, \dots, N_C+N_P$), using Newton-Raphson iteration we have

$$\sum_{i=1}^{N_C+N_P} \frac{\partial F_j}{\partial X_i} \Delta X_i = -F_j \quad j=1, \dots, N_C + N_P \quad (D.7)$$

where j is a row index and i is a column index (here j as a row index can be thought of as also representing an “extended” basis set including the equilibrium minerals). In matrix form Eqs. (D.7) reduce to

$$\mathbf{J}\Delta\mathbf{X} = -\mathbf{F} \quad (D.8)$$

where \mathbf{J} is the so-called Jacobian matrix. The matrix elements are evaluated in Appendix E. The values of $\Delta\mathbf{X}$ are used to update the primary variables:

$$X_i^{s+1} = X_i^s + \Delta X_i^s \quad (D.9)$$

where s labels iteration number. $|\Delta X_i|$ are expected to decrease in successive iterations. The system of equations is considered satisfactorily solved when

$$\max_j \left(\frac{|F_j^c|}{T_j^0} \right) \leq \tau \quad j=1, \dots, N_C \quad (D.10)$$

where τ is specified tolerance limit. In order to avoid negative values for concentrations of the basis species, the relative change is restricted to one (called under-relaxation), or $\frac{|\delta X_i|}{X_i} \leq \tau \quad i=1 \dots N_C + N_P + N_S$ ($i=1 \dots N_C$). As a consequence, although the iteration

method becomes more robust, the rate of convergence may slow down in some cases. When a

negative value of X_i ($i = N_C + 1, \dots, N_C + N_P$) is obtained, the corresponding mineral is considered exhausted and must be removed from the chemical system, and its corresponding equation disappears (Reed, 1982). In this case, the speciation in solution may change drastically. This might have a strong effect on kinetic rate laws. So when a change occurs in the mineral assemblage, one might have to limit the time step to retain accuracy in rate law integration. In addition, for given time step the code check dissolution of a mineral cannot be more than the amount present in the volume, in order to avoid “over-dissolution”.

The solution of the reaction system requires knowing initial total concentrations of basis species j in the equilibrium system (aqueous and mineral) or U_j^0 in Eqs. (D.5a), and the time step Δt_r . Adding kinetic mineral dissolution/precipitation processes does not require additional primary equations, because the reaction rate is a function of the concentrations of the basis species. Once the concentrations of the basis species are obtained, all other secondary variables can be computed in a straightforward manner.

Appendix E: Evaluation of the Jacobian Matrix for Chemical Equations

The structure of the Jacobian matrix Equation (D.8) is:

$$\begin{array}{cc} & \begin{array}{c} N_C \\ N_P \end{array} \\ \begin{array}{c} N_C \\ N_P \end{array} & \begin{array}{cc} \frac{\partial F_j^c}{\partial c_i} & \frac{\partial F_j^c}{\partial p_i} \\ \frac{\partial F_j^p}{\partial c_i} & \frac{\partial F_j^p}{\partial p_i} \end{array} \end{array}$$

Based on Equations (D.3) and (D.5), and by neglecting the derivatives of activity coefficients with respect to the concentration of basis species, the entries of the Jacobian matrix are

$$J^{cc} = \frac{\partial F_j^c}{\partial c_i} = \delta_{ji} + \sum_{k=1}^{N_x} v_{kj} v_{ik} \frac{c_k}{c_i} + \sum_{n=1}^{N_q} v_{nj} v_{ni} \frac{k_n A_n \Omega_n}{c_i} \quad (\text{E.1})$$

$$J^{cp} = \frac{\partial F_j^c}{\partial p_i} = v_{mj} \quad (\text{E.2})$$

$$J^{pc} = \frac{\partial F_j^p}{\partial c_i} = \frac{v_{mj}}{c_i} \quad (\text{E.3})$$

$$J^{pp} = \frac{\partial F_j^p}{\partial p_i} = 0 \quad (\text{E.4})$$

Let J^{cc} , J^{cp} , J^{pc} and J^{pp} be the submatrices expressed in Equations (E.1) through (E.4), then the Jacobian system of equations can be written as

$$\begin{bmatrix} \mathbf{J}^{cc} & \mathbf{J}^{cp} \\ \mathbf{J}^{pc} & \mathbf{J}^{pp} \end{bmatrix} \begin{bmatrix} \Delta \mathbf{c} \\ \Delta \mathbf{p} \end{bmatrix} = \begin{bmatrix} -\mathbf{F}^c \\ -\mathbf{F}^p \end{bmatrix} \quad (\text{E.5})$$

where $-\mathbf{F}^c$ and $-\mathbf{F}^p$ are the residual terms that can be calculated from Equations (D.5) and (D.6), respectively.

Appendix F: Effects of Mineral Precipitation/Dissolution on Hydrologic Properties

F.1. Porosity Change

Porosity changes in matrix and fractures are directly tied to the volume changes as a result of mineral precipitation and dissolution. The molar volumes of minerals created by hydrolysis reactions (i.e., anhydrous phases, such as feldspars, reacting with aqueous fluids to form hydrous minerals such as zeolites or clays) are often larger than those of the primary reactant minerals; therefore, constant molar dissolution-precipitation reactions may lead to porosity reductions. These changes are taken into account in the code as follows:

The porosity of the medium (fracture or matrix) is given by

$$\phi = 1 - \sum_{m=1}^{nm} fr_m - fr_u \quad (\text{F.1})$$

where nm is the number of minerals, fr_m is the volume fraction of mineral m in the rock ($V_{\text{mineral}}/V_{\text{medium}}$, including porosity), and fr_u is the volume fraction of nonreactive rock. As the fr_m of each mineral changes, the porosity is recalculated at each time step. The porosity is not allowed to go below zero.

F.2. Fracture Permeability Change

Fracture permeability changes can be approximated using the porosity change and an assumption of plane parallel fractures of uniform aperture (cubic law; Steefel and Lasaga, 1994). The modified permeability, k , is then given by

$$k = k_i \left(\frac{\phi}{\phi_i} \right)^3 \quad (\text{F.2})$$

where k_i and ϕ_i are the initial permeability and porosity, respectively. This law yields a zero permeability only under the condition of zero fracture porosity.

In most experimental and natural systems, permeability reductions to values near zero occur at porosities significantly greater than zero. This generally is the result of mineral precipitation in the narrower interconnecting apertures. The hydraulic aperture, as calculated from the fracture spacing and permeability (as determined through air-permeability measurements) assuming a cubic law relation, is a closer measure of the smaller apertures in the flow system. Using the hydraulic aperture, a much stronger relationship between permeability and porosity can be developed. This relationship can be approximated as follows:

The initial hydraulic aperture $b_{0,h}$ (m) is calculated using the following cubic law relation:

$$b_{0,h} = [12k_0s]^{1/3} \quad (\text{F.3})$$

where k_0 is the initial fracture permeability (m^2) and s is the fracture spacing (m). The permeability (k') resulting from a change in the hydraulic aperture, is given by

$$k' = \frac{(b_{0,h} + \Delta b)^3}{12s} \quad (\text{F.4})$$

where Δb is the aperture change resulting from mineral precipitation/dissolution.

The aperture change resulting from a calculated volume change can be approximated by assuming precipitation of a uniform layer over the entire geometric surface area of the fracture, assuming also that this area as well as the fracture spacing remains constant. The actual distribution of mineral alteration is much more heterogeneous and depends on many processes that are active at scales much smaller than the resolution of the model; however, the combined effect of the initial heterogeneities and localized precipitation processes can only be treated through model sensitivity studies and experiments.

The initial aperture available for precipitation (b_g , the geometric, rather than the hydraulic, aperture) can be calculated from the ratio of the initial fracture porosity ($\phi_{f,0}$) to the fracture surface area (A_f), as follows:

$$b_g = \phi_{f,0} / A_f \quad (\text{F.5})$$

For a dual permeability model, changes in the fracture porosity are calculated based on the porosity of the fracture medium, so that Δb can be approximated by

$$\Delta b = \frac{(\phi'_{fm} - \phi_{fm,0})}{\phi_{fm,0}} b_g \quad (\text{F.6})$$

Equations (F.3), (F.4), and (F.6) were implemented in TOUGHREACT with input parameters of b_g and s . An example of this type of porosity and permeability relationship is given in Sample problem 4 (Section 8.4: Heat test)

F.3. Matrix Permeability Changes

Matrix permeability changes are calculated from changes in porosity using ratios of permeabilities calculated from the Carman-Kozeny relation (Bear, 1972), and ignoring changes in grain size, tortuosity and specific surface area as follows:

$$k = k_i \frac{(1 - \phi_i)^2}{(1 - \phi)^2} \left(\frac{\phi}{\phi_i} \right)^3 \quad (\text{F.7})$$

The simple cubic law (Eq. F.2) and Kozeny-Carman (Eq. F.7) porosity-permeability equations may not reflect complex relationship of porosity and permeability in geologic media that depends on a interplay of many factors, such as pore size distribution, pore shapes, and connectivity (Verma and Pruess, 1988). Laboratory experiments have shown that modest reductions in porosity from mineral precipitation can cause large reductions in permeability (Vaughan, 1987). Detailed analysis of a large set of field data also indicated a very severe dependence of permeability on small porosity changes (Pape et al., 1999). This is explained by

the convergent-divergent nature of natural pore channels, where pore throats can become clogged by precipitation while disconnected void spaces remain in the pore bodies (Verma and Pruess, 1988). The permeability reduction effects depend not only on the overall reduction of porosity but on details of the pore space geometry and the distribution of precipitate within the pore space. These may be quite different for different media, which makes it difficult to achieve generally applicable predictions. To evaluate the effects of a more sensitive coupling of permeability to porosity, we also implemented an improved porosity-permeability relationship presented by Verma and Pruess (1988)

$$\frac{k}{k_i} = \left(\frac{\phi - \phi_c}{\phi_i - \phi_c} \right)^n \quad (\text{F.8})$$

where ϕ_c is the value of “critical” porosity at which permeability goes to zero, and n is a power law exponent. Parameters ϕ_c and n are medium-dependent. An example of this porosity-permeability relationship is given in Sample problem 8 (Section 8.8: Injection well scaling)

F.4. Effects of Permeability and Porosity Changes on Capillary Pressures

Changing permeability and porosity will likely result in changes in the unsaturated flow properties of the rock. These changes are approximated by modification of the calculated capillary pressure (P_c) using the Leverett scaling relation (Slider, 1976) to obtain a scaled P_c' as follows:

$$P_c' = P_c \sqrt{\frac{k_i \phi}{k \phi_i}} \quad (\text{F.9})$$

Scaled capillary pressures are subject to the maximum capillary pressure prescribed in the capillary pressure function in the ROCKS or RPCAP blocks (see TOUGH2 V.2 users manual).

Appendix G: Mineral Reactive Surface Areas

G.1. Fracture

In the dual permeability method, the porosity of the fracture medium can be taken as 1.0. However, for modeling of mineral dissolution and precipitation, there would then be no rock to dissolve. Because the dissolution rates of many minerals are quite small at temperatures below 100°C, only a small volume of rock adjoining the open space of the fracture needs to be considered as the starting rock fraction. Reactive surface areas of minerals on fracture walls were calculated from the fracture-matrix interface area/volume ratio, the fracture porosity, and the derived mineral volume fractions. These areas can be calculated based on the fracture densities, fracture porosities, and mean fracture diameter. The wall of the fracture is treated as a surface covered by mineral grains having the form of uniform hemispheres. The grain diameter and spatial density are not included in this calculation, so that the area is actually only marginally greater than the fracture geometric surface area. An alternative method to approximating the surface area in excess of the geometric area would be to include a roughness factor. The geometric surface area of the fracture wall can be approximated by:

$$A_r = \frac{\pi A_{f-m}}{2\phi_{f-m}} \quad (\text{G.1})$$

where A_r is the reactive surface area ($\text{m}^2 / \text{m}^3_{\text{fracture medium}}$), A_{f-m} is the fracture-matrix interface area/volume ratio ($\text{m}^2_{\text{fracture}} / \text{m}^3_{\text{fracture+matrix}}$ volume), and ϕ_{f-m} is the fracture porosity of the rock. A_{f-m} is the surface area used as input (in FLOW.INP) to the model simulations as an approximation of the reactive surface area. This model for the fracture surface area considers that the areal coverage is approximately equivalent to the mineral volume fraction. A further modification, which was implemented in TOUGHREACT, relates the 3-D cross-sectional area to the 2-D surface area in the fracture, which yields a factor of 3/2, i.e. an increase of 50 % in the reactive surface area. The reactive surface area of each mineral (in units of $\text{m}^2_{\text{mineral}} / \text{kg}_{\text{water}}$) that is used in geochemical calculations is then given by:

$$A_m (m^2 / kg_{water}) = \frac{A_r f_m}{\rho_w \phi_f} \quad (G.2)$$

where f_m is the volume fraction of the mineral in the mineral assemblage, ρ_w is the density of water (in kg/m^3) and ϕ_f is the porosity of the fracture medium, as opposed to the fracture porosity of the rock. This is the surface area/water mass ratio for a mineral in a liquid-saturated system. To provide the correct rock/water ratio in an unsaturated system, the form of this surface area can be written as:

$$A_m (m^2 / kg_{water}) = \frac{A_r f_m}{\rho_w \phi_f S_w} \quad (G.3)$$

where S_w is the water saturation. However, as S_w goes to zero, the reactive surface area would tend to infinity. Clearly, at a very low liquid saturation, the surface area of the rock contacted by water is likely much smaller than the total area. Two methods have been implemented to address this phenomenon. The first method considers that the surface area contacted by water diminishes proportionately to the saturation. This yields the saturated surface area given by Equation G.1. The second method employs the active-fracture-model concept (Liu et al. 1998) modified to consider water-rock reactions taking place below the residual saturation. The form of the active fracture parameter for reaction is then given by the following set of equations:

$$S_{ar} = (S_w - S_m) / (1 - S_m) \quad (G.4)$$

$$a_{fmr} = S_{ar}^{(1+\gamma)} \quad (G.5)$$

where S_m is the minimum liquid saturation for which water-rock reactions are considered and S_{ar} is the effective saturation for reaction. The active fracture parameter, γ , is obtained from the calibrated hydrological property set. The factor that reduces the surface area contacted by the water phase is given by a_{fmr} . In all simulations S_m is set to the very small saturation of 1×10^{-4} , to ensure that reactions take place until virtually no water is left (e.g., during dryout via ventilation or heating). Finally, the reactive surface area, using this modified form of the active fracture model, is given by:

$$A_m (m^2 / kg_{water}) = \frac{A_r a_{fmr}}{\rho_w \phi_f S_w} \quad (G.6)$$

The surface area calculated in this way is applicable only to reactions taking place in the fracture medium, and is used directly in Equation (B.5) of Appendix B. Note that this area is not the input surface area.

G.2. Matrix (porous medium)

Mineral surface areas in the rock matrix (or porous medium) were calculated using the geometric area of a cubic array of truncated spheres that make up the framework of the rock (Sonnenthal and Ortoleva, 1994). Clay minerals are considered as coatings of plate-like grains. The mineral surface areas of framework grains (truncated spheres) in contact with the open pore space are calculated using an initial grain diameter, followed by successive truncation of the grains in the vertical direction until the porosity of this system is close to the measured porosity of the rock. The abundance of secondary phases (i.e., those that formed as alteration products or low-temperature coatings on the primary assemblage), such as clay minerals, is used to reduce the free surface area of the framework grains. The surface areas of the secondary phases are calculated assuming a tabular morphology. The full details of the geometric calculations are given in Bodvarsson (2001). Note that the surface area calculated by the above method for the matrix is an input parameter in chemical.inp file.

Appendix H: Calculations of Activity Coefficients of Aqueous Species

H.1 Activity Coefficients of Charged Aqueous Species

Activity coefficients of charged aqueous species are computed using an extended Debye-Huckle equation and parameters derived by Helgeson et al. (1981) (HKF). The assumption is made that the dominant cation and anion in solution are sodium and chloride, respectively, so that HKF Equation 298 (Helgeson et al., 1981) can be used directly, as follows:

$$\log(\gamma_j) = -\frac{A_\gamma z_j^2 I^{0.5}}{\Lambda} + \log(1 + 0.0180153m^*) - \left[\omega_j b_{\text{NaCl}} + b_{\text{Na}^+, \text{Cl}^-} - 0.19(|z_j| - 1) \right] I \quad (\text{H.1})$$

and

$$\Lambda = 1 + \text{\AA} B_\gamma \bar{I}^{1/2} \quad (\text{H.2})$$

$$\omega_j = \eta \frac{z_j^2}{r_{e,j}} \quad (\text{H.3})$$

where the subscript j refers to each ion, γ is the activity coefficient of the ion, Debye-Huckle parameters $b_{\text{Na}^+, \text{Cl}^-}$, b_{NaCl} , A_γ and B_γ are given in HKF Tables 1, 29, and 30, Debye-Huckle parameter \AA is calculated as discussed below, z is the ion electric charge, I is taken as the true ionic strength of the solution, ω is the Born coefficient, η is a constant equal to 1.66027 (Å cal/mol), and $r_{e,j}$ is the ion effective ionic radius given in HKF Table 3 or estimated as shown on Table H.1 when not available.

Debye-Huckle parameters $b_{\text{Na}^+, \text{Cl}^-}$, b_{NaCl} , A_γ and B_γ were regressed as a function of temperature and the resulting functions and regression coefficients are currently built into TOUGHREACT. Values of \AA are calculated by TOUGHREACT using effective ionic radius values $r_{e,j}$. Making the assumption that NaCl is the dominant electrolyte, and using the ion charge to determine stoichiometry coefficients, HKF Equation 125 simplifies to (as implemented in models by Reed, 1982):

$$\hat{a}_j = 2 (r_{e,j} + 1.91 |z_j|) / (|z_j| + 1) \text{ for anions} \quad (\text{H.4})$$

$$\hat{a}_j = 2 (r_{e,j} + 1.81 |z_j|) / (|z_j| + 1) \text{ for cations} \quad (\text{H.5})$$

where the subscript j refers to each ion and other parameters are as defined above. The values of 1.91 and 1.81 in the above equations correspond to r_{e,Na^+} and r_{e,Cl^-} , respectively. Values of $r_{e,j}$ are input from the TOUGHREACT database and can be changed as deemed necessary in this database.

Table H.1. Estimated values of effective ionic radii ($r_{e,j}$) currently in the TOUGHREACT thermodynamic database for species that are not reported in HKF Table 3. When available, values from HKF Table 3 are used directly instead of those shown here.

Ion Charge	$r_{e,j}$	Source
-1	1.81	Cl- value
-2	3.00	Rounded average of CO ₃ ⁻⁻ and SO ₄ ⁻⁻ values
-3	4.2	Estimated from straight line fit with charge
+1	2.31	NH ₄ ⁺ value
+2	2.8	Rounded average for +2 species in HKF Table 3
+3	3.6	Rounded average for +3 species in HKF Table 3
+4	4.5	Estimated using HKF Equation ___ and average crystallographic radii of +4 species in CRC Handbook
< -3		Linear Extrapolation (charge × 4.2/3.0)
> +3		Linear Extrapolation (charge × 4.5/4.0)

The limits of applicability of this method depend on how well the assumption of NaCl dominance in solution is respected. Also, consistency between the activity coefficient model and the types of ion pairs included in the thermodynamic database is critical. A good example is that of the NaCl⁰ ion pair. HKF fitted their Debye-Huckle data assuming that no significant formation of NaCl⁰ took place. Excluding this ion pair from the thermodynamic database, the model reproduces fairly well the mean activity coefficients determined by Robinson and Stokes (1965) at 25°C (Figure H.1) up to at least 6M NaCl (ionic strength 6). However, this is not true when

NaCl^0 and the dissociation constants from Shock et al. (1989), for example, are included in the database (at least at 25°C). The reverse is true for species like MgSO_4 and Na_2SO_4 , for which accurate activities cannot be computed without including the MgSO_4 and NaSO_4^- species in the thermodynamic database. In this case, using dissociation constants from Shock et al. (1989) for these species, and the HKF activity coefficient model discussed above, mean activities determined by Robinson and Stokes (1965) at 25°C can be reproduced fairly well up to 2M MgSO_4 (ionic strength 8) and 1M Na_2SO_4 (ionic strength 3) (Figures H.2). Although no general rule can be made as to the limit of applicability of the activity coefficient model, we would not recommend using this model at ionic strengths greater than 3 or 4, especially at higher temperatures.

Figure H.1. Mean-ion activity coefficients of NaCl and CaCl₂ derived from individual activity coefficients calculated with Equation H.1. Symbols represent data from measurements by Robinson and Stokes (1965).

Figure H.2. Activities of MgSO₄ and Na₂SO₄ derived from individual activity coefficients calculated with Equation H.1. Symbols represent data from measurements by Robinson and Stokes (1965). Actual activities, rather than activity coefficients, are compared here because significant ion association takes place.

H.2 Activity of Water

The activity of water is also calculated from equations and parameters given by Helgeson et al. (1981) (HKF). First, a simplification of HKF Equation 190 is used to compute the osmotic coefficient of the solution, Φ , as follows:

$$\Phi = -\frac{2.303}{m^*} \sum_j \left[m_{t,j} \left[\frac{A_\gamma z_j^2 \bar{I}^{0.5} \sigma}{3} + \frac{\log(1 + 0.0180153 m^*)}{0.0180153 m^*} - 0.5 (\omega_j b_{\text{NaCl}} \bar{I}) + (b_{\text{Na}^+, \text{Cl}^-} - 0.19 (|z_j| - 1)) \frac{mchr}{2} \right] \right] \quad (\text{H.6})$$

with

$$\sigma = \frac{3}{a B_\gamma^3} \bar{I}^{3/2} \left[\Lambda - \frac{1}{\Lambda} - 2 \ln(\Lambda) \right]$$

and with

$$\Lambda = 1 + a B_\gamma \bar{I}^{1/2} \quad \text{and} \quad \omega_j = \eta \frac{z_j^2}{r_{e,j}}$$

where the subscript j refers to each charged species in solution, m^* is taken as the sum of the molalities of all species in solution, m_t is the total molality of each charged species, $mchr$ is the sum of the molalities of all charged species, and \bar{I} is taken as the stoichiometric ionic strength. Other parameters are as defined for Equation H.1. The simplifications made in Equation H.6 assume dominance of NaCl in solution, and are essentially the same as the simplifications made to derive Equation H.1. Two differences are the use of the stoichiometric ionic strength instead of the true ionic strength, and the use of $mchr/2$ instead of true ionic strength. These modifications were made because they seemed to reproduce water activity data reported by Stokes and Robinson (1965) better than without these modifications. Once the osmotic coefficient is calculated, the water activity is then given by HKF Equation 126:

$$\ln(a_w) = -\Phi m^* \frac{1}{55.51} \quad (\text{H.7})$$

Examples of calculated and measured water activities at 25°C are shown on Figure H.3.

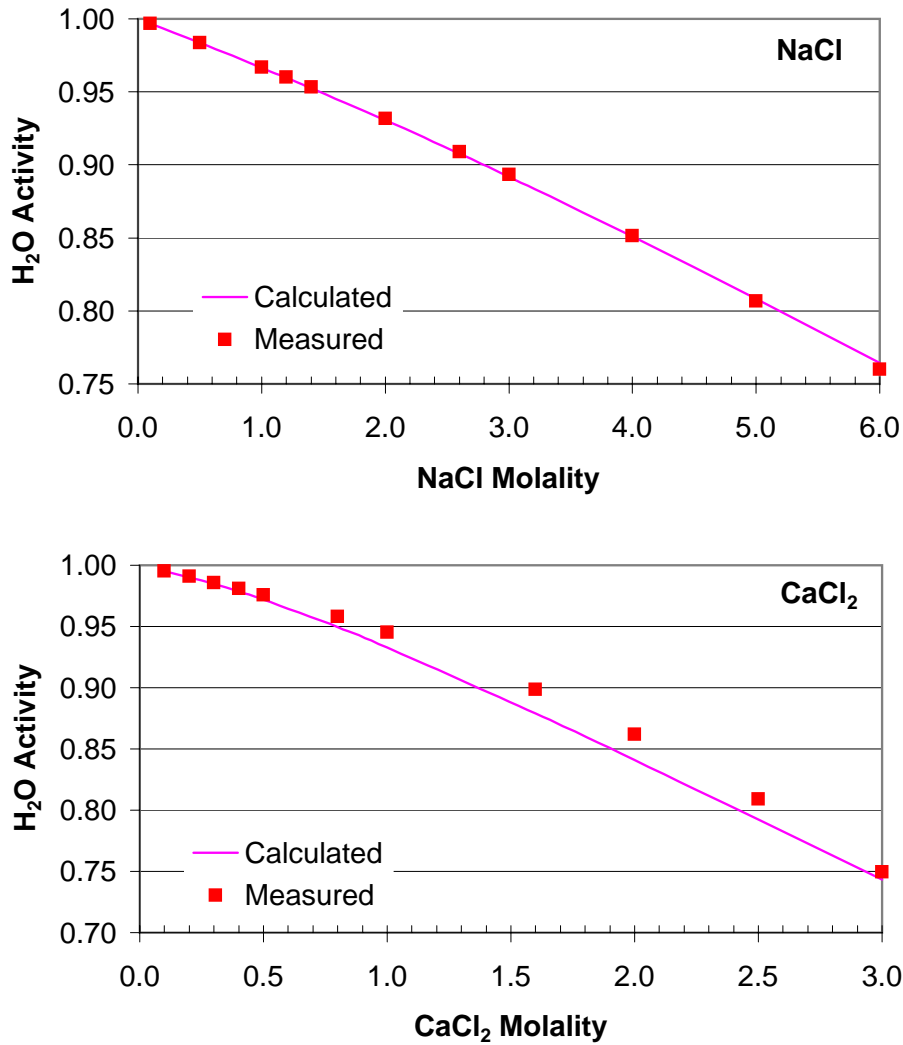

Figure H.3. Activities of water in NaCl and CaCl₂ solutions calculated with Equations H.6 and H.7. Symbols represent data from measurements by Robinson and Stokes (1965). The dashed lines show activities assumed equal to mole fractions.

H.3 Activity Coefficients of Neutral Aqueous Species

For uncharged molecular species such as dissolved gases, weak acids, and organic species, activity coefficients can be computed as (e.g. Langmuir 1997):

$$\log(\gamma_i) = K_i I \quad (\text{H.8})$$

where K_i are salting-out coefficients and I is the true ionic strength of the solution. Currently, values of K_i are assumed independent of temperature. These values are input from the TOUGHREACT thermodynamic database, and default to zero (unit activity coefficients).

Appendix I: Treatment for Mineral Solid Solutions

Currently, the only solid solution model implemented in TOUGHREACT is an ideal solid solution model. This model is only available for minerals that react under kinetic constraints.

The condition of equilibrium for a solid solution is

$$\left(\frac{Q_{ss}}{K_{ss} a_{ss}} \right) = 1 \quad (\text{I.1})$$

where the subscript *ss* refers to the solid solution, and *Q* and *K* are the ion activity product and equilibrium constant for that solid solution, respectively, and *a* is the activity of the solid solution.

By convention, $a_{ss} = 1$.

A similar expression can be written for the condition of equilibrium for each end-member of the solid solution:

$$\left(\frac{Q_i}{K_i a_i} \right) = 1 \quad (\text{I.2})$$

In this case, the subscript *i* refers to each end member, and $a_i \neq 1$.

In the case of an ideal solid solution, the activity of each endmember, a_i , is assumed to equal its mole fraction x_i in the solid solution. Making this assumption and combining Equations (I.1) and (I.2) (with $a_{ss} = 1$) yields:

$$\left(\frac{Q_i}{K_i x_i} \right) = \left(\frac{Q_{ss}}{K_{ss}} \right) \quad (\text{I.3})$$

For a solid solution composed of *n* end-members, Equation (I.3) is consistent with the relation (e.g. Reed, 1982):

$$\left(\frac{Q_{ss}}{K_{ss}}\right) = \sum_{i=1}^n \left(\frac{Q_i}{K_i}\right) \quad (I.4)$$

Alternatively, combining Equations (I.3) and (I.4) yields

$$x_i = \frac{\left(\frac{Q_i}{K_i}\right)}{\sum_{i=1}^n \left(\frac{Q_i}{K_i}\right)} \quad (I.5)$$

For a solid solution reacting under kinetic constraints we can then write a rate law similar to Equation (B.5) in Appendix B.

$$R_{ss} = k_{ss} A_{ss} \left[1 - \left(\frac{Q_{ss}}{K_{ss}}\right) \right] \quad (I.6)$$

where R , A , and k stand for the reaction rate, surface area, and rate constant of the whole solid solution ss . We then make the assumption that

$$k_{ss} A_{ss} = \sum_{i=1}^n (x_i k_i A_i) \quad (I.7)$$

Combining Equations (I.7), (I.6), and (I.3), the following relationship can be derived:

$$R_{ss} = \sum_{i=1}^n [R_i + k_i A_i (x_i - 1)] \quad (I.8)$$

where

$$R_i = k_i A_i \left[1 - \left(\frac{Q_i}{K_i} \right) \right] \quad (\text{I.9})$$

Equation (I.8) is implemented in TOUGHREACT by adding a term equal to $k_i A_i (x_i - 1)$ to the computed rates R_i of each individual mineral assumed to form a solid solution, and using Equation (I.5) to compute x_i . It should be noted, however, that this method is currently valid only for rate expressions without exponents on the affinity term (i.e. with exponents m and n set to 1 in Equation B.5).

Appendix J: Utility Programs for Chemical Database

J.1. Converting EQ3/6 to TOUGHREACT Database

Description

Program DBCONV2 reads the thermodynamic database of EQ3/6 v7.2b (data0.dat), and formats the data for input into TOUGHREACT. The source code (dbconv2.f) is given in the distribution CD (subdirectory: treat/utility-programs/convert-eq36). For the most part, the conversion requires only reformatting of the same data values. However, the program also regresses input equilibrium constant values as a function of temperature in the form: $\log(K)_T = a * \ln(Tk) + b + c*Tk + d/Tk + e/Tk^2$ where Tk is temperature in degrees K. The program also assigns values of effective ionic radii to aqueous species by reading these values in a special input file (rej.dat). Currently, this file contains effective ionic radii from Helgeson, Kirkham and Flowers (1981; AJS, 1249-1516, Table 3). Radii of species for which data listed in rej.dat are computed as a function of ionic charge as shown in Table H.1 in Appendix H.

Input and output files:

The program needs to read in two input files and generates four output files. Samples of two input files are given in the distribution CD (subdirectory: treat/utility-programs/convert-eq36). The names of input and output files are entered interactively when running the program. File contents and default names are as follows:

data0.dat	Main input file - original EQ3/6 thermodynamic database.
rej.dat	Input data file containing effective ionic radii from Helgeson, Kirkham and Flowers (1981, AJS, 1249-1516, Table 3). The species listed in this file must have the same spelling as the species in the input thermodynamic database. If no match is found, rej values are computed based on ionic charge (See Table H.1 in Appendix H).
dbconv2.out	Main output file - converted database (for the file format, see Section 6.4 of this manual).

dump_aux.out	Separate subset of main output file containing converted data for auxiliary species only. To complete the conversion of the database, this file is to be manually inserted in dbconv2.out at the location indicated in that file.
checkfit.out	Print-plot file to visually check the quality of the log(K) regression. A user should always look at this file before using the output data.
checkdat.out	Printout of species for which one or more regressed log(K) value exceeds 0.1 log(K) units (generally, but not necessarily, indicating some problems with the regression).

Range of input parameters:

The input file must have the format of EQ3/6 thermodynamic databases, with the following successive blocks of data. All these blocks are required in the input file and these data blocks must occur in the same order as shown below, otherwise input errors occur:

```

+-----
basis species

+-----
auxiliary species

+-----
aqueous species

+-----
solids species

+-----
gases

+-----
solid solutions

```

The program will work only with input log(K) grids comprising eight values, at the following temperatures: 0, 25, 60, 100, 150, 200, 250, and 300°C. A log(K) value of 500 is interpreted as

“no available data” and regression of $\log(K)$ values is not performed if at least one of $\log(K)$ value is set to 500.

J.2. Switching Basis (Primary) Species

Description

The program (KSWITCH) reads TOUGHREACT thermodynamic database entries and creates another identical set of entries with one of the component species "switched" with a derived species. For example, use KSWITCH to replace Al^{+++} (as a basis species) with new component species such as AlO_2^- . The source code is given in the distribution CD (subdirectory: `treact/utility-programs/switch-basis`).

Input data files and formats

One input file is needed (with default name `thermok.dat`, but any name can be chosen and input interactively). This file contains component species data, reaction stoichiometries and $\log(K)$ data entries that must have the same format as the entries for aqueous species, gases, and minerals in the TOUGHREACT thermodynamic database, including the same structure as the thermodynamic database (with a top record specifying temperature values for the $\log(K)$ data, then component (basis) species, derived species, minerals, and gases separated by records starting with 'null'). The entire thermodynamic database, or a subset of it, can be used as an input file. Also, any number of headers can appear at the top of the file before the temperature header. The remaining input is done interactively with self-explanatory prompts that ask for the names of input and output files, the species to switch (use the exact same spelling as in the input file), and the molecular weight of the switched species. The latter is used only for inclusion in the new component species entry and is not used in calculations. Note that the new component species must always be a derived species that is present in the input file. Also, only one switch is allowed for each run. For multiple switches, run the program more than once, reading the output of each run as input for the following run.

An example of the input file (`eq36O2g`) is given in the distribution CD (subdirectory: `treact/utility-programs/switch-basis`). This file is converted from EQ3/6 database (`data0`) `eq36O2g.dat`. In `eq36O2g.dat`, $\text{O}_2(\text{g})$ is used for component (basis) species of redox reactions.

TOUGHREACT must use $O_2(aq)$ as the basis species. Basis species $O_2(g)$ must be replaced by $O_2(aq)$, in order to use TOUGHREACT. Steps for running the basis switch program are given below.

Run the program using the provided input file eq36O2g.dat. When asked for the name of the component species to replace, type $O_2(g)$, and for the name of the new component species type $O_2(aq)$. One output file will be created (the default is switch.out, in this example eq36o2aq.dat is used) containing the same data as the input file, in the same format, but with switched species and adjusted stoichiometry and $\log(K)$ values and regression coefficients that reflect the switch. The new stoichiometry is then checked visually to be in mass and charge balance. The new $\log(K)$ and regression coefficient values are checked manually for a few derived species, minerals and temperatures. Stoichiometries and $\log(K)$ data for aqueous species, minerals, and/or gases that do not contain one of the switched species will be unchanged, and this can be checked visually.

J.3. Regressing $\log(K)$ Data

Description

Program KREG1 is used to regress $\log(K)$ data in the thermodynamic database of TOUGHREACT as a function of temperature, and to generate records for aqueous species, minerals, and/or gases including the $\log(K)$ regression coefficients formatted for input into this thermodynamic database. The source code is given in the distribution CD (subdirectory: treact/utility-programs/regress-logK).

Input data files and formats

The names of input and output files are entered interactively when running the program. One input file (default name: kreg.dat) is required, containing: the first record identical to the first record of the thermodynamic database indicates the temperatures for which $\log(K)$ data are given, followed by records identical to those in the thermodynamic database for derived aqueous species, minerals, and/or gases. (3 records per entry: the first for stoichiometry, second for individual $\log(K)$ values, and the third for regression coefficients. The regression coefficients can be left blank, but the name of the species, mineral, or gas preceding the regression coefficients

must be present). The entire thermodynamic database, with component species removed, can also be used as an input file.

J.4. Checking Mass and Charge Balances

Description

Program THERMOCHK1 reads the thermodynamic database of TOUGHREACT and checks the mass and charge balances of all reactions entered in that database. It does so by adding the molecular weights multiplied by stoichiometric coefficients (mass balance) and adding ionic charges multiplied by stoichiometric coefficients (charge balance) of each specified reaction. The program then flags non-zero charge balances and mass balances greater than 5×10^{-5} times the molecular weight of the species/mineral/gas to which the reaction pertains. The source code is given in the distribution CD (subdirectory: treat/utility-programs/check-balance).

Input data files and formats

The program needs to read in two input files and generates two output files. The names of input and output files are entered interactively when running the program. File contents and default names are as follows:

thermok.dat (default)	Main input file (TOUGHREACT database to check)
molwt_aq.dat	Input file with molecular weights of aqueous species, used only if this information is not already provided in the thermok.dat input file (i.e., as in earlier versions of the database).
thermochk.out	Output file listing charge and mass balances for all reactions.
error.out	Output file listing only those species, minerals, and gases for which reactions have non-zero charge balances and mass balances exceeding 5×10^{-5} times the molecular weight of the species, mineral, or gas in question.

 Sink (reaction) 6, 18, 19, 20, 158, 160
 Solubility 62, 88
 Solver (linear) 18
 Solution method 9, 158, 164
 Solid solution 26, 66, 185
 Source (see Sink)
 SNIA (sequential non-iterative approach)
 11, 12
 Speciation data 14
 Species
 Primary (basis) 6, 19, 24, 25, 29, 31,
 32, 38, 40, 148
 Secondary (derived) 6, 27, 41, 148,
 152
 Stability condition 12
 Supergene copper 100
 Supersaturation window 28, 152
 Surface area (see Reactive surface area)

T

Temperature 5, 7, 13, 14, 15, 27, 28, 31, 40,
41, 147, 149, 152, 154
Templates 2, 48
Thermodynamic
state variables 11
database 13, 40
Thermophysical properties 8, 112
Tiwi geothermal field 119
Time
automatic 11
discretization 11, 161
stepping 11
Tortuosity 20, 147, 158, 172
Total dissolved concentration 6, 146
TOUGH2 V2 1, 2, 13, 15, 18, 45
Tracer 8, 49, 147

U

Units 21
Upstream weighting 20, 49, 159
Utility programs 188

V

Vadose zone 2
van Genuchten 78, 91
Vapor pressure lowering 2, 73
Variables
primary (see Primary variables)
secondary 167
Verma-Pruess 36, 121, 172, 173
Viscosity 5, 8, 111, 147
Void space 173
Volume elements (see also Grid blocks) 13,
19, 25, 29, 148, 172

W

Weighting
Parameter 20
time 20, 159
upstream (see Upstream weighting)
Well
field 91
radius 128

Writing control variable 21, 51

X

X- 55

Y

Yucca Mountain 4, 17, 61, 73

Z

Zones (initial)

cation exchange 13, 16, 50
gas 13, 16, 50
linear Kd 13, 16, 50
mineral 13, 16, 50
porosity-permeability 34, 35
water 39, 49, 51 55
