The Dissertation of Joanna Irene Rosa Camba-Colón is approved:

Committee Chairperson

University of California, Riverside

Acknowledgements:

This is the culmination of a very long and arduous journey. There are many people who have helped me along the way. I would like to thank my P.I. Dr. Frances Sladek for giving me a chance at pursuing a PhD. She has patiently given me the support, financial and otherwise, that were necessary in order to complete this process. I would also like to thank the other members of my committee, Dr. Dan Straus and Dr. Ameae Walker, whose thoughtful insights and suggestions helped shape my PhD experience. Thank you too to all the professors and administrators that have provided me guidance and mentorship. Special thanks go out to the Sladek lab members, past and present, whose camaraderie and support I will always cherish. Finally, I would like to thank my husband, Nicholas, and my children, Alexandria, Cameron, and Katrina for believing in me and for providing a support and a loving home outside of the lab.

Dedication:

This work is dedicated to my husband, Nicholas, and children, Alexandria, Cameron, and Katrina, who continue to inspire me every day. This work is also dedicated to my mother, Evelyn A. Camba, whose early demise made me realize how precious our time is with our friends and loved ones.

ABSTRACT OF THE DISSERTATION

Role of the Maternal Liver in Lactating Mice

by

Joanna Irene Rosa Camba-Colón

Doctor of Philosophy,
Graduate Program in Cell, Molecular, and Developmental Biology
University of California, Riverside, March 2010
Dr. Frances M. Sladek, Chairperson

Lactation brings about numerous maternal physiological and metabolic changes in order to sustain viable offspring. The liver plays a role in meeting the high energetic and metabolic needs of lactation as it is a key player in various biological processes that include lipid metabolism and homeostasis. A growing body of evidence suggests that the metabolic and physiological changes that lactation brings to the nursing mother results in a maternal profile that lowers the incidence of metabolic diseases. In this study, we examine *in vivo* and gene expression profiling data of fasted, age-matched virgin (V), non-lactating (NL), and lactating (L) C57Bl/6 mice in an attempt to understand the role the maternal liver plays in lactation in a global context. Our model allows us to examine the long term effects of lactation, since both the lactating and non-lactating mice have previously nursed pups. *In vivo*

results highlight maternal adaptations to lactation that include rapid weight loss, increased liver weight, increased plasma triglyceride levels, and decreased hepatic triglyceride storage. Gene expression profiling reveals molecular signatures of different classes of genes that may explain the resulting maternal adaptations to lactation. Our model suggests a highly metabolically active liver that plays a role in supplying the energy that the lactating mammary gland needs, by synthesizing triglycerides and secreting them into the blood stream, thus making them available to the lactating mammary gland.

Chapter 1:

Introduction

Chapter 1: Introduction

Background: Pregnancy and Lactation

The ultimate goal of reproduction is the survival of off-spring that are reproductively viable (Hurley ; Buhimschi 2004) . The processes involved, pregnancy and lactation, are closely linked. Pregnancy provides a safe, warm, and sterile environment that promotes the growth and development of the fetus in utero. Lactation is an adaptation that allows the mother to continue the maternal-fetal metabolic relationship that was established and nurtured throughout pregnancy outside of the womb. Lactation includes breast development (mammogenesis) which occurs during pregnancy; milk synthesis and secretion (lactogenesis 1 and 2) which starts at mid-pregnancy (lactogenesis 1) and is triggered at parturition (lactogenesis 2); and the maintenance of milk production (galactopoiesis) which occurs due to suckling by the baby (Hartmann et al. 1996). Not only do mammogenesis and lactogenesis coincide with pregnancy, but the hormones that regulate pregnancy regulate lactation as well (Hadley 1996).

Studies have shown that lactation benefits infants in various ways: providing protection against infection (Cochi et al. 1986; Pabst and Spady 1990; Alho et al. 1990; Lucas and Cole 1990; Lerman, Slepon, and Cohen 1994; Holberg et al. 1991), illnesses and morbidity (Koutras and Vigorita 1989; Wright et al. 1989); promoting infant survival (Habicht, DaVanzo, and Butz 1986); providing protection against allergies (Chandra, Puri, and Hamed 1989; Merrett et al. 1988); enhancing development and intelligence (Lucas et al. 1992; Morrow-Tlucak, Haude, and

Ernhart 1988); decreasing risk factors for diseases such as diabetes mellitus (Samuelsson, Johansson, and Ludvigsson 1993; Mayer et al. 1988), childhood cancer (Shu et al. 1999; Davis, Savitz, and Graubard 1988), Hodgkin's disease (Schwartzbaum et al. 1991), and juvenile rheumatoid arthritis (Mason et al. 1995), to name a few. As an added bonus, lactation provides benefits for mothers as well: delays fertility (Diaz 1983; Shirkie 1982), decreases the risk for cancers (McTiernan and Thomas 1986; Schneider 1987; Newcomb and Trentham-Dietz 2000), ameliorates gestational diabetes (Davies et al. 1989), and promotes postpartum weight loss (Kramer et al. 1993). Successful reproduction, therefore, requires successful lactation which is vital to the growth, development, and survival of mammals (Holman and Grimes 2003; Buhimschi 2004).

Pregnancy and lactation bring about many physiological and metabolic changes due to the increasing nutrient demands of the growing fetus (Beers and Berkow 1999). Increasing levels of estrogen and progesterone, along with the metabolic demands of the fetus, placenta, and uterus, bring on early changes in pregnancy (Ciliberto and Marx 1998). Those changes include glucose and lipid metabolism (Samsioe and Gustafson 1975), blood chemistries (Knopp et al. 1985; Chiang A-N et al. 1995), blood volume (Beers and Berkow 1999), metabolite excretion (Scott, Chakraborty, and Marks 1986), serum protein levels (Dube et al. 1977), cardiac output (Everson 1998), biliary lipid metabolism and gall bladder function (Everson et al. 1982; Kern et al. 1981). Starting at mid-pregnancy, changes in the mother brought on by pregnancy are anatomical in nature (Ciliberto and Marx 1998) and

are due to the growth/expansion of the fetus, placenta, uterus, and mammary glands (Allen 2002). The net results are effects on the cardiovascular, urinary, respiratory, gastrointestinal, and hepatobiliary systems (Ciliberto and Marx 1998). The high metabolic rate of the lactating breast demands much higher nutrient requirements for the mother compared to her pregnant nutrient requirements (Hartmann et al. 1996; Allen 2002). Besides providing the nutritional and immunological needs of the infant, lactation also provides the emotional support and connection that are also needed for the survival of the newborn (Holman and Grimes 2003).

The Role of Hormones During Pregnancy and Lactation: Progesterone, Estrogen, Prolactin, and Growth Hormone

Hormones play an important role in orchestrating pregnancy and lactation. The levels of hormones, however, differ between species. In humans, progesterone prepares the endometrium for implantation (Itskovitz and Hodgen 1988; Okada et al. 2003), plays some role in maternal immune tolerance of the fetus (Okada et al. 2003; Siiteri et al. 1977; Stites and Siiteri 1983; Szekeres-Bartho 2002), and prepares the breasts for lactation by increasing ductal branching (Fuchs 1986; Soares and Talamantes 1982). Progesterone levels increase throughout pregnancy and antagonize uterine smooth muscle contractions, contributing the maintenance of the pregnancy (Pepe and Albrecht 1995; Hadley 1996). Lower levels of progesterone at term allows parturition and signal the end of pregnancy (Hadley 1996). In the mice and rats, however, the estrous cycle is brief. In order for

pregnancy to occur, progesterone is needed to produce a pseudopregnancy, and then move on to pregnancy.

Another important hormone in pregnancy is estrogen. Placental estrogen increases throughout gestation (Oakey 1970). Estrogen plays a major role in the increased biosynthesis of progesterone (Pepe and Albrecht 1995). It also contributes to the circulatory changes that occur during pregnancy (Perrot-Applanat 1999), neovascularization (angiogenesis) of the fetus (Pepe and Albrecht 1995; Cullinan-Bove and Koos 1993; Presta 1988), and increases ductal elongation in the breasts, thereby contributing to breast development for lactation (Pepe and Albrecht 1995). In addition, rising estrogen levels toward the end of pregnancy enhance uterine excitability which causes a cascade of events that lead to the initiation of parturition.

In addition to progesterone and estrogen, a third hormone also plays a pivotal role in breast development and lactation - - prolactin (PRL) (Freeman et al. 2000; Naylor et al. 2005). PRL belongs to the prolactin/growth hormone/placental lactogen family (Horseman and Yu-Lee 1994). PRL affects mammogenesis (mammary gland development) where it is absolutely required for the development of secretory alveoli, lactogenesis (milk synthesis), and galactopoiesis (milk secretion maintenance) (Freeman et al. 2000). The initial step in PRL action is binding to a specific membrane-bound receptor, prolactin receptor (PRLR) (Bole-Feysot et al. 1998).

PRL concentrations increase as gestation progresses due to the influence of increasing concentrations of estrogen on pituitary PRL production (Hadley 1996) in humans. In mice, however, prolactin levels are low during mid-pregnancy, which are then increased by gestation day 18 (Swartz, Ogren, and Talamantes 1986). In humans, progesterone increases PRL levels by reducing hypothalamic dopamine, an inhibitor of PRL gene expression (Rakoff and Yen 1978; Sprangers, Brenner, and Bethea 1989). Meanwhile, estrogen and progesterone levels decrease dramatically at parturition while increased concentrations of PRL are maintained (Allen 2002). This rapid decrease of progesterone in addition to high plasma concentrations of PRL trigger lactogenesis (Kuhn 1969; Buhimschi 2004). In rats, progesterone levels decrease during the last days of pregnancy, while estrogen and progesterone levels increase right before parturition. Studies have also shown that suckling is an important stimulus for prolactin release which affects the maintenance of lactation once it has been established (galactopoiesis) (Howie et al. 1980; Delvoeye, Demaegd, and Delogne-Desnoeck 1977).

A fourth hormone that plays a role in pregnancy and lactation is growth hormone (GH) (Hull and Harvey 2002). GH also belongs to the prolactin/growth hormone/placental lactogen family. It is activated by ligand binding to growth hormone receptor (Goffin and Kelly 1997). There is a progressive increase in circulating GH in rodents during the second half of pregnancy (Kishi, Hirashiba, and Hasegawa 1991), which then declines right before parturition. The rise in GH during pregnancy may be caused by rising levels in estrogen (Jahn, Rastrilla, and

Deis 1993) and placental lactogens (Kishi, Hirashiba, and Hasegawa 1991). In rats, circulating GH levels rise during parturition and remain elevated for several days afterward (Carlsson, Eden, and Jansson 1990). Circulating levels of GH are also increased during lactation (Etherton and Bauman 1998). Several studies have shown that circulating GH levels are increased with suckling (Wehrenberg and Gaillard 1989; Rushen, Foxcroft, and De Passille 1993; Schams et al. 1994). The increased levels of circulating GH promotes mammary development and milk production (Hull and Harvey 2001). In rats, prolactin promotes mammary gland development and milk production.

Pregnancy, Lactation, and Disease

The demands of pregnancy on the mother makes her organs work harder. As a result, gestational syndromes may develop when the organ system cannot meet the increased demands of the pregnancy. Some researchers have suggested that by unmasking less than optimal organ systems, pregnancy can act as a maternal stress test and predict a woman's health in later life (Williams 2003). For example, pregnancy can temporarily trigger metabolic conditions that can exacerbate pre-existing undiagnosed conditions and trigger diseases that can re-emerge later in life as the woman ages (Williams 2003; Sattar and Greer 2002; Seely and Solomon 2003). Some of the diseases include insulin resistance and hypertension (pre-eclampsia) (Redman, Sacks, and Sargent 1999; Sibai, Sarinoglu, and Mercer 1992; von Dadelszen, Magee, and Roberts 2003), cardiovascular disease (Bosio et al. 1999;

Martin et al. 1999), hypercoagulation leading to thrombosis (Greer 1999; van Walraven et al. 2003), and diabetes mellitus (Kuhl 1991). Liver ailments that can develop during pregnancy and then lead to serious liver disease include haemolysis elevated liver enzymes, and low platelets (HELLP) syndrome and acute fatty liver of pregnancy (AFLP) (Rahman and Wendon 2002). If either of these conditions is left untreated, it can be fatal.

Recently, there has been great concern about the growing number of people that may develop metabolic syndrome. Metabolic syndrome includes risk factors that increase the chances of developing cardiovascular disease and type 2 diabetes (Love-Gregory et al. 2008; Klein, Klein, and Lee 2002; Malik et al. 2004). Such risk factors include visceral obesity, insulin resistance, diabetes, hypertension, and dyslipidemia (Chan, Barrett, and Watts 2004; Ginsberg and Stalenhoef 2003). Some of the metabolic changes that occur with pregnancy may put the mother at risk for metabolic syndrome. For example, the weight gain that accompanies pregnancy may lead to obesity and increase the chances of developing metabolic syndrome after pregnancy (Gunderson et al. 2009; Jain et al. 2007; Davis and Olson 2009). In addition, the development of gestational diabetes may also increase the risk for developing maternal metabolic syndrome (Pirkola et al. 2009; Retnakaran 2009).

On the other side of this equation, there is a growing body of evidence that shows an inverse relationship between lactation and metabolic syndrome (Gunderson et al. 2007). This may be due to the metabolic changes that occur with lactation. For example, nursing women were found to have lower risk for type 2 diabetes (Stuebe

et al. 2005) and cardiovascular disease (Kallio et al. 1992). Other studies suggest that this maternal health benefit against metabolic syndrome may also have long term effects (Ram et al. 2008; Schwarz et al. 2009; Gunderson 2008).

The Liver

The liver is the largest and most metabolically complex organ in humans (Schiff, Sorrell, and Maddrey 2003; Sherlock and Dooley 2002; Worman 1999; Zakim and Boyer 2003; Samson ; Worobetz et al. ; www.siemed.edu/~dking2/erg/liver.htm 2002). The liver plays an important role in glucose homeostasis. The liver stabilizes glucose levels by glycogenesis (the formation of glycogen from glucose), glycogenolysis (the formation of glucose from glycogen), and gluconeogenesis (the formation of glucose from certain amino acids, lactate, or glycerol). The liver also synthesizes plasma proteins including albumins and globulins such as fibrinogen, prothrombin II, blood coagulation factors V, VII, IX, and X. In addition, the liver breaks down amino acids to urea, and in the process detoxifies ammonia. The liver takes up fatty acids and converts these into triglycerides which it then packages with cholesterol, phospholipids and apoprotein into lipoproteins. The liver also synthesizes cholesterol. Bile salts are a product of cholesterol catabolism which also occurs in the liver.

Role of the Liver During Pregnancy and Lactation

The liver plays an important role during pregnancy and lactation (Bauman 2000; Bell and Bauman 1997; Herath et al. 2004). It provides for the metabolic needs of

the mother and fetus and acts as a detoxification center for both. Nonetheless, despite the critical role of the liver in these important physiological processes, there are no published studies about the role of liver enriched transcription factors (LETF), such as HNF4 α , during pregnancy or lactation. HNF4 α has been directly linked to diseases such as Maturity Onset Diabetes of the Young 1 (MODY 1) and hemophilia (Ryffel 2001; Sladek and Seidel 2001; Yamagata et al. 1996; Gupta and Kaestner 2004). HNF4 α regulates glucose metabolism in the liver as well as the expression of blood coagulation factors VII-X; both are critical to pregnancy, as mentioned above. Other target genes for HNF4 α are the apolipoproteins Apo A1; Apo A2; Apo A4; Apo B; Apo C1; and Apo C3, the protein components of high density lipoprotein (HDL, Apo A1), low density lipoprotein (LDL, Apo B), which transport cholesterol and triglycerides throughout the body. Studies have shown that hyperlipidemia, an increase in triglycerides and cholesterol, is common in pregnancy (Chiang A-N et al. 1995). Levels of HDL and LDL cholesterol and triglycerides are important in gestational diabetes and in cardiovascular disease. Low levels of HDL, high levels of LDL, and high levels of triglycerides indicative of cardiovascular disease (Cekmen et al. 2003). In addition, HNF4 α activates the expression of many cytochrome P450 genes that carry out steroid, drug, and xenobiotic metabolism important in detoxification (Sladek and Seidel 2001). There could also be a role for HNF4 α in the kidney during pregnancy since it, along with hypoxia inducible factor (HIF), up regulates the erythropoietin (*EPO*) gene whose product stimulates the red blood cell production required for the increased blood

volume that occurs during pregnancy (Samsioe and Gustafson 1975; Zhu, Jackson, and Bunn 2002). Lactation, as mentioned earlier, imposes heavy demands on the mother, especially the liver (Widdowson 1976; Bauman 2000). HNF4 α may also have links to prolactin (PRL), an important hormone of lactation, since it is a positive regulator of the prolactin receptor (*PRLR*) gene (Moldrup et al. 1996). Given that HNF4 α increases expression of the *PRLR*, and lactation has been shown to provide beneficial effects on glucose and lipid metabolism in women with gestational diabetes (Kjos et al. 1993; Davies et al. 1989), it is not unreasonable to propose that HNF4 α may play a role in pregnancy and lactation.

Role of the maternal liver in lactation?

The purpose of this study is to globally characterize the changes that occur in the maternal liver with lactation. We hypothesize that the demands of lactation cause differential expression of genes in the liver. We will utilize bioinformatics in order to tease out molecular signatures of differentially up regulated and down regulated genes as a result of lactation and connect them with maternal adaptations that occur in order to meet the demands of the lactating mammary gland and the suckling pups. At the same time, we will also be looking at liver enriched transcription factors, such as HNF4 α , and the role they might play in lactation.

HNF4 α is a Member of the Nuclear Receptor Superfamily

Background on Nuclear Receptors

Nuclear receptors (NR) are ligand-activated transcription factors involved in diverse biological and physiological functions such as reproduction, differentiation, development, metabolism, metamorphosis, and homeostasis (Escriva, Delaunay, and Laudet 2000). They are also therapeutic targets for human diseases such as cancer, obesity, diabetes, and heart disease (Gronemeyer, Gustafsson, and Laudet 2004; Nettles and Greene 2005; Sladek 2003). These nuclear receptors constitute a superfamily whose members share a highly conserved DNA binding domain (DBD) as well as a hydrophobic ligand binding domain (LBD). The DBD contains two zinc fingers and binds specific DNA sequences known as hormone response elements (HRE). Nuclear receptors bind DNA as heterodimers, homodimers, or monomers (Mangelsdorf and Evans 1995).

There are several groups of receptors within this superfamily based on protein dimerization, the structure of the cognate DNA binding site, and intracellular localization (Jiang et al. 1995) (Fig. 1.1). Group I receptors are bound to heat shock proteins (HSP) in the cytoplasm or in the nucleus in the absence of a ligand. In the presence of a ligand, the receptors are disassociated from the HSP and are translocated to the nucleus, form predominantly homodimers and bind DNA elements composed of direct repeats. Examples of Group I receptors are: the steroid hormone receptors, glucocorticoid receptor (GR), estrogen receptor (ER), and progesterone receptor (PR). Group II receptors exist primarily in the nucleus

and bind DNA either as monomers, homodimers, or heterodimers. They have a preference to form heterodimers on DNA, particularly with RXR α . They bind DNA elements composed of direct repeats, with the exception of certain thyroid hormone response elements, which are indirect repeats. Examples of Group II receptors are retinoid acid receptor (RAR), retinoid X receptor (RXR), vitamin D receptor (VDR), and peroxisome proliferators-activated receptor (PPAR). Group III receptors exist as monomers in solution and are found in both the nucleus and the cytoplasm. They bind extended half-sites as monomers, although at least two members (NGFI-B and NURR1) also form heterodimers with RXR α . Examples of Group III receptors are NGFI-B, FTZ-F1, steroidogenic factor 1 (SF-1), ROR α 1, and NURR1. Finally, Group IV has the following characteristics: it is similar to Group II in terms of its amino acid sequence, preference for direct repeat (DR) binding sites, and nuclear localization. It is also similar to Group I receptors: it exists in solution as a stable homodimer and binds DNA exclusively as a homodimer. However, it is not complexed with HSP in the absence of a ligand. Currently, Group IV has one member, HNF4.

Figure 1.1: The nuclear receptor superfamily
 Members of the nuclear receptor superfamily can be grouped into several classes based on their ligand-binding, dimerization, and DNA-binding properties. Shown are different classes and representative receptors for each group. Nuclear Receptors as Transcription Factors: Structure, Function, Mechanism of Transactivation

Structure and Function

As transcription factors, nuclear receptors control the expression of genes spatially and temporally in response to a wide range of developmental, physiological, and environmental cues. In order to understand how nuclear receptors work, one must take a closer look at their structure (Fig.1.2). Nuclear receptors have several domains (Mangelsdorf and Evans 1995; Mangelsdorf et al. 1995; Escriva, Delaunay, and Laudet 2000; Schrem, Klempnauer, and Borlak 2002; Robinson-Rechavi, Escriva Garcia, and Laudet 2003; Germain et al. 2003;

Giguere 1999). These domains are: the A/B domain with ligand-independent activation function, the DNA binding domain (DBD), the hinge domain, the ligand binding domain (LBD), and the C-terminal domain.

The N-terminal or A/B domain is the least conserved and is highly variable in terms of length and primary sequence. The A/B domain typically contains an activation function (AF-1) that mediates ligand-independent transactivation. The A/B region can activate transcription constitutively when linked to a heterologous, DBD, (e.g., the Gal 4 DBD)(Germain et al. 2003). It can interact directly with steroid receptor coactivators (SRCs) to enhance the activity of the receptor complex (Giguere 1999; Onate et al. 1998). It is subject to alternative splicing and differential promoter usage, and to posttranslational events such as phosphorylation (Germain et al. 2003). The AF-1 displays cell, DNA binding domain (DBD), and promoter specificity.

The DNA-binding domain (DBD) is the most highly conserved region (Robinson-Rechavi, Escriva Garcia, and Laudet 2003; Germain et al. 2003; Giguere 1999; Escriva, Delaunay, and Laudet 2000; Glass 1994). It contains two zinc fingers encoded by 66 to 70 amino acid residues and a carboxy-terminal extension (CTE) that spans ~ 25 residues (Giguere 1999). The CTE provides a protein-DNA interface and a protein-protein interface (Rastinejad, Evilia, and Lu 1995; Zhao et al. 1998). The DBD contains several sequence elements: P (proximal), D (distal), T, and A boxes. These sequence elements contribute to response element specificity and dimerization. In addition, these sequence

elements make contact with the DNA backbone and residues flanking the DNA core recognition sequence.

The hinge region is variable in terms of length and primary sequence. It is located between the DBD and the LBD and serves as a “hinge” between these two domains. The hinge region is very flexible, allowing the DBD and LBD to adopt several different conformations without creating steric hindrance. It allows the DBD to rotate 180° so that some receptors bind as dimers to both direct and inverted HREs (Glass 1994). Studies have shown that the hinge region may serve as a docking site for corepressor proteins (Horlein et al. 1995; Chen and Evans 1995). In addition, the hinge region contains the nuclear localization signal (NLS) (Ylikomi et al. 1992; Germain et al. 2003; Robinson-Rechavi, Escriva Garcia, and Laudet 2003).

The ligand binding domain (LBD) is the largest domain and is moderately conserved (Escriva, Delaunay, and Laudet 2000; Robinson-Rechavi, Escriva Garcia, and Laudet 2003; Germain et al. 2003; Giguere 1999). It is highly structured with a variable primary sequence and a conserved secondary structure of 12 helices. The LBD is a multifunctional domain that mediates ligand binding, dimerization, interaction with heat shock proteins, nuclear localization, transactivation functions, and repression. A highly conserved helix (helix 12 or AF-2) is found at the carboxy terminal end of the LBD. The AF-2 is responsible for ligand-dependent transactivation by recruiting coactivators.

The C-terminus or F-domain has little evolutionary conservation (Germain, Altucci, and al. 2003) . Although its function is unknown, studies have shown that it might play a role in coactivator recruitment to the LBD (E domain) and in determining the specificity of the LBD coactivator interface (Germain et al. 2003; Peters and Khan 1999; Sladek et al. 1999). It has been suggested that, because this domain may affect antagonist action, it fine-tunes the molecular events associated with the transcriptional properties of the LBD (Germain et al. 2003; Montano et al. 1995; Nichols, Rientjes, and Stewart 1998).

Fig 1.2 : Structure of a typical nuclear receptor
Nuclear receptors have the following domains from left to right: the least conserve N-terminal or A/B domain; the highly conserved DNA binding domain (DBD) or C domain; the variable hinge-region or D domain; the moderately conserved ligand binding domain (LBD) or E-domain; and the variable C-terminal domain or F-domain. Journal of Biological Chemistry. 2001; 276(40):36863-36864. © the American Society for Biochemistry and Molecular Biology

Mechanism of Transactivation

Nuclear receptors act in three steps: repression, derepression, and transcription activation (Robinson-Rechavi, Escriva Garcia, and Laudet 2003; Giguere 1999) (Fig. 1.3) (Bastien and Rochette-Egly 2004). Chromatin structure plays an important role in gene activation at all three stages (Schrem,

Klempnauer, and Borlak 2002; Wolffe 1997). Chromatin displays basal levels of histone acetylation and transcription in the absence of a receptor. In the absence of a ligand, many nuclear receptors are transcriptional silencers (Chen and Evans 1995; Baniahmad, Kohne, and Renkawitz 1992). Apo receptors (unliganded receptors) recruit a co-repressor complex with histone deacetylase activity (HDAC) to keep the chromatin in a repressed state (Nagy et al. 1997; Heinzl et al. 1997; Wong et al. 1998). Ligand-binding leads to a conformational change in the LBD, in which helix 12 (AF-2) changes position. (Brzozowski et al. 1997; Wagner et al. 1995). The repressor complex dissociates from the receptor and the receptor is then free to interact with coactivator complexes which include p300/CBP and p/CAF (p300/CBP-associated factor), both of which have been shown to possess histone acetylase activity (HAT). This results in chromatin decondensation and derepression (Ogryzko et al. 1996; Lanz et al. 1999; Robinson-Rechavi, Escriva Garcia, and Laudet 2003). Although a permissive chromatin environment is required for efficient gene expression (Schrem, Klempnauer, and Borlak 2002), it alone is not sufficient for transcriptional activation. In addition to chromatin modulation, interactions between nuclear receptors and the general transcription machinery are required to regulate gene expression (Wong, Shi, and Wolffe 1997) Transcription occurs as a result of the dissociation of the HAT complex and the assembly and recruitment of a second coactivator complex (TRAP/DRIP/ARC/ often referred

to as the mediator complex) which then makes contact with the basal transcription machinery(Rachez and Freedman 2001).

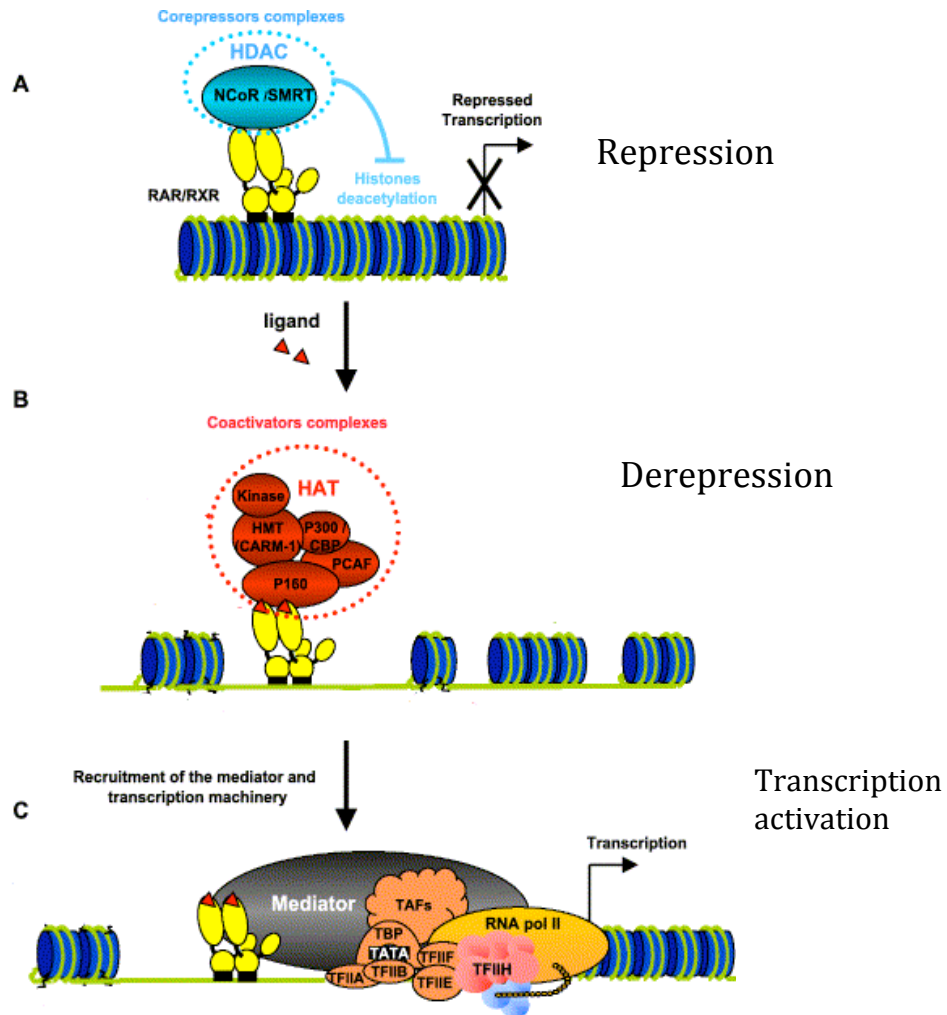

Figure 1.3: Mechanism of Nuclear Receptors

Nuclear receptors act in three major steps: repression, depression, and transcription activation.

A: Apo-receptors recruit a co-repressor complex with histone deacetylase activity (HDAC) to keep chromatin condensed (repression).

B: Upon ligand-binding, the co-repressor complex dissociates from the receptor allowing it to associate with co-activator complexes with histone acetylase activity (HAT) and results in chromatin decondensation (derepression).

C: Dissociation of HAT complex and recruitment of a second co-activator complex (mediator) which makes contact with the basal transcription machinery and ultimately results in transcription.

Background

As reviewed by Sladek, FM (Sladek and Seidel 2001; Bolotin, Schnabl, and Sladek 2009), HNF4 (NR2A1) was originally detected as an activity in crude liver nuclear extracts that bound DNA elements required for the transcription of transthyretin (TTR) and apolipoprotein C3 (ApoC3), two liver-specific genes (Costa, Grayson, and Darnell 1989). Subsequent purification and cloning of HNF4 indicated that it was a member of the nuclear receptor superfamily because it exhibited a high degree of sequence similarity to the DBD and LBD of other nuclear receptors (Sladek et al. 1990). Its amino acid sequence is most similar to that of the retinoid X alpha receptor (RXR α), to the chick ovalbumin upstream promoter-transcription factor (COUP-TF) I and apolipoprotein regulatory protein-1 (ARP-1). HNF4 is highly conserved and has been cloned from rat, human, mouse, frog, bovine, chimp, and other species. The original HNF4 gene was renamed HNF4 alpha (HNF4 α) when two other related genes were cloned from *Xenopus*—HNF4 β and HNF4 γ . There are two HNF4 genes in human and mouse—HNF4 α and HNF4 γ . HNF4 α was originally described as a liver specific transcription factor, and highly expressed in the liver. In addition, it is expressed in the kidney, intestine, pancreas, stomach, and colon in mammals, and also in functionally equivalent organs in invertebrates such as the fat body, malpighian tubules, and gut, respectively.

HNF4 α plays an important role in the regulation of hundreds of genes involved in numerous metabolic pathways including glucose, fatty acid, cholesterol, and xenobiotic drug metabolism (Odom et al. 2004; Waxman and Holloway 2009; Gupta and Kaestner 2004; Bolotin et al. 2009). It is one of several transcription factors essential for liver-specific gene expression. Since HNF4 α controls the expression of another transcription factor important in the regulation of several hepatic genes (HNF1), HNF4 α establishes a transcriptional hierarchy (Miura and Tanaka 1993; Kuo et al. 1992). HNF4 α also plays an important role in embryogenesis, for example, disruption of murine HNF4 α leads to embryonic lethality (Chen et al. 1994; Duncan et al. 1994; Holewa et al. 1996). In addition, it plays an important role in cell differentiation (Spath and Weiss 1997; Suaud et al. 1997).

HNF4 α splice variants and tissue distribution

The human HNF4 α gene consists of at least 12 exons and spans 30 kb (Furuta et al. 1997; Bolotin, Schnabl, and Sladek 2009) and maps to human chromosome 20 q 12-13.1 between PLCG1 and D20S17 (Argyrokastritis et al. 1997). The HNF4 α gene potentially encodes nine isoforms (HNF4 α 1 through HNF4 α 9), several of which were previously identified by cloning (Sladek and Seidel 2001) (Fig 1.4). HNF4 α isoforms arise from alternative splicing and alternate promoter (proximal promoter P1 and distal promoter P2) usage (Fig.

1.4) (Eeckhoute et al. 2003; Thomas et al. 2001; Boj et al. 2001; Hansen et al. 2002; Briancon et al. 2004). Alternative splicing is common among nuclear receptors (Gronemeyer and Laudet 1995). The widespread use of alternative promoters in mammals allows for the differential expression of genes with complex spatio-temporal expression patterns (Landry, Mager, and Wilhelm 2003).

HNF4 α promoter P1 initiates transcripts that are expressed in the liver and kidneys (Ihara et al. 2005; Servitja and Ferrer 2004). These transcripts contain exon 1A and give rise to isoforms HNF4 α 1 through HNF4 α 3 (Eeckhoute et al. 2003). The most prevalent isoform for the adult liver is HNF4 α 2 (Hata, Tsukamoto, and Osumi 1992). HNF4 α 2 and HNF4 α 3 are alternative splice variants of HNF4 α 1, differing only in their F domains. HNF4 α 2 has an insertion of 10 amino acids in the F domain (Hata, Tsukamoto, and Osumi 1992), while HNF4 α 3 has an F domain with a completely different sequence (Kritis et al. 1996). Promoter P2, on the other hand, initiates transcripts that are predominantly expressed in the pancreatic islet cells (Ihara et al. 2005; Hansen et al. 2002). These transcripts contain exon 1D which result in isoforms HNF4 α 7 through HNF4 α 9 (Thomas et al. 2001; Boj et al. 2001).

The predominant tissues for most of the vertebrate isoforms tested are the liver, kidney, intestine, and colon (Nakhei et al. 1998; Kritis et al. 1996; Drewes et al. 1996; Hata, Tsukamoto, and Osumi 1992; Sladek et al. 1990). They are also

detected in the pancreas and the stomach and barely detectable in testis and skeletal muscle (Kritis et al. 1996; Drewes et al. 1996). Studies using reverse transcriptase polymerase chain reaction (RT-PCR) and RNAase protection have shown that HNF4 α 2 mRNA is more abundant than HNF4 α 1 in rat, mouse, and human liver and kidney and the human hepatocarcinoma cell line, HepG2 (Chartier et al. 1994; Hata, Tsukamoto, and Osumi 1992; Hata et al. 1995; Sladek and Seidel 2001). Others have shown a lower expression of HNF4 α 3 in all tissues analyzed (Kritis et al. 1996). Nakhei et al (Nakhei et al. 1998) hypothesized the presence of HNF4 α 7 in a stem cell population since it is present at high levels in the stomach, absent in kidney, present in a dedifferentiated cell line (F9 cells), and barely detected in other tissues that typically lack HNF4 α , namely the ovary, heart, bladder, and brain. Other researchers have detected HNF4 α 7 and HNF4 α 8 in embryonic liver and fetal-like hepatoma cells (Torres-Padilla, Fougere-Deschatrette, and Weiss 2001; Torres-Padilla, Sladek, and Weiss 2002) while other studies have shown that HNF4 α 8 is selectively expressed in pancreatic b cells (Ihara et al. 2005).

The HNF4 α isoforms have similarities and differences. Since they have identical DNA binding and dimerization domains, they are all expected to bind the same response elements and to heterodimerize with one another, although neither has been tested in a rigorous fashion (Sladek and Seidel 2001). HNF4 α 1, HNF4 α 2, and HNF4 α 3 activate transcription well in a constitutive fashion while

others (HNF4 α 7) do not (Nakhei et al. 1998; Kritis et al. 1996; Drewes et al. 1996; Sladek et al. 1990). Sladek et al. (Sladek et al. 1999) have reported that HNF4 α 2 activates transcription better than HNF4 α 1 in some cell lines while Suaud et al., (Suaud, Formstecher, and Laine 1999) have reported the opposite in other cell lines. Nakhei et al. (Nakhei et al. 1998) have reported the transactivation of HNF4 α 7 to be a function of cell type used in transfection assays (Nakhei et al. 1998; Torres-Padilla, Fougere-Deschatrette, and Weiss 2001). Although the significance of the different HNF4 α isoforms in human disease is not yet known, the different isoforms will probably play different roles in the liver and other organs (Sladek and Seidel 2001).

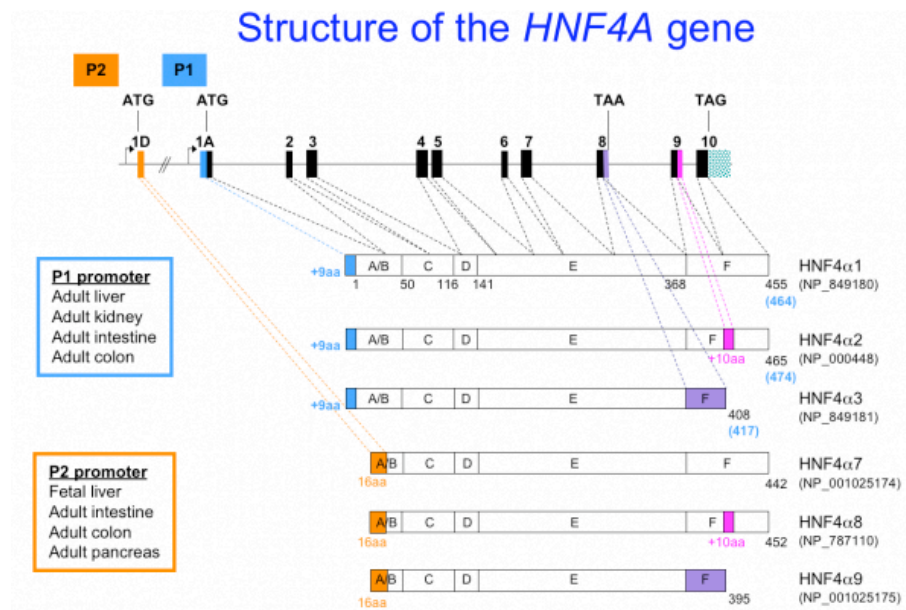

Fig 1.4 Structure of HNF4 α gene and HNF4 α isoforms.

A schematic representation of the HNF4a gene and its promoters P1 and P2. The proximal promoter P1 drives the expression of the HNF4 α 1-3 isoforms. The distal promoter, P2, drives HNF4 α 7-9. Bolotin, E., et. All (Updated November 11, 2009). HNF4 α . From the Transcription Factor Encyclopedia. <http://www.cisreg.ca/tfa>. Accessed December 12, 2009.

HNF4 α and its ligand

HNF4 α was originally considered to be an orphan receptor because it activated transcription in a constitutive fashion – i.e., in the absence of exogenous ligands in a variety of cell types as well as in vitro (Sladek et al. 1999; Sladek et al. 1990; Malik and Karathanasis 1996). This suggested that either the putative ligand is present in all cells or it is not required for transactivation by HNF4 α . A study in 1998 proposed fatty acylcoenzyme A thioesters were not shown to act as a as ligands for HNF4 α (Hertz et al. 1998). Since these thioesters are important in pathways that are regulated by HNF4 α such as glucose and fatty acid metabolism (Gurr and Harwood 1991), it would make sense for them to act as ligands for HNF4 α . A ligand, in the classical sense, binds in the hydrophobic pocket in the LBD which results in a conformational change that removes co-repressors and recruits co-activators (Glass and Rosenfeld 2000). However, the fatty acyl CoA thioesters were not shown to act as a traditional ligand: They did not alter the conformation of HNF4, decrease binding to a co-repressor, or increase binding to a co-activator (Bogan et al. 2000; Ruse, Privalsky, and Sladek 2002). Recent findings show that HNF4 α expressed in mammalian cells preferentially binds linoleic acid, an essential fatty acid from the diet, and that this binding is reversible in vivo (Yuan et al. 2009). However, a classical function for Linoleic acid in HNF4 α function has not yet been demonstrated.

HNF4 α and disease

HNF4 α regulates many essential genes related to transport and metabolism of nutrients such as amino acids, lipids, vitamins, and glucose (Bolotin, Schnabl, and Sladek 2009). In addition, HNF4 α regulates genes involved in the regulation of serum proteins such as blood coagulation factors, erythropoietin, and anti-thrombin III. HNF4 α has also been directly linked to human diseases such as hemophilia B Leyden, a chromosome linked recessive bleeding disorder, and maturity onset diabetes of the young (MODY), an inherited form of non-insulin independent diabetes (Sladek and Seidel 2001; Yamagata et al. 1996; Bolotin, Schnabl, and Sladek 2009). HNF4 α is also known to play a critical role in apolipoprotein gene regulation. The apolipoproteins ApoAI, and ApoB are the protein components of high density lipoproteins (HDL) and low density lipoproteins (LDL) respectively. HDL and LDL are important carriers of cholesterol and are linked to atherosclerosis (Barth and Arntzenius 1991), cardiovascular disease (Ballantyne, Arroll, and Shepherd 2005) and diabetes (Taskinen 2005). Other HNF4 α target genes potentially link HNF4 α to cancer; they include: hepatitis B virus (HBV) (Tang and McLachlan 2001; Zheng, Li, and Ou 2004), cytochrome p450, and acylcoenzyme A oxidase (ACO) (Sladek and Seidel 2001; Bolotin, Schnabl, and Sladek 2009).

Liver –Specific Gene Expression

The adult liver is predominantly composed of parenchymal cells or hepatocytes that carry out most of the specialized functions of the liver (Cereghini 1996). The transcription of several hepatic genes is activated during liver development and is later fine-tuned due to extracellular stimulation (Shiojiri, Lemire, and Fausto 1991; Cascio and Zaret 1991; Schmid and Schulz 1990). The transcription rate of genes encoding liver-specific proteins is higher in hepatocytes compared to other cell types (Powell et al. 1984). Studies have shown that the synthesis of these liver-specific proteins is regulated primarily at the level of transcription initiation (Derman et al. 1981; Aran, Cassuto, and Reshef 1995).

There are six families of liver-enriched transcription factors (LETf): HNF-1, HNF-3, HNF-4, HNF-6, C/EBP, and BZIP. The LETfs are a heterogeneous class of evolutionarily conserved transcription factors required for cellular differentiation and metabolism and are not exclusively expressed in the liver although their tissue distribution is limited (Cereghini 1996; Schrem, Klempnauer, and Borlak 2002; Sladek and Darnell 1992).

Studies of these transcription factors have led to the hypothesis that the cooperation of these factors and ubiquitous transactivating factors is necessary and possibly even sufficient for the maintenance of liver specific gene expression (Hayashi et al. 1999). For example, studies of specific promoter elements show that HNFs act in various combinations to direct cell-specific transcription during cellular differentiation (Duncan et al. 1998).

Earlier studies have pointed to a transcriptional hierarchy involved in maintaining the hepatic phenotype, where HNF4 α is an upstream regulator of HNF1 α (Kuo et al. 1992). Later studies established a positive autoregulation loop between HNF4 α and HNF1 α (Bailly et al. 2001; Spath and Weiss 1997, 1998). It has been shown that the HNF4 α promoter contains HNF1 α and HNF3 α binding sites but lacks a TATA box (Taraviras et al. 1994). Studies by Duncan et al (Duncan et al. 1998) have shown that HNF3 β positively regulates the expression of HNF4 α and HNF1 α and their downstream targets. Hence, a more elaborate picture is emerging: the liver enriched transcription factors are connected not just functionally but in a complex regulatory network that responds to signals to ultimately regulate gene expression (Sladek and Seidel 2001). For example, in the model proposed by Hatzis and Taliandis (Hatzis and Talianidis 2001), multiple interdependent regulatory pathways control the expression of HNF1 and HNF4 α in a stringent manner (Fig. 1.5). This maintains balanced levels of HNF1 α and HNF4 α in the cell. During the early stages of liver development, HNF1 β and GATA6 synergistically activate HNF4 α . During the later stages, an increase in HNF1 α levels, along with a decrease in HNF1 β levels, switches the control of HNF4 α to HNF1 α . A reciprocal regulatory loop between HNF1 α and HNF4 α is then established which may lead to high concentrations of both HNF1 α and HNF4 α if left unchecked. This is regulated by COUP-TFII, which negatively regulates HNF4 α and positively regulates HNF1 α . Increased levels of HNF1 α serves as its own negative control, which would also

prevent further activation of HNF4 α . The efficient transactivation of HNF4 α by HNF1 α requires HNF6, which may provide an added level of control.

More recent studies have expanded the regulatory network of HNFs and established a link between the liver and pancreas. They show HNF involvement in general and HNF4 α involvement in particular, in transcriptional regulatory loops that control the activity of human hepatic and islet cells (Smith et al. 2005; Odom et al. 2004; Gupta et al. 2005; Kulkarni and Kahn 2004).

 Multiple interdependent regulatory pathways control the expression of HNF1 and HNF4 α in a stringent manner. Figure used with permission from the American Society for Microbiology (ASM). Hatzis and Talizndis 2001.

PGC1 α coactivator

Coactivators serve as a link between physiologic stimuli to transcription factor activities (Finck and Kelly 2006). Peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC1 α) is an example of these coactivators. PGC1 α was identified through its interaction with Peroxisome proliferator-activated receptor gamma (PPAR γ) in brown adipose tissue (Puigserver et al. 1998). PGC1 α serves as a pleiotropic regulator of multiple pathways involved in cellular energy metabolism (Knutti and Kralli 2001; Puigserver and Spiegelman 2003). PGC1 α has a variety of targets including PPAR α (Vega, Huss, and Kelly 2000), HNF4 α (Rhee et al. 2003), and FOXO1 (Puigserver et al. 2003). PGC1 α is highly expressed in brown adipose tissue, heart, and slow-twitch skeletal muscle (Puigserver et al. 1998; Lin et al. 2002; Kressler et al. 2002). PGC1 α expression is stimulated by stress, for example, by fasting in the liver (Rhee et al. 2003) and exercise in the skeletal muscle (Goto et al. 2000; Terada and Tabata 2004; Pilegaard, Saltin, and Neufer 2003).

The goal of this study

The goal of this study is to characterize the global changes that occur in the maternal liver during lactation. We will utilize genome-wide expression profiling in order to tease out molecular signatures of differentially up regulated and down regulated genes as a result of lactation and connect them with maternal adaptations that occur in order to meet the demands of the lactating mammary gland and the suckling pups. At the same time, we will focus on liver enriched transcription

factors, such as HNF4 α , and the role they might play in lactation. Chapter 2 will focus on maternal adaptations that occur in order to meet the demands of the lactating breast and the suckling pups. We will be looking at maternal physical changes (i.e. whole body weight, whole liver mass), and metabolic changes (i.e. glucose levels, triglyceride levels) that occur during lactation. Chapter 3 is devoted to expression profiling of mRNA from the livers of virgin, non-lactating, and lactating mice. A close examination of the differential expression of genes during lactation should enable us to understand the role of the liver in lactation, and also find a link between the physical and/or metabolic changes that lactation brings and the possible health benefits to the mother.

Chapter 2

Maternal Adaptations in Response to Lactation

Chapter 2

Maternal Adaptations in Response to Lactation

Introduction

The goal of pregnancy and lactation is the survival of reproductively viable offspring. Lactation includes the development of mammary tissue, synthesis and secretion of milk, and maintenance of milk production for the suckling young (Hartmann, Owens, and al. 1996; Lemay et al. 2007). Lactation is the most energetically demanding period in the life cycle of female mammals (Thompson and Nicoll 1986; Naya et al. 2008). The lactating mammal has developed maternal adaptations in order to meet the high energy demands of lactation. Maternal adaptations to lactation include overeating and phenotypic plasticity (Speakman and Krol 2005; Hammond and Kristan 2000). Phenotypic plasticity is an adaptive process (Agrawal 2001) that allows an organism to change its traits (i.e. organ morphology, body composition) in response to internal or external environmental changes, and these changes are reversible (Piersma and Drent 2003).

The liver plays an important role in lactation. The liver, along with the mammary gland and adipose tissues, is one of the three major sites of metabolism of fatty acids (Vernon 2005), which are a major component of milk. Lactation in turn has extensive effects on the liver (Drackley, Beaulieu, and Elliott 2001; Vernon et al. 2002). The high energy demands of lactation require the redirection of nutrients to the lactating mammary gland through the collaborative changes in the metabolic

activities of a variety of other tissues such as the liver and adipose tissue (Bauman and Currie 1980; Dunphy, Snell, and Clegg 1992).

Studies have shown that lactation lowers the incidence of metabolic syndrome among lactating mothers (Stuebe et al. 2005; Gunderson et al. 2007), and this health benefit may have long-term effects (Ram et al. 2008; Schwarz et al. 2009; Gunderson 2008). Metabolic Syndrome is a cluster of risk factors whose primary clinical outcome is cardiovascular disease (CVD) (Huang et al. 2009; Grundy et al. 2004). Metabolic syndrome includes hyperglycemia/insulin resistance, obesity, and dyslipidemia, (Huang et al. 2009; Grundy 2007; Zimmet, Alberti, and Shaw 2005), conditions that involve the liver (Xie et al. 2009; Kusminski et al. 2009). Nonalcoholic fatty liver disease (NAFLD), which involves the accumulation of fat in the liver, has also been associated with metabolic syndrome (Marchesini et al. 2003).

The liver enriched transcription factor Hepatocyte Nuclear Factor 4 α (HNF4 α) is vital to the development and functions of the liver (Chen et al. 1994; Hayhurst et al. 2001; Sladek and Seidel 2001). It regulates many essential genes related to transport and metabolism of nutrients such as amino acids, lipids, vitamins, and glucose. In addition, HNF4 α has been associated with diseases such as diabetes, atherosclerosis, obesity, and metabolic syndrome (Yamagata et al. 1996; Sladek and Seidel 2001; Bagwell et al. 2005; Black et al. 2008; Weissglas-Volkov et al. 2006).

A healthy liver is important in lactation. It plays an important role in the detoxification of xenobiotics, and in glucose and lipid homeostasis. HNF4 α plays an important role in adult liver functions such as lipid and glucose metabolism. We will be looking at maternal physiological and metabolic changes during lactation in mice. Examples of changes are maternal whole body weight, maternal whole liver weight, plasma glycerol concentration, plasma glucose concentration, hepatic triglyceride concentration, and plasma triglyceride concentration. Taken together, we may be able to paint a global picture of the liver during lactation, and thereby learn more about its function in lactation.

Materials and Methods

Animal care and treatment

Care and treatment of experimental animals was in accordance with guidelines from the University of California, Riverside, Institutional Animal Care and Use Committee (IACUC). Female, age-matched, virgin and timed pregnant C57Bl/6 mice were purchased from Charles River Laboratories (Charles River Laboratories, Wilmington, MA). All timed pregnant mice went through one successful round of reproduction (pregnancy, lactation, weaning) before mating for a second round. Timed pregnant mice were received at 15 days gestation at the UCR vivarium and were allowed to acclimate to their new environment for about 17 days. Virgin mice were never mated. At parturition, 12 dams were allowed to lactate for 10-12 days postpartum (lactating) and pups were adjusted to 6 pups/lactating dam at parturition. For the pregnant but non-lactating group (n=12), all pups were taken away at parturition. Each lactating dam (L) was housed separately with 6 suckling pups per cage. Non-lactating dams (NL) were also housed separately at parturition. Virgin mice (V) were housed 5 mice per cage. All mice were kept in a temperature-controlled room, exposed to 12 h light cycle, 12 h dark cycle, and fed a regular chow diet (Harlan Teklad, TD7012; Harlan Teklad, Madison, WI).

Fasting, whole body weights, and blood collection

In order to control for the effects that diet may have on lactation, each mouse (with suckling pups when applicable) was fasted for 18-21 h before sacrifice in the following manner. Each mouse (and their suckling pups when applicable) was transferred to a new cage without food. Virgin mice (5 per cage) were also transferred to a new cage. The bedding of each cage was changed to Sani-Chips (cat # 7090, Harlan Teklad, Madison, WI), non-edible wood chips that do not provide a source of nutrients as does standard bedding. All mice were allowed a bottle of water during the fast. At around 15 h post initiation of fast, (9:00 a.m. the next day) whole body weights were recorded for each mouse. Mice in their cages were then placed under a 60-watt heat lamp for 10 minutes. Each mouse was restrained, and their tails were nicked. Whole blood was then collected in two heparinized hematocrit tubes (Fisher Scientific, catalog # 21-176-6) per animal. Whole blood was subjected to centrifugation at 16,000 RCF for 10 min at 4°C. Blood plasmas (supernatants) were collected, transferred to new Eppendorf tubes, and stored at -20°C. After blood collection, mice were returned to their cages and allowed to recover before being sacrificed at around noon (18-21 h total fasting).

Tissue harvesting

Mice were euthanized by CO₂ exposure for 40 seconds. Whole body weights were recorded and tissues were harvested in a cold room (4°C). The portal artery was cut and allowed to bleed before each liver was taken out and weighed. The largest liver

lobe (lobe 1) was harvested and stored for the following assays: two samples (10-30 mg) for RNA isolation, one sample (100 mg) for triglyceride (TG) assay, one sample (100 mg) for sectioning, the rest of lobe 1 (300 mg), for storage. The remaining liver (lobes two-six; 200 – 300 mg) was chopped up with a razor blade and stored in two aliquots for nuclear extraction. All liver samples were stored in screw cap cryovials (Nunc, cat # 12-565-170N, Thermo Fisher Scientific, Waltham, MA) in liquid nitrogen.

Plasma glycerol and plasma triglyceride quantification

Preparation of standards and sample plasmas

Plasma glycerol and plasma triglyceride concentrations were quantified using a triglyceride quantification assay kit (Cat# ETGA-200, BioAssay Systems, Hayward, Ca), as per the manufacturer's instructions. Briefly, assay standards (0 mmol/L, 0.3 mmol/L, 0.6 mmol/L, 1 mmol/L) were prepared as per the manufacturer's instructions. Heparinized plasmas (see Fasting, whole body weights, and blood collection section for whole blood collection details) of each animal (sample plasmas) were thawed on ice and diluted 5-fold in double distilled water.

Assay Procedure

Standards (10 μ L) were added to their appropriate wells (standard wells) in singlicate, per manufacturer's instructions, in a 96-well plate (Costar assay plate 3595, Corning Scientific, Corning, NY). Each sample plasma (10 μ L) was added to

the appropriate wells in singlicate (sample wells) and the same sample plasmas (10 μ L) were added to separate wells (blank wells) in singlicate. The appropriate amount of working reagent (with lipase) and control reagent (no lipase) were prepared. Working reagent (100 μ L) was added to each standard well and each sample well (all in singlicate), and 100 μ L of control reagent was added to each blank well. The plate was tapped to mix all reagents. The plate was incubated at room temperature for 30 min. Standard, sample, and blank optical densities were determined by a plate reader (V Max kinetic microplate reader, Molecular Devices, Sunnyvale, CA), set at 570 nm.

Generating the standard curve

The standard curve was generated by subtracting the raw OD value of the zero standard from each raw OD value of all standards. These were plotted against known standard concentrations. The slope of the line was determined by linear regression.

Calculating plasma triglyceride concentrations

Plasma triglyceride concentrations of sample plasmas were determined by subtracting blank OD values of sample plasmas from their respective sample OD values. These were then divided by the slope, then multiplied by the dilution factor (in this case, 5). These values (in nmol/L) were multiplied by 88.5 (1 mmol/L TG equals 88.5 mg/dL) to get final values in mg/dL.

Calculating plasma glycerol concentrations

Plasma glycerol concentrations were calculated by subtracting the raw OD value of the zero standard from raw OD values of sample plasma blanks. These values were then divided by the slope of the standard curve and multiplied by the dilution factor (in this case, 5; unit: mmol/L).

Glucose Quantification

Preparation of standards and unknown samples

Plasmas were thawed and their fasting glucose levels were measured with a glucose assay kit per the manufacturer's instructions (cat # K606-100, BioVision, Mountain View, CA). A stock glucose standard was prepared by adding 10 μL of the Glucose Standard to 990 μL of Glucose Assay Buffer, for a final concentration of 1 nmol/ μL . Zero nmol, 2 nmol, 4 nmol, 6 nmol, 8 nmol, and 10 nmol standards were prepared by adding Glucose Assay buffer to 0 μL , 2 μL , 4 μL , 6 μL , 8 μL , and 10 μL of stock glucose standard in their corresponding eppendorf tubes. Each standard volume was adjusted to 50 μL per reaction, making enough for 2.5 reactions per standard. Unknown samples were diluted to 4 % in Glucose Assay Buffer (2 μL unknown sample in 48 μL Glucose Assay Buffer for 1 per reaction) in their respective Eppendorf tube, making enough for 2.5 reactions per unknown sample.

Glucose assay procedure

50 μ L of all prepared standards and unknown samples were added to their assigned wells in a 96 well plate (Costar assay plate 3595, Corning Scientific, Corning, NY) in duplicate. Glucose Reaction Mix (Reaction mix) was prepared as per the manufacturer's instructions. Prepared Reaction mix (50 μ L/well) was added to all standard and unknown sample wells, and mixed well by pipeting up and down. The plate was wrapped in foil and allowed to incubate at 37°C for 30 min. Standard and unknown optical densities were determined by a plate reader (V Max kinetic microplate reader, Molecular Devices, MDS Inc, Toronto, Canada), set at 570 nm.

Data Analysis

Data were collected and analyzed by using SoftMax Pro version 3.6 (Molecular Devices, MDS Inc, Toronto, Canada). The background was corrected by subtracting the raw value obtained from 0 nmol standard from all raw unknown sample values. Glucose concentrations of unknown samples were extrapolated from the standard curve generated.

Hepatic Triglyceride Quantification

Hepatic Triglyceride Isolation

Triglycerides (TG) were isolated from previously frozen liver chunks as per BioVision TG quantification kit instructions (cat # K622-100, BioVision, Mountain View, CA). Liver chunks were homogenized in the appropriate volume of 5%

Triton-X100 solution (5% Triton-X100 in water; 100 mg liver chunk in 1 mL 5% Triton-X100 solution). Homogenates were then transferred to 15 mL conical tubes and placed in an 80°C-100°C water bath for 2-5 minutes until cloudy. Heated homogenates were allowed to cool down to room temperature. Triglycerides were allowed to solubilize by heating cooled homogenates in an 80°C-100°C water bath for 2-5 minutes for a second time. Solubilized homogenates were spun at 400 x g in a table top clinical centrifuge (CL model, IEC). Supernatants (hepatic triglycerides) were transferred to Eppendorf tubes and stored at -20°C.

Preparation of standards and hepatic triglyceride samples

Hepatic triglycerides were quantified using a triglyceride quantification assay kit (Cat# ETGA-200, BioAssay Systems, Hayward, Ca), as per the manufacturer's instructions. Briefly: Assay standards (0 mmol/L, 0.3 mmol/L, 0.6 mmol/L, 1 mmol/L) were prepared (see Plasma glycerol and plasma triglyceride quantification section). Hepatic triglycerides samples (HTS) were thawed and diluted 10-fold in double distilled water.

Assay Procedure

Prepared standards (10 µL) were added to their assigned wells (standard wells) in singlicate, in a 96-well plate (Costar assay plate 3595, Corning Scientific, Corning, NY). HTS (10 µL) were added to both assigned wells (HTS wells) as well as to blank wells. The appropriate amount of working reagent (with lipase) and control reagent

(no lipase) were prepared as per the manufacturer's instructions. Working reagent (100 μ L) was added to each standard well and each HTS well (all in singlicate), and 100 μ L of control reagent was added to each HTS blank well. The plate was tapped to mix all reagents. The plate was incubated at room temperature for 30 min. Standard, HTS, and HTS blank optical densities were determined by a plate reader (V Max kinetic microplate reader, Molecular Devices, MDS Inc, Toronto, Canada), set at 570 nm.

Generating the standard curve

The standard curve was generated by subtracting the raw OD value of the 0 standard from each raw OD value of all standards. These were plotted against known standard concentrations. The slope of the line was determined by linear regression.

Calculating hepatic triglyceride concentrations

Hepatic triglyceride concentrations were determined by subtracting HTS blank OD values from their respective HTS OD values. These were then divided by the slope of the standard curve, then multiplied by the dilution factor (in this case, 10; unit mmol/L). The values (in mmol/L) were then multiplied by their respective total extract volumes (TEV) in liters and then normalized to their respective liver chunk weights in grams (normalized unit: mmol/g). Normalized values (mmol/g)

were then multiplied by the molecular weight of triglycerides (885 g/mmol) to get final units of mg/g.

Liver staining

Liver tissue chunks from liver lobe 1 per animal were placed in molds in (cat # 22-038-217, Fisher Scientific) containing OCT freezing medium (cat # 14-373-65 Andrew Scientific N.:4583, Fisher Scientific). Tissue samples in the molds were covered with OCT freezing tissue medium and placed on dry ice. These were then stored at -80°C and sent to AML laboratories (AML laboratories, Rosedale,MD) on dry ice for Oil Red O staining. Whole mounts of Oil Red O-stained liver tissues were photographed at 200X. Oil Red-O stains fat red. All images were processed in an identical fashion. Red staining was enhanced by using the Auto Levels command in Adobe Photoshop CS, version 8.0. Images were further modified by using Powerpoint (Microsoft Office 2008) by adjusting their brightness levels (V image: -16%, NL image: -36%, L image: -22%) in the picture editing mode.

Preparation of maternal liver nuclear extracts

Crude mouse liver nuclear extracts (NE) were prepared using a combination of previously published methods (Costa et al. 1988; Sladek et al. 1990) with the following modifications. Frozen liver samples ear-marked for nuclear extract preparation were kept in liquid nitrogen until the time of extraction. Each frozen minced liver chunk was homogenized in 2mL Buffer A-T (10 mM Hepes, pH 7.8, 0.32 M sucrose, 0.3% Triton X-100, 25 mM KCl, 0.15 mM spermine, 0.5 mM spermidine, 1

mM EGTA, 1 mM EDTA, 1 mM DTT, 0.5 mM PMSF) containing protease and phosphatase inhibitors (P8340, P2850, P5726 cocktails, Sigma, St. Louis, MO) with an electric tissue grinder. The homogenate was passed through a 100 μ m cell strainer (cat # 352360 BD Falcon, BD Biosciences, San Jose, CA) homogenized manually and centrifuged at 822 x g for 10 min at 4°C (Jouan CR4-12, Jouan, Winchester, VA). The supernatant was decanted and the pellet containing the nuclei was resuspended in Buffer A-T followed by two washes at 347 x g for 5 min at 4°C (Jouan CR4-12, Jouan, Winchester, VA) in Low Salt Buffer (as Buffer A-T except without sucrose or Triton X-100 but with 20% glycerol) before re-suspending in the same buffer and slowly adding High Salt Buffer (as Low Salt Buffer but with 0.5 M KCl) to a final salt concentration of 0.33 M KCl. The nuclei were extracted for 45-60 min with gentle agitation. The chromatin was pelleted and the supernatant (nuclear extract) was removed, aliquotted, snap-frozen on dry ice, and stored at -80°C. All steps were carried out at 4°C. Protein concentrations were determined by the BioRad Protein Assay (cat # 500-0201, Bio-Rad Laboratories, Hercules, CA).

Quantification of HNF4 α protein by competitive ELISA

The HNF4 α competitive ELISA (H4 ELISA) was developed and validated in our lab (Camba-Colón 2005), based on modifications of a procedure from Lomax et al (Lomax et al. 1998). The assay involves plate preparation, pre-incubation, competition, 2^o AB, substrate, and plate reading.

Preparation of standard antigen, GST.HNF4 α .LBD/F (LBD/F)

GST.HNF4 α .LBD/F (GST.LBD/F) was used as the standard antigen. Construction and expression of GST.LBD/F was in *E.coli* as previously described in Ruse et al (Ruse, Privalsky, and Sladek 2002). Expression of GST.LBD/F was verified by immunoblot (IB) analysis as described previously (Jiang et al. 1995; Maeda et al. 2002). GST.LBD/F was released from GST by cleavage with PreScission Protease (Amersham Biosciences, Piscataway, NJ) as per the manufacturer's protocol and verified by IB. The LBD/F concentration was determined using SDS-PAGE followed by transfer to Polyvinylidene fluoride (PVDF) transfer membrane (cat # ISEQ00010, Immobilon-PSQ membrane, Millipore, Billerica, MA) and staining with Coomassie Brilliant Blue. Different known quantities of bovine serum albumin (BSA) were loaded as standards. The NIH ImageJ program, a public domain Java image processing program, was used for quantification of the BSA and LBD/F bands.

Plate preparation

On day 1: 96-well non-treated, flat-bottomed, polystyrene microplates (Costar assay plate 3595, Corning Scientific, Corning, NY) were coated as follows. Day 1: HNF4 α .LBD/F was diluted in 50mM carbonate buffer (16 mM Na₂CO₃, 34 mM NaHCO₃, pH 9.6) to a concentration of 4 mg/mL. 50 mL of 0.4 mg/mL HNF4 α .LBD/F was added to each well, for a total of 20 ng per well. Three wells designated as non-specific binding (NSB) wells received 50 μ L/well of NSB buffer (1% non-fat milk in 50 mM carbonate buffer) but no HNF4 α .LBD/F. The plate was covered and

incubated overnight at 4°C on a tabletop shaker (Innova 4000, New Brunswick Scientific). On day 2: Plates were washed three times (1 min soak, followed by aspiration) with 200 µL/well phosphate buffered saline containing detergent (PBST: 0.02 M sodium phosphate, 0.15 M sodium chloride, pH 7.2, 0.05% Tween 20) to remove unbound HNF4α.LBD/F (antigen) and blocked by adding 50 µL/well of block solution (2% non-fat milk, PBST) to all wells. The plates were incubated for 45 min at 37°C on a platform shaker and then washed three times with PBST. The plate was aspirated, air dried, covered, and sealed in plastic and stored at 4°C overnight.

Preparation of 1° Antibody (α445-AP)

Also on day 2, a 1:500 dilution of affinity purified HNF4α primary antibody (Sladek et al. 1990) in PBST was prepared right before the preparation of standards, NSB sample, and unknowns. α445-AP is an affinity-purified antibody to HNF4α that reacts with the very C terminus of human, rat, and mouse HNF4α.

Preparation of standards, NSB sample, and unknowns

Day 2: Standards were prepared by serially diluting LBD/F in PBST. Standard concentrations were the following: 1600 ng/mL, 800 ng/mL, 400 ng/mL, 200 ng/mL, 100 ng/mL, 50 ng/mL, 25 ng/mL, 0 ng/mL. The unknowns were prepared by diluting maternal liver nuclear extracts 1:5 in PBST. The NSB sample consisted of PBST only. 100 µL of each standard, unknown, and NSB sample was transferred to

labeled Eppendorf tubes. 100 μL of α 445-AP (diluted 1:500 in PBST from a starting concentration of 1.0 mg/mL) was added to prepared standards, NSB, and unknowns for a final volume of 200 μL per tube and nutated overnight at 4°C.

Competition

Day 3: 50 μL of each pre-incubated sample (NSB, standards, and unknowns) were added to wells in triplicate per sample. The plates were covered and sealed in plastic and incubated at room temperature on a nutator for three hours.

2° Antibody (G α R-AP)

Day 3 (cont): The samples were aspirated from the wells with micropipet tips. The wells were washed as described above for antigen coating. Goat anti-rabbit Alkaline phosphatase (G α R-AP) was diluted 1:2000 in PBST. 50 μL of G α R-AP was added to each well. The plates were covered and incubated for 1.5 h at room temperature with gentle shaking.

Substrate and color development

The substrate was prepared 15 min before the end of the 2° AB incubation by diluting 3 mL of 5x diethanolamine buffer (Bio-RAD, Hercules, CA) in 12 mL of deionized water in a 50 mL conical tube that was covered in aluminum foil and inverted several times. Three tablets of p-nitrophenylphosphate (PNP) (BIO-RAD, Hercules, CA) were completely dissolved in the diluted diethanolamine buffer by

shaking the conical tube vigorously. The plates were washed in PBST as previously described. 50 μ L of the prepared substrate was added to each well. The plates were covered and wrapped in aluminum foil and then incubated at room temperature while shaking for 40 min to 1 h. The plates were read with a microplate reader (V Max kinetic microplate reader, Molecular Devices, MDS Inc, Toronto, Canada) at 450 nm.

Data Analysis

The program Softmax Pro version 3.6 (Molecular Devices, MDS Inc, Toronto, Canada) was used to initially gather and record the measurements of the samples (raw data). The raw data was then manually transcribed to Microsoft Excel and copied and pasted into Softmax Pro tables for further analysis. Softmax Pro generated standard curves from the raw data using the four parameter logistical curve fit (4-PL). Values for the unknowns were extrapolated by the program from the standard curve. Data from Softmax Pro was further analyzed using Microsoft Excel.

Quantitative Real Time Polymerase Chain Reaction (qPCR)

RNA Isolation

Liver chunks from each mouse (10-30 mg) ear-marked for RNA isolation were incubated overnight at 4°C in 500 μ L RNALater (cat # AM7023, Ambion, Austin, TX),

an RNA stabilization solution. RNALater was removed from the previously incubated liver chunk the next day, and the remaining liver chunk was stored at -80°C . RNA was then isolated from RNA-stabilized frozen liver chunks using the RNeasy mini kit (Qiagen, Valencia, CA). Briefly, each liver chunk was homogenized in complete cRLT buffer (1% beta mercaptoethanol in RLT buffer) in a 1.5 mL tube using a motor homogenizer until completely homogeneous. Homogenized lysates were centrifuged in room temperature at maximum speed (Eppendorf 5424,) for 2 min. to clear the lysate. The supernatant (cleared lysate) was transferred to a new 1.5 mL tube. An equal volume of 70% ethanol was added to the cleared lysate and immediately mixed by pipetting. Up to 700 μL cleared lysate in 70% ethanol was added to the spin column (spin columns come with collection tubes). Spin columns were then centrifuged at maximum speed for 15 sec at room temperature. The flow-through was discarded, and the remaining cleared lysate in 70% ethanol was added to the same spin column and centrifuged at maximum speed for 15 sec at room temperature, and the flow-through was discarded. The spin column was washed with Buffer RW1 by centrifuging at maximum speed for 15 sec at room temperature, and the flow-through discarded. The same column was washed this time with 500 μL of Buffer RPE by centrifuging at maximum speed for 15 sec at room temperature, then discarding the flow-through. The same tube was washed a second time with 500 μL of Buffer RPE, this time centrifuging at maximum speed for 2 min at room temperature to dry the spin column. Spin columns were then centrifuged at maximum speed for 1 min at room temperature, this time using fresh

collection tubes, to remove all ethanol. RNA was eluted by placing spin columns in fresh Eppendorf tubes and adding 50 μ L RNase free water then centrifuging at maximum speed for 1 min at room temperature. The flow-through (eluate) in the 1.5 mL tube is the RNA. A second elution was done by adding the eluate from the previous step to the collection tube and then centrifuged a final time at maximum speed for 1 min at room temperature. RNA concentration and quality were checked by nanodrop. RNA was stored at -80°C.

Digestion of genomic DNA

Digestion reactions were prepared for each RNA sample as per manufacturer's instructions (cat # 10 776 785 001 Roche Applied Science, Penzberg, Germany): DNase I mastermix (1x final concentration of 10x Incubation buffer, 0.5 units final concentration of DNase I recombinant RNase-free reagent for a total of 1.5 μ L/reaction) was prepared for the appropriate number of reactions. RNA (final concentration of 0.3 mg/reaction) was added to 1.5 μ L DNase I mastermix, then adjusted with RNase-free water for a total volume of 10 μ L. Each reaction was incubated at room temperature for 20 min. DNase inactivation reagent (2 μ L) (AM1906, Ambion, Austin, Tx) was added to each reaction and incubated at room temperature for 2 min. Reactions were then spun at 15000 RPM for 1.5 min at room temperature. Each supernatant (DNase I treated RNAs) were transferred to new Eppendorf tubes and stored at -80°C.

cDNA preparation

cDNAs were prepared using the SuperScript™ III Synthesis System for RT-PCR (Invitrogen, Carlsbad, CA) as per the manufacturer's instructions. DNase I-treated RNAs were thawed on ice. The appropriate amount of primer mastermix (P-MM) (for one reaction: 1 μ L 50 ng/ μ L random hexamers, 1 μ L 10 mM dNTP mix) was prepared. DNase I-treated RNA (1 μ g) was added to 2 μ L of P-MM. Diethyl polycarbonate (DEPC)-treated water was added to each reaction tube for a total volume of 10 μ L/reaction tube. Each reaction tube was then gently vortexed, then spun at 13,000 RPM at 4°C for 15 sec. All reaction tubes (RNA-P) were then incubated at 65°C for 5 min and placed on ice. The appropriate amount of cDNA synthesis mix master mix (cS-MM) was prepared (for one reaction: 10X RT buffer (2 μ L), (4 μ L) 25 mM MgCl₂, 0.1 M DTT (2 μ L), RNaseoUT™ (1 μ L, 40 U/mL), SuperScript™ III reverse transcriptase (1 μ L, 200 U/mL). cS-MM (10 μ L) was added to each RNA-P mixture. All tubes were vortexed and spun 13,000 RPM at 4°C for 20 sec. All tubes were incubated in the PCR thermocycler with the following settings: step 1 at 25°C for 10 min, step 2 at 50°C for 50 min, step 3 at 85°C for 5 min, and step 4 at 4°C. All samples were then taken out of the thermocycler and placed on ice. Samples were then centrifuged at 13000 RPM at 4°C for 20s. Rnase H (1 μ L) was added to each sample. All samples were gently vortexed then centrifuged at 13,000 RPM at 4°C for 20 sec, then incubated at 27°C for 20 min. These are the cDNAs. All cDNAs were diluted 1:10 with DEPC-treated water. Standards for quantitative real time PCR (qPCR) were prepared by pooling all cDNA samples (180

μL total volume). Individual cDNAs and pooled cDNA were stored at -20°C for future use.

Quantitative real time PCR (qPCR)

Gene specific primers were validated before hand as previously described (Yuan et al. 2009). Briefly, primers were validated over four orders of magnitude and analyzed with the iQ5 Optical System Software. Primer pairs were deemed valid if an input log plot amount versus CT generated an efficiency of $100\% \pm 10\%$ and a correlation coefficient of $R^2=0.950 \pm 0.05$. Each condition (virgin, non-lactating, lactating) had three biological replicates. Each biological replicate was done in triplicate (technical replicate). The relative expression level of the genes was evaluated using the Pfaffl method (Pfaffl 2001), normalized to cyclophilin A (*Ppia*) expression.

Statistical Analysis

Statistical analysis was performed using the Student's t test. Differences were considered significant at $p < 0.05$. Uncertainty in our measurements was determined by calculating the standard deviation.

Results:

Trends in whole body weight in virgin, non-lactating, and lactating mice

In order to determine the effects of lactation on the maternal liver, we established 3 groups of mice: virgin (V), non-lactating (NL), and lactating (L). All 3 groups were age-matched. Virgin mice were never mated. Non-lactating and lactating mice had gone through one successful round of reproduction (pregnancy, lactation, weaning) then mated a second time. Mice were approximately 98 days old at second mating. Refer to the *Animal care and treatment* section of this chapter for details. All animals were fasted for 18-21 hours before sacrifice to normalize the amount of food they had eaten. Whole body weights of each animal were determined at different fasting time points (0 h, 15 h, 18-21 h) and plotted in Fig 2.1. At 0 h fasting, maternal whole body weights were slightly but significantly less in the non-lactating mothers compared to virgin mice ($p_{NLvsV}=3.80E-2$), but were much greater in the lactating mothers($p_{LvsV}=2.34E-08$); the difference between non-lactating whole body weight and lactating whole body weight was also very significant ($p_{LvsNL}=4.30E-09$). The same trends were observed in both 15-h and 18-21-h fasting time points (Fig 2.1).

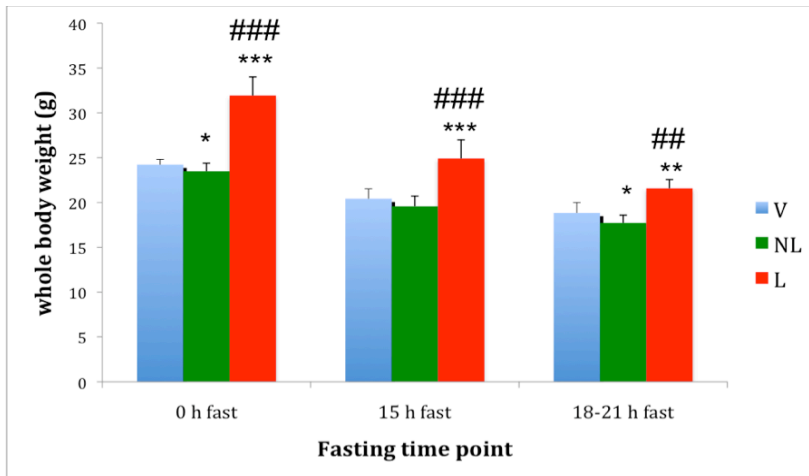

Fig 2.1: Lactation increases maternal whole body weight. Age-matched virgin (V, blue bars, $n_{0h}=5$, $n_{15h}=10$, $n_{18-21h}=9$), non-lactating (NL, green bars, $n_{0h}=11$, $n_{15h}=11$, $n_{18-21h}=9$) and lactating (L, red bars, $n_{0h}=11$, $n_{15h}=11$, $n_{18-21h}=5$) mice were weighed at different fasting time points (0 h, 15 h, 18-21 h) on the day of sacrifice. Average whole body weights were subjected to the student T-test in order to determine whether differences in whole body weights for each group were significant: *=NL vs V or L vs V; #=L vs NL; * or #, $p<5.00E-02$; ** or ##, $p<5.00E-04$; *** or ###, $p<5.00E-08$.

Trends in percent of body weight lost (PWL)

Although maternal whole body weight increased with lactation, all mice lost weight during the 15-h fasting and 18-21-h fasting time points. In order to assess whether lactation affects weight loss, we calculated the percent of body weight lost (PWL) after the first 15h of fasting, and between 15 and 21h of fasting (Fig 2.2). During the first 15h of fasting, the percent of body weight lost (PWL) significantly increased with non-lactation ($PWL_{V0-15h} = 12.90\%$, $PWL_{NL0-15h} = 16.67\%$, $p_{NLvsV}=1.08E-02$), and increased even more significantly with lactation ($PWL_{L15h}=21.82\%$, $p_{LvsV}= 7.06E-05$). The difference in PWL between L and NL mice was also significant ($p_{LvsNL}=2.05E-03$). The same trend was observed at 15-21-h fasting although the percent changes were smaller. All mice continued to lose weight, with the most significant PWL occurring with lactation ($PWL_{L15-21h}=10.23\%$,

$PWL_{NL15-21h}=8.82\%$, $PWL_{V18-21h}=7.73\%$, $PWL_{V15-21h}=7.73\%$, $p_{LvsV}=3.16E-03$,
 $p_{LvsNL}=4.46E-02$, $p_{NLvsV}=4.27E-02$).

Fig 2.2: Percent of body weight lost (PWL) increases with lactation
Age-matched virgin (V, blue bars, $n_{0-15h}=5$, $n_{15-21h}=4$), non-lactating (NL, green bars, $n_{0-15h}=11$, $n_{15-21h}=9$) and lactating (L, red bars, $n_{0-15h}=11$, $n_{15-21h}=5$) mice were weighed at different fasting time points (0 h, 15 h, 18-21 h) on the day of sacrifice. Percent weight loss (PWL) for 15-h fasting time point for each animal was calculated by dividing the weight lost at 15h fasting time point (maternal whole body weight at 0-h fasting – maternal whole body weight at 15-h fasting) by maternal whole body weight at 0h fasting time point, all multiplied by 100%. PWL for fasting time point 15-21-h for each animal was calculated by dividing maternal whole body weight lost at 15-21h fasting time point (maternal whole body weight at 15-h fasting – maternal whole body weight at 18-21-h fasting) by maternal whole body weight at 15h fasting time point, all multiplied by 100%. Average PWL for animals per group were subjected to the student T-test in order to determine whether differences in PWL between groups were significant: *=NL vs V or L vs V; #=L vs NL; * or #, $p<5.00E-02$; ** or ##, $p<5.00E-04$.

Trends in rate of body weight lost (RWL)

In order to examine further the effect of lactation on weight loss, we looked at the trends in the rate of body weight lost among virgin, non-lactating, and lactating mice. We calculated the rate of body weight lost (RWL) at 0-15-h fasting and 15-21-h fasting (Fig 2.3). At 0-15h fasting, lactating mice had the highest rate of weight loss ($RWL_{V0-15h}=0.208$ g/h, $RWL_{NL0-15h}=0.260$ g/h, $RWL_{L0-15h}=0.468$ g/h). The RWL for lactating mice was also significant for this time point ($p_{NLvsV0-15h}=1.61E-02$, $p_{LvsV0-15h}=4.34E-06$, $p_{LvsNL0-15h}=7.00E-06$). The same trend is seen for 15-21h fasting

($RWL_{V15-21h}=0.363$ g/h, $RWL_{NL15-21h}=0.38$ g/h, $RWL_{L15-21h}=0.54$ g/h). The difference in RWL between non-lactating and virgin mice at 15-21h fasting was not significant ($p_{NLvsV}=2.88E-01$). Differences in RWL between lactating and virgin mice ($p_{LvsV15-21h}=1.21E-04$) and between lactating and non-lactating mice ($p_{LvsNL15-21h}=2.55E-04$) were significant.

Fig 2.3: Rate of body weight lost (RWL) increases with lactation. Age-matched virgin (V, blue bars, $n_{0-15h}=5$, $n_{15-21h}=9$), non-lactating (NL, green bars, $n_{0-15h}=11$, $n_{15-21h}=9$) and lactating (L, red bars, $n_{0-15h}=11$, $n_{15-21h}=5$) mice were weighed at different fasting time points (0 h, 15 h, 18-21 h) on the day of sacrifice. Rate of body weight lost (RWL) at the 0-15h fasting time point was calculated by dividing the amount of weight lost (maternal whole body weight at 0 h fasting - maternal whole body weight at 15 h fasting) by 15 h. RWL for 15-21h time point was calculated by dividing the amount of whole body weight lost (maternal whole body weight at 15 h fasting - maternal whole body weight at 18-21 h fasting) by 4.5 h (the average number of hours between 15 h time point and 18-21 h time point). Average RWL for animals per group were subjected to the student T-test in order to determine the significance in the differences between groups: *=NL vs V or L vs V; ##=L vs NL; * or #, $p<5.00E-02$; ** or ##, $p<5.00E-04$.

Lactation affects plasma glycerol levels

Glycerol release is a marker of adipose tissue lipolysis (Judd et al. 1998).

Previous animal and human *in vivo* studies have quantified the appearance of glycerol in the circulation as an index of fat mobilization (Issekutz, Shaw, and

Issekutz 1975; Bougneres et al. 1982; Beylot et al. 1987; Klein et al. 1986). In order to determine if the weight loss that occurred during lactation in our study was due to lipolysis of fat stores (adipocytes), we quantified plasma glycerol concentrations in virgin, non-lactating, and lactating mice (Fig 2.4). Plasma glycerol levels increased significantly with lactation compared to virgin ($p_{LvsV}= 1.78E-03$) and non-lactating levels ($p_{LvsNL}= 5.52E-03$). There is also a strong correlation between percent weight lost (PWL) at 15-h fasting and plasma glycerol concentrations of virgin, non-lactating, and lactating mice (Fig 2.5a, $R^2=0.96635$). This correlation holds true for the percent weight lost (PWL) at 18-21 h fasting time point as well (Fig 2.5b, $R^2=0.964$).

Fig 2.4: Plasma glycerol levels were significantly increased with lactation. Plasma glycerol levels of virgin (V, blue bar, n=10), non-lactating (NL, green bar, n=10), and lactating (L, red bar, n=11) quantified using a triglyceride assay kit (Cat# ETGA-200, BioAssay Systems, Hayward, Ca) per the manufacturer's instructions. Average plasma glycerol levels for each group were subjected to the student T-test in order to determine the significance in differences between groups. *=NL vs V or L vs V; #=L vs NL; * or #, $p<5.00E-02$.

Fig 2.5 Strong correlation between percent of body weight lost (PWL) during fasting with increased plasma glycerol. Average PWL of age-matched virgin (n= 5), non-lactating (n=11) and lactating (n=11) mice were plotted against average plasma glycerol levels of virgin (n= 5), non-lactating (n=10), and lactating (n=11) mice. Linear regression was used to quantify the correlation between these factors. Panel 2.5a. Average PWL data at 15-h fasting time point are plotted against average plasma glycerol levels (refer to Fig 2.4 for details). Panel 2.5b. Average PWL data at 18-21 h fasting time point are plotted against average plasma glycerol levels. Please refer to Fig 2.2 and Fig 2.4 for PWL and plasma glycerol levels details.

Lactation affects maternal liver weight

In order to determine whether lactation had an effect on the maternal liver, whole livers of virgin (V), non-lactating (NL), and lactating (L) mice were weighed and recorded on the day of sacrifice after 21h of fasting. Average whole liver weights (WLW) were plotted in Fig 2.6a. Whole liver weights were normalized to maternal whole body weights in order to obtain the liver to body weight ratio (LBWR) (Fig 2.6b). Liver weights of virgin and non-lactating mice were equivalent ($V_{WLW}=0.97\text{g}$, $NL_{WLW}=0.91\text{g}$). Livers from lactating mice had a significantly greater mass than livers from virgin mice ($L_{WLW}=1.5\text{ g}$, $L_V=0.97\text{ g}$, $p_{LVSV}= 7.98\text{E-}06$) as well as from non-lactating mice ($L_{WLW}=1.5\text{ g}$, $L_{NL}=0.91\text{ g}$, $p_{LVsNL}= 1.41\text{E-}06$). This was true

even when whole liver weights were normalized to maternal whole body weights (Fig 2.6b).

Fig 2.6: Lactation increases maternal whole liver weight
Panel 2.6a: Livers of age-matched virgin (V, blue bars, n=10), non-lactating (NL, green bars, n=9) and lactating (L, red bars, n=5) mice were harvested and weighed at sacrifice (18 to 21h fasting). Panel 2.6b: Maternal liver weights (as in panel 2.4a) were normalized to maternal whole body weights in order to obtain liver to body weight ratios of V, NL and L mice. Average liver weights and liver to body weight ratios were subjected to the student T-test in order to determine the significance of differences between groups of animals.

Trends in blood glucose levels

In order to assess whether lactation affects overall maternal health, we measured blood glucose levels of virgin, non-lactating and lactating mice (Fig 2.7). As the data in Fig 2.7 show, there was no discernable change in blood glucose levels for the three groups of mice since the differences in blood glucose levels were not statistically significant ($p_{NL \text{ vs } V}=0.14$, $p_{L \text{ vs } V}=0.22$, $p_{L \text{ vs } NL}=0.36$).

Fig 2.7 Blood glucose levels increase with non-lactation
 Blood glucose levels of virgin (V, blue bar, n=8), non-lactating (NL, green bar, n=10), and lactating (L, red bar, n=5) were quantified using a glucose assay kit (Cat # K606-100, BioVision, Mountain View, Ca) per the manufacturer's instructions. Average blood glucose levels for each group were subjected to the student T-test in order to determine the significance in differences between groups. *=NL vs V or L vs V; #=L vs NL; * or #, $p < 5.00E-02$; ** or ##, $p < 5.00E-04$; *** or ###, $p < 5.00E-08$.

Trends in hepatic triglyceride levels

Hepatic fat accumulation (fatty liver) results in insulin resistance (Adams and Angulo 2005; Yki-Jarvinen and Westerbacka 2005). Fatty liver has also been associated with cardiovascular disease and type 2 diabetes (Targher et al. 2007; Edens, Kuipers, and Stolk 2009; Kotronen et al. 2008). For these reasons, we looked at hepatic triglyceride levels of virgin, non-lactating, and lactating mice (Fig 2.8). Hepatic triglyceride levels were significantly decreased with lactation ($p_{LvsV}=9.07E-05$, ($p_{LvsNL}=7.65E-04$). Since there was no significant difference in hepatic triglyceride levels between non-lactating and virgin mice, the drop in hepatic triglyceride levels must be due to lactation and not due to pregnancy and/or parturition. Liver Oil-Red-O staining confirmed the hepatic triglyceride

quantification data (Fig 2.9). Oil Red O is a lysochrome, a fat soluble dye used for staining neutral triglycerides on frozen sections. Overall, Red staining reflected hepatic fat content, although the lipid was present in different compartments in the virgin versus non-lactating group, in the sinusoids of the virgin animals and in lipid droplets in the non-lactating animals. Liver tissue from lactating mice were negative for Oil Red O staining.

Fig 2.8: Hepatic triglyceride levels were significantly decreased with lactation Triglycerides (TG) from livers of virgin (V, blue bar, n=9), non-lactating (NL, green bar, n=9), and lactating (L, red bar, n=4) mice Average TG levels for each group were subjected to the student T-test in order to determine the significance in differences between groups. *=NL vs V or L vs V; #=L vs NL; * or #, $p < 5.00E-02$; ** or ##, $p < 5.00E-04$.

Fig 2.9 Lactation decreased hepatic fat content Hepatic fat content of virgin (V n=2), non-lactating (NL, n=2), and lactating (L, n=2) were visualized by Oil Red O staining. Images shown are representative of two tissue samples per animal group. See Materials and Methods for further details.

Trends in plasma triglyceride levels

Plasma triglyceride levels are another important health parameter. Several studies have shown that fasting circulating triglyceride levels is a marker for metabolic syndrome (Hokanson and Austin 1996; Lahdenpera et al. 1996; Gaziano 1999; Kompoti et al. 2006). For this reason, we quantified plasma triglyceride levels of fasted virgin, non-lactating, and lactating mice (Fig 2.10). Plasma triglyceride levels significantly increased with lactation ($p_{LvsV}=1.31E-05$, $p_{LvsNL}=1.04E-05$). Plasma triglyceride levels of virgin mice were similar to circulating triglyceride levels of non-lactating mice ($p_{NLvsL}=3.7E-01$).

Fig 2.10 Plasma Triglyceride levels significantly increased with lactation. Plasma triglyceride (TG) levels of virgin (V, blue bar, n=10), non-lactating (NL, green bar, n=10), and lactating (L, red bar, n=4) mice were quantified from tail vein plasma. Average plasma TG levels for each group were subjected to the student T-test in order to determine the significance in differences between groups. *=NL vs V or L vs V; #=L vs NL; * or #, $p<5.00E-02$; ** or ##, $p<5.00E-04$.

HNF4 α protein increases postpartum

HNF4 α plays a major role in adult liver functions including lipid metabolism. HNF4 α has also been linked to diseases such as diabetes. We looked at HNF4 α protein levels in order to determine whether lactation affects the expression of this liver enriched transcription factor. HNF4 α protein was quantified in nuclear extracts prepared from V, NL, and L livers by competitive ELISA (H4 ELISA, Camba-Colón 2005) (Fig 2.11). HNF4 α protein expression increased significantly with non-lactation (HNF4 α_V =1.21 ng/ μ g, HNF4 α_{NL} =3.15 ng/ μ g, p_{NLvsV} = 1.60E-03). HNF4 α protein expression also increased significantly with lactation (HNF4 α_L =3.14 ng/ μ g, p_{LvsV} =1.53E-02). There was no significant difference in nuclear HNF4 α protein concentration between non-lactation and lactation (p_{LvsNL} =4.92E-01) suggesting that the increase was the result of pregnancy and/or parturition rather than lactation.

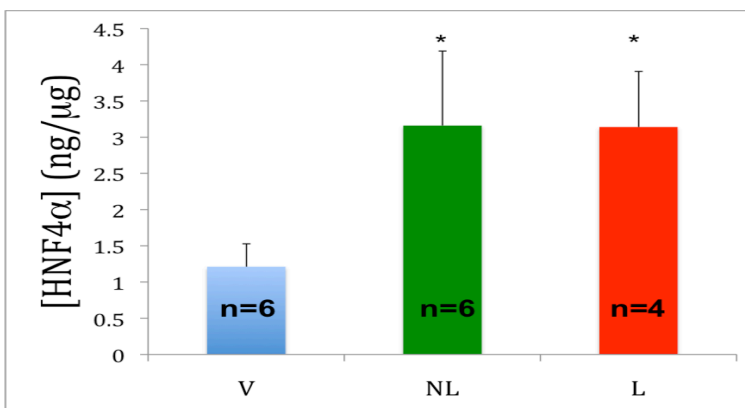

Figure 2.11: HNF4 α protein expression increases postpartum
HNF4 α protein was quantified from nuclear extracts (NE) prepared from virgin (V, blue bar, n=6), non-lactating (NL, green bar, n=6), and lactating (L, red bar, n=6) maternal livers by H4 ELISA (Camba-Colón, 2005). Representative H4 ELISA. Average HNF4 α concentrations were subjected to the student T-test in order to determine the significance in differences between groups. *=NL vs V or L vs V; #=L vs NL; * or #, $p < 5.00E-02$.

HNF4 α gene expression increases postpartum

In order to determine whether lactation affects HNF4 α expression at the transcription level, we quantified HNF4 α mRNA by real time PCR (qPCR) (Fig 2.12). As seen in Fig 2.12, HNF4 α mRNA expression increased significantly with both non-lactation (HNF4 $\alpha_V=1$, HNF4 $\alpha_{NL}=1.86$, $p_{NLV}=1.05E-03$), and lactation (HNF4 $\alpha_L=$, $p_{LVS}=6.78E-02$) compared to virgin mice.

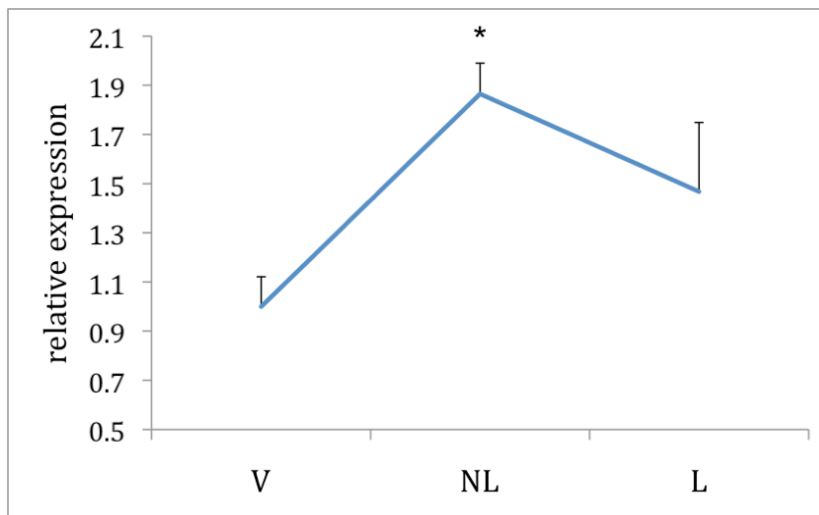

Fig 2.12: HNF4 α mRNA expression increased postpartum
HNF4 α mRNA expression was quantified from virgin (V, n=4), non-lactating (NL, n=4), and lactating (L, n=4) maternal livers by real time polymerase chain reaction (qPCR). Average HNF4 α mRNA expression for each group were subjected to the student T-test in order to determine the significance in differences between groups. *=NL vs V or L vs V; #=L vs NL; * or #, $p<5.00E-02$; ** or ##, $p<5.00E-04$; *** or ###, $p<5.00E-08$.

Discussion

Lactation is the most energetically demanding period in the life cycle of female mammals (Thompson and Nicoll 1986; Naya et al. 2008). The glucose needs of the mammary gland are greater during lactation (Bauman and Currie 1980; Burnol et al. 1986). The lactating mammal has made several adaptations in order to meet this need. Increased food intake, for example, is a common characteristic of lactation in all mammals (Dunphy, Snell, and Clegg 1992; Speakman and Krol 2005) during this highly demanding period. As a response to the increased food intake, the lactating female's intestines, stomach, and liver increase in size (Naya et al. 2008; Barber et al. 1990). This is an example of phenotypic plasticity. Overeating, however, may not by itself be sufficient to meet the energy needs of the lactating mammary gland if food is limiting. Also occurring are changes in the metabolic activities of the mammary gland and other tissues such as adipose tissue and the liver (Vernon 2005; Bell and Bauman 1997). The net result is a change in the allotment of nutrients to the mammary gland, and also the amassing of stored energy in adipose tissue and the liver (McNamara 1997).

Effects of Lactation

Our results show a significant increase in whole body weight in lactating mice, compared to virgin and non-lactating mice (Fig 2.1). This could be explained by overeating in response to lactation. At first glance, the differences in whole body weights between virgin, non-lactating, and lactating mice may not point to lactation

as being beneficial to lactating females in terms of weight loss, because clearly, the lactating mouse is heavier than both virgin and non-lactating mice, and, non-lactating mice lost weight compared to virgin mice. Upon closer inspection, however, it seems that lactation is beneficial to the fasted, lactating mouse. Our experiment enabled us to monitor weight loss in our mice during a 24-hour period of lactation and fasting. Although the percent of body weight lost (PWL, Fig 2.2) significantly decreased in non-lactating mice at the 15-h fasting point, ($p_{NLvsV15h}=1.08E-02$), the increase of PWL in lactating mice was far more significant at this fasting time point ($p_{LvsV15h}=7.06E-05$, $p_{LvsNL15h}=2.35E-03$). The rate of weight lost (RWL, Fig 2.3) at the 15-h fasting time point was also greatest in lactating mice. This was also true of RWL at the 18-21 h fasting time point. The weight loss apparent with lactation can be explained by the mobilization of fat stores in order to meet the energy needs of the mammary gland. Animal studies have shown that the loss of fat stores (lipolysis) during lactation is common in mammals (Robinson 1986; Rauw et al. 2003; Hood, Oftedal, and Kunz 2006; Oftedal 2000). For example, lactating female rodents suckling many litters, gain body mass, probably from fat stores, during early lactation, and lose body mass later in lactation, in order to augment consumption when demands of the litter are highest (Hood, Oftedal, and Kunz 2006). Rauw et al (Rauw et al. 2003) in particular have shown that the absolute lipid mass and lipid percentage were higher in virgin females than in lactating female mice. This would explain the rapid weight lost during lactation in our experiment. Our data confirm findings of other studies that suggest the

mobilization of body stores during lactation (Rogowitz 1998; Hood, Oftedal, and Kunz 2006). Other studies have shown enhanced lipolysis in adipocytes in order to meet the energy demands of lactation (Vernon 1989; Aitchison, Clegg, and Vernon 1982; Sumner and McNamara 2007; McNamara 1997). A marker of increased lipolysis is the presence of glycerol in the circulation. Although we did not specifically measure the fat content of these animals, our data show a significant increase in glycerol plasma levels during lactation (Fig 2.4). In addition, there is a strong correlation between the percent of body weight lost during lactation and the increase in plasma glycerol levels (Fig 2.5). Taken together, this suggests that in order to meet the energy demands of lactation, the lactating mammal mobilizes the maternal lipid stores she accumulated during her pregnancy by increasing lipolysis of adipocytes. A benefit of this adaptation is the rapid and significant weight loss that occurs during lactation, as evidenced by the decrease in maternal whole body weights at different fasting time points for all groups of mice (Fig 2.2, Fig 2.3) (for comment a19).

We also observed evidence of phenotypic plasticity during lactation, as seen in the significant increase in whole liver weight ($WLW_V=0.97$ g, $WLW_{NL}=0.91$ g, $WLW_L=1.50$ g, $p_{LvsV}=7.98E-06$, $p_{LvsNL}=1.41E-06$) and liver to body weight ratio ($LBWR_V=0.05$, $LBWR_{NL}=0.05$, $LBWR_L=0.07$, $p_{LvsV}=1.34E-07$, $p_{LvsNL}=1.44E-07$) during lactation. The increase in liver size is in response to the increase in food demands in order to meet the energy demands of lactation (Naya et al. 2008). Our data

confirm the findings of other studies (Derting and Compton 2003). The increase in liver weight is most likely a consequence of hypertrophy (enlargement of an organ due to an increase in cell size), as opposed to hyperplasia (enlargement of an organ due to an increase in the number of cells) as Dunphy et al (Dunphy, Snell, and Clegg 1992) have demonstrated that hepatic proliferation does not occur during lactation. Rather, the increase in liver size is an indication of a metabolically active organ responding to the energy demands of lactation (Naya et al. 2008; McBride and Kelly 1990; Wang, Busk, and Overgaard 2001). Canas et al (Canas, Romero, and Baldwin 1982) report that there is a rise in metabolism in organs such as the liver during lactation, which is mostly due to an increase in organ weight with higher maintenance costs. Other contributors to consider in the liver weight increase would be liver growth factors such as Growth Hormone (GH) and Insulin-like Growth Factor 1 (IGF-1).

Lactation and Maternal Health

Lactation has been shown to bring about changes to the nursing mother that result in lowering the incidence of unhealthy conditions.(for comment pc21). In order to study the effects of lactation, we compared maternal adaptations in age-matched, fasted, virgin, non-lactating, and lactating mice. Although the non-lactating mice were not lactating during our experiment, they had a history of lactation (since they previously lactated).

In order to determine whether lactation affects the health of the lactating mother, we looked at several markers of overall health: plasma glucose levels (Fig 2.7), hepatic triglyceride levels (Fig 2.8, Fig 2.9), and plasma triglyceride levels (Fig 2.10). Our data did not show any significant differences between plasma glucose levels in virgin, non-lactating, and lactating mice. In contrast, hepatic triglyceride levels decreased dramatically and significantly with lactation (Fig 2.8, Fig 2.9). At first glance, the decrease in hepatic triglycerides indicates a positive effect of lactation on maternal health, since it suggests that lactation may decrease the incidence of fatty liver. In our system, however, both groups of postpartum mice (lactating and non-lactating) previously lactated. Our data therefore suggest that this “health benefit” is only apparent in currently lactating animals, and may not be a long term benefit after all since the non-lactating animals have higher hepatic triglyceride storage.

Plasma triglyceride levels, on the other hand, significantly increased with lactation (Fig 2.10). The increase in plasma triglyceride levels could be a result of increased adipocyte lipolysis. The increased plasma glycerol levels (Fig 2.4) during lactation indicates an increase in lipolysis (Judd et al. 1998). Previous studies have shown an increase of adipocyte lipolysis in order to provide for the demands of lactation (Vernon 1989; Aitchison, Clegg, and Vernon 1982; Sumner and McNamara 2007; McNamara 1997). An increase in lipolysis then leads to an increase of free fatty acids available for hepatic lipogenesis and the lipids are released in the circulation as very low density lipoproteins (VLDL, triglycerides) (Vernon 2005).

Studies have shown that there is an increase in hepatic lipogenesis during lactation (Grigor et al. 1982; Williamson et al. 1983; Casey et al. 2009). Thus, the high energy demands of lactation causes a mobilization of fat stores (increased lipolysis), the consequences of which include significant weight loss and an increase in the lipolytic marker, glycerol in the circulation. Lipolysis then increases free fatty acids, which serve as substrates for hepatic triglyceride synthesis, the product of which are triglycerides. The liver then packages the triglycerides (VLDL), which are secreted into the circulation. This would explain the low hepatic triglyceride levels during lactation, and also the high plasma triglyceride levels that occur at this time. The time point we have chosen is peak lactation, when the demand for lipids is presumably the greatest. The mice have also been constitutively lactating, up to the time of sacrifice. High plasma triglycerides may be a manifestation of this energy source being made available for the mammary gland.

Most of the changes we have observed are beneficial to the lactating mother: significant weight loss and no evidence of fatty liver (compared to non-lactating mice). Although these beneficial changes benefit the lactating mother, in mice, the benefits do not seem to be long-term. The previously lactating non-lactating mice had the opposite trends of less weight loss and increased hepatic storage. The elevated plasma triglycerides that accompany lactation are a reflection of the lactating mother's attempt to keep up with the energy demands of the mammary gland.

Although elevated triglyceride levels are considered an unhealthy marker, elevated triglyceride levels seem to be due to the increased hepatic lipogenesis and increased lipolysis going on in adipocytes. A close inspection of the liver tissue sections did not show evidence of inflammation (personal communication with Dr. Walker). Inflammation would accompany certain diseases such as atherosclerosis, although this would not be in the liver (Libby 2002). Our experiment, however, may suggest that in terms of plasma triglyceride levels, lactation may have a long-term benefit after all, since the previously lactating (and now non-lactating) mice had lower plasma triglyceride levels compared to the currently lactating mice, although the non-lactating plasma triglyceride levels are similar to the virgin animals.

The Liver, Lactation, and HNF4 α

In order to understand the role of the maternal liver in lactation, we looked at the liver enriched transcription factor, HNF4 α . A member of the nuclear receptor superfamily, HNF4 α plays an important role in adult liver functions such as lipid metabolism and lipid homeostasis. It has also been linked to diseases such as obesity, atherosclerosis, and diabetes (Petrescu et al. 2002; Gupta and Kaestner 2004; Crestani et al. 2004). Given that changes in liver function are important in both pregnancy and lactation (Vernon 2005) and that HNF4 α plays an important role in adult liver function, it is conceivable that HNF4 α may also play a role in changes in response to lactation. For example, HNF4 α regulates hepatic glucose metabolism and also the transport of cholesterol and triglycerides throughout the

body (Sladek and Seidel 2001; Bolotin, Schnabl, and Sladek 2009). The liver is also an important source of lipids during lactation (Vernon 2005), and HNF4 α controls hepatic lipid metabolism and transport (Xie et al. 2009; Rhee et al. 2006; Bolotin et al. 2009). We quantified HNF4 α protein in nuclear extracts prepared from virgin, non-lactating, and lactating mouse livers by a competitive ELISA (H4 ELISA, Camba-Colón 2005). We also performed qPCR to examine the level of HNF4 α mRNA. Our findings show a significant increase in HNF4 α expression postpartum both at the level of protein and the mRNA (Fig 2.11, Fig 2.12). However, there was no significant difference in the levels of HNF4 α between lactating and non-lactating mouse livers. Our qPCR result for HNF4 α points to a trend of a decrease in HNF4 α levels in lactating livers, which might lead to a decrease in HNF4 α protein levels at a later time point after lactation. Our data show that a long term effect of lactation may be an increase in HNF4 α expression, since this is the trend in our non-lactating mice. Further studies need to be done on pregnant, but never lactated mice in order to understand the role HNF4 α may play in lactation.

Conclusions:

We have looked at physiological changes that occurred during peak lactation in mice in order to examine the role of the maternal liver during this important process. We saw an increase in maternal whole body weight and an increase in maternal whole liver weight during lactation. Although overeating accompanies lactation in mammals, the lactating animal needs to modulate its metabolism in order to meet the nutrient and energy needs of the mammary gland. In our experiment, we see rapid weight loss, exhibiting a significant change in maternal whole body weight of fasted lactating mice in a 24-hour period. This could be explained by the utilization of maternal stores, such as maternal lipids, in order to sustain lactation. The increase in maternal whole liver weight during lactation also reflects the increased metabolic activity of the liver during lactation. Other maternal adaptations in response to lactation include an increase in plasma glycerol, a decrease in the incidence amount of fat stored in the liver, and an increase in plasma triglyceride levels. These adaptations are a consequence of the increased mobilization of fat stores (adipocyte lipolysis) and hepatic lipogenesis that occur as a means to meet the increased metabolic demands of lactation. Finally, there is the trend of an increase in HNF4 α gene expression postpartum which calls for more studies in pregnant but never lactated mice in order to investigate the possible role HNF4 α may play in lactation.

There is a growing body of evidence that points to lactation as having beneficial effects against maternal metabolic syndrome. Although in our system, it would

seem that the benefits of lactation only apply in currently lactating mice. The maternal metabolic adaptations in response to lactation need to be looked at more closely. A closer examination of the lactating liver transcriptome will help us understand the role of the maternal liver during lactation, and, in the process, help us understand the maternal and metabolic changes (maternal adaptations) we observed in currently lactating mice, including a possible role of the liver enriched transcription HNF4 α as well.

Chapter 3:

Expression Profile Analysis of Maternal Liver Genes During Lactation

Chapter 3:

Expression Profile Analysis of Maternal Liver Genes During Lactation

Introduction

Pregnancy and lactation

The ultimate goal of reproduction (pregnancy and lactation) is the survival of reproductively viable offspring. This goal brings about many maternal adaptations during reproduction. For example, the acquisition of fat stores during pregnancy, as well as the use of such fat stores during lactation and mammary gland development (mammogenesis), milk synthesis and secretion (lactogenesis 1 and 2) all occur before, during, and after pregnancy. These adaptations continue well beyond gestation and continue postpartum with lactation. Hence, maternal adaptations during reproduction place high demands on maternal organs, the liver in particular.

The liver and metabolic syndrome

The liver acts as a detoxification center and plays an essential role in metabolism for both the mother and her offspring. The high physiologic and metabolic demands of reproduction can sometimes bring about diseases during pregnancy, such as gestational diabetes, acute fatty liver of pregnancy, and pre-eclampsia to name a few. Aspects of these diseases involve liver functions and diseases which manifest during pregnancy, may be harbingers of later susceptibility to metabolic syndrome. Metabolic syndrome is a cluster of risk factors linked to diabetes and cardiovascular

disease (Ginsberg and Stalenhoef 2003; Alexander et al. 2003; Chan, Barrett, and Watts 2004). Studies have shown that lactation offers benefits the health of both mothers and their breast-fed offspring. For example, lactation ameliorates maternal diabetes (Stuebe *et al.* 2005) and lowers the incidence of maternal metabolic syndrome in menopausal women (Gunderson 2008; Ram et al. 2008; Schwarz et al. 2009).

Bioinformatics

We have laid the groundwork to understand the role of the maternal liver in lactation. Against this backdrop, broad strokes if you will, we begin the next step: adding details to our picture. We will use bioinformatics techniques to analyze microarray data (global gene expression profiling). Global gene expression profiling has been instrumental in increasing our understanding of the transcriptional basis of complex biological systems. It has allowed researchers to provide molecular signatures of diverse complex biological phenomena such as aging, reproduction, and growth and metabolism (Sharov *et al.* 2008; Helguera *et al.* 2009; Gleason *et al.* 2010). There is a growing body of evidence using gene expression profiling aimed at understanding the regulation of lactation, although most of the research has focused on bovine mammary gland (Lemay et al. 2007; Bionaz and Looor 2008; Ramanathan et al. 2008) and bovine liver (Looor *et al.* 2005; Wathes *et al.* 2007). Although there are some similarities between cows and humans (Elsik *et al.* 2009), the regulation of lactation is different. The mouse offers easy handling and quick

turnaround on processes such as lactation, which still make it an attractive and powerful experimental subject even though it also differs from the human in aspects of its reproductive physiology. To our knowledge, there are very few papers that examined molecular signatures of the mouse lactating liver, and none at the beginning of this project. Rudolph et al (Rudolph *et al.* 2007) used global expression profiling to examine lipid synthesis in the lactating mouse mammary gland and compared this to the lactating mouse liver, with an emphasis on the mammary gland. He et al. (He *et al.* 2007) used global expression profiling to examine the xenobiotic functions of the rat liver during pregnancy and lactation. In contrast, our study uses expression profiling of the liver to examine molecular signatures during peak lactation (day 10-12 postpartum) in the lactating mouse and compares those to livers from non-lactating (10-12 d postpartum) and age-matched virgin controls.

Goal of this study

The goal of this study is to examine the role of the liver in facilitating the additional demands of lactation. Transcription factors are vital in liver function, a close examination of liver-enriched transcription factor gene profiles is therefore warranted. Reproduction is regulated by hormones and growth factors, so we will look closely at hormone and growth factor receptor gene expression profiles. Since lipids are an important component of breast milk, we will be looking at genes involved in lipid production, lipid transport, and lipid secretion. Lipid homeostasis also plays an important role in diseases such as diabetes. Taken together, gene

expression profiles of these groups of genes may help us understand the role of the liver in lactation, and also the protective role that lactation plays against metabolic syndrome in the mother.

Materials and Methods

Animal care and treatment

Care and treatment of experimental animals was in accordance with guidelines from the University of California, Riverside, Institutional Animal Care and Use Committee (IACUC). Female, age-matched, virgin and timed pregnant C57Bl/6 mice were purchased from Charles River Laboratories (Charles River Laboratories, Wilmington, MA). All timed pregnant mice went through one successful round of reproduction (pregnancy, lactation, weaning) before mating for a second round. At parturition, 12 dams were allowed to lactate for 10-12 days postpartum (lactating) and pups were adjusted to 6 pups/lactating dam at parturition. For the pregnant but non-lactating group (n=12), all pups were taken away at parturition. Each lactating dam (L) was housed separately with 6 suckling pups per cage. Non-lactating dams (NL) were also housed separately at parturition. Virgin mice (V) were housed 5 mice per cage. All mice were kept in a temperature-controlled room, exposed to 12 h light cycle, 12 h dark cycle, and fed a regular chow diet (Harlan Teklad, TD7012; Harlan Teklad, Madison, WI).

Fasting, whole body weights, and blood collection

In order to control for the effects that diet may have on lactation, each mouse (with suckling pups when applicable) was fasted at 18-21 h before sacrifice in the following manner. Each mouse (and their suckling pups when applicable) was transferred to a new cage without food. Virgin mice (5 per cage) were also

transferred to a new cage. The bedding of each cage was changed to Sani-Chips (cat # 7090, Harlan Teklad, Madison, WI), non-edible wood chips that do not provide a source of nutrients as does standard bedding. All mice were allowed a bottle of water during the fast. At around 15 h post fasting, (9:00 a.m. the next day) whole body weights were recorded for each mouse. Mice in their cages were then placed under a 60-watt heat lamp for 10 minutes. Each mouse was restrained, and their tails were nicked. Whole blood was then collected in two heparanized hematocrit tubes (Fisher Scientific, catalog # 21-176-6) per animal. Whole bloods were spun (microcentrifuge specifics) for 10 min at 4°C. Blood plasmas (supernatants) were collected, transferred to new Eppendorf tubes, and stored at -20°C. After blood collection, mice were returned to their cages and allowed to recover before being sacrificed at around noon (18-21 h total fasting).

Tissue harvesting

Mice were euthanized by CO₂ exposure for 40 seconds. Whole body weights were recorded and tissues were harvested in a cold room (4°C). The portal artery was cut and allowed to bleed before each liver was taken out and weighed. The largest liver lobe (lobe 1) was harvested and stored for the following assays: two samples (10-30 mg) for RNA isolation, one sample (100 mg) for triglyceride (TG) assay, one sample (100 mg) for sectioning, the rest of lobe 1 (300 mg), for storage. The remaining liver (lobes two-six; 200 – 300 mg) was chopped up with a razor blade and stored in two aliquots for nuclear extraction. All liver samples were stored in screw cap cryovials

(Nunc, cat # 12-565-170N, Thermo Fisher Scientific, Waltham, MA) in liquid nitrogen.

RNA Isolation

Liver chunks from each mouse (10-30 mg) ear-marked for RNA isolation were incubated overnight at 4°C in 500 µL RNALater (cat # AM7023, Ambion, Austin, TX), an RNA stabilization solution. RNALater was pipeted out the next day, and the remaining liver chunk was stored at -80°C. RNA was then isolated from RNA-stabilized frozen liver chunks using the RNeasy mini kit (Qiagen, Valencia, CA). Briefly, each liver chunk was homogenized in complete cRLT buffer (1% beta mercaptoethanol in RLT buffer) in a 1.5 mL tube using a motor homogenizer until completely homogeneous. Homogenized lysates were centrifuged in room temperature at maximum speed (Eppendorf 5424,) for 2 min. to clear the lysate. The supernatant (cleared lysate) was transferred to a new 1.5 mL tube. An equal volume of 70% ethanol was added to the cleared lysate and immediately mixed by pipetting. Up to 700 µL cleared lysate in 70% ethanol was added to the spin column (spin columns come with collection tubes). Spin columns were then centrifuged at maximum speed for 15 sec at room temperature. The flow-through was discarded, and the remaining cleared lysate in 70% ethanol was added to the same spin column and centrifuged at maximum speed for 15 sec at room temperature, and the flow-through was discarded. The spin column was washed with Buffer RW1 by centrifuging at maximum speed for 15 sec at room temperature, and the flow-

through discarded. The same column was washed this time with 500 μL of Buffer RPE by centrifuging at maximum speed for 15 sec at room temperature, then discarding the flow-through. The same tube was washed a second time with 500 μL of Buffer RPE, this time centrifuging at maximum speed for 2 min at room temperature to dry the spin column. Spin columns were then centrifuged at maximum speed for 1 min at room temperature, this time using fresh collection tubes, to remove all ethanol. RNA was eluted by placing spin columns in fresh Eppendorf tubes and adding 50 μL RNase free water then centrifuging at maximum speed for 1 min at room temperature. The flow-through (eluate) in the 1.5 mL tube is the RNA. A second elution was done by adding the eluate from the previous step to the collection tube and then centrifuged a final time at maximum speed for 1 min at room temperature. RNA concentration and quality were checked by nanodrop. RNA was stored at -80°C .

Quantitative Real Time Polymerase Chain Reaction (qPCR)

Digestion of genomic DNA

Digestion reactions were prepared for each RNA sample as per the manufacturer's instructions (cat # 10 776 785 001, Roche Applied Science, Penzberg, Germany): DNase I mastermix (1x final concentration of 10x Incubation buffer, 0.5 units final concentration of Dnase I recombinant RNase-free reagent for a total of 1.5 μL /reaction) was prepared for the appropriate number of reactions. RNA (final concentration of 0.3 mg/reaction) was added to 1.5 μL DNase I mastermix,

then adjusted with RNase-free water for a total volume of 10 μ L. Each reaction was incubated at room temperature for 20 min. DNase inactivation reagent (2 μ L) (AM1906, Ambion, Austin, Tx) was added to each reaction and incubated at room temperature for 2 min. Reactions were then spun at 15,000 RPM for 1.5 min at room temperature. Each supernatant (DNase I-treated RNAs) were transferred to new 1.5-mL tubes and stored at -80°C.

cDNA preparation

cDNAs were prepared using the SuperScriptTM III Synthesis System for RT-PCR (Invitrogen, Carlsbad, CA) as per the manufacturer's instructions. DNase I-treated RNAs were thawed on ice. The appropriate amount of primer mastermix (P-MM) (for one reaction: 1 μ L 50 ng/ μ L random hexamers, 1 μ L 10 mM dNTP mix) was prepared. DNase I-treated RNA (1 μ g) was added to 2 μ L of P-MM. Diethyl polycarbonate (DEPC)-treated water was added to each reaction tube for a total volume of 10 μ L/reaction tube. Each reaction tube was then gently vortexed, then spun at 13,000 RPM at 4°C for 15 sec. All reaction tubes (RNA-P) were then incubated at 65°C for 5 min and placed on ice. The appropriate amount of cDNA synthesis mix master mix (cS-MM) was prepared (for one reaction: 10X RT buffer (2 μ L), (4 μ L) 25 mM MgCl₂, 0.1 M DTT (2 μ L), RNaseoUTTM (1 μ L, 40 U/mL), SuperScriptTM III reverse transcriptase (1 μ L, 200 U/mL). cS-MM (10 μ L) was added to each RNA-P mixture. All tubes were vortexed and spun 13,000 RPM at 4°C for 20 sec. All tubes were incubated in the PCR thermocycler with the following

settings: step 1 at 25°C for 10 min, step 2 at 50°C for 50 min, step 3 at 85°C for 5 min, and step 4 at 4°C. All samples were then taken out of the thermocycler and placed on ice. Samples were then centrifuged at 13000 RPM at 4°C for 20s. Rnase H (1µL) was added to each sample. All samples were gently vortexed then centrifuged at 13,000 RPM at 4°C for 20 sec, then incubated at 27°C for 20 min. These are the cDNAs. All cDNAs were diluted 1:10 with DEPC-treated water. Standards for quantitative real time PCR (qPCR) were prepared by pooling all cDNA samples (180 µL total volume). Individual cDNAs and pooled cDNA were stored at -20°C for future use.

Primer Design

Primers for mouse hepatocyte nuclear factor 4alpha (*HNF4α*), peroxisome proliferator –activated receptor gamma coactivator-1alpha (*Ppargc1a* or *Pgc1α*), cyclophilin A (*Ppia*), the long form of prolactin receptor (Prlr-L), and the 3 short forms of prolactin receptor (Prlr-S1, Prlr-S2, Prlr-S3) were designed by first going to Pubmed to identify the cDNA sequence of the genes (<http://www.ncbi.nih.gov/entrez/query.fcgi>). Exons were found by using the UCSC Genome database (<http://genome.ucsc.edu>). Specific primers for the gene in question were designed using the Primer3 program (http://frodo.wi.mit.edu/cgi-bin/primer3/primer3_www.cgi). This gave the melting temperature and product size of the primers. The specificity of the primers was checked by using the in silico PCR function in the UCSC Genome browser (<http://www.genome.ucsc.edu>).

Primers were further optimized by using the Scitools program on the IDT website (<http://idtdna.com/Scitools/Scitools.aspx>) to predict the hairpin structure, homodimerization ΔG and, heterodimerization ΔG . Primers were designed to go across two exons, have a product size <200 bp, homodimerization $\Delta G \geq -10$, and heterodimerization $\Delta G \geq -10$.

Table 1: Primers for genes used in real time PCR (qPCR). Primers for Hnf4a were modified from Briancon et al 2004. Primers for prolactin receptor isoforms (Prlr-L, Prlr-S1, Prlr-S2, Prlr-S3) were based on accession numbers from Fleenor et al 2006.

Quantitative real time PCR (qPCR)

Gene specific primers were validated before hand as previously described (Yuan *et al.* 2009). Briefly: Primers were validated over four orders of magnitude and analyzed with the iQ5 Optical System Software. Primer pairs were deemed valid if an input log plot amount versus CT generated an efficiency of $100\% \pm 10\%$ and a correlation coefficient of $R^2=0.950 \pm 0.05$. Each condition (virgin, non-lactating, lactating) had three biological replicates. Each biological replicate was done in triplicate (technical replicate). The relative expression level of the genes was

evaluated using the Pfaffl method (Pfaffl 2001), normalized to cyclophilin A (*Ppia*) expression.

Microarray

Microarray study design

Three conditions were studied: virgin (V), non-lactating (NL), and lactating (L) as described in chapter 2. RNA samples isolated from mice were pooled and hybridized to Affymetrix MG_430A 2.0 chips as per the manufacturer's protocol in the Genomics Core at the UCR Institute for Integrated Genome Biology. Two microarray chips were used for each condition. Each virgin (V) array had 3 biological replicates/chip, for a total of 6 animals for this condition. Each non-lactating (NL) array also had 3 biological replicates/chip for, for a total of 6 animals for this condition. Each lactating (L) array had 2 biological replicates/chip for a total of 4 animals for this condition.

Microarray data analysis

Raw data from all 6 arrays were analyzed using GC Robust Multi-Array Average (GCRMA) background adjustment and quantile normalization on probe-level data sets with R software (<http://www.bioconductor.org>) by the lab's bioinformatics expert, Eugene Bolotin. Genes that were up regulated or down regulated at least 1.5-fold (L vs V) were looked at more closely. The gene sets were filtered further by eliminating genes whose non-log expression values were below 100.

Statistical Analysis

Statistical analysis was performed using the Student's t test. Differences were considered statistically significant at $p < 0.05$. Uncertainty in our measurements was determined by calculating the standard deviation.

Gene ontology (GO) analysis

Genes that were up regulated or down regulated at least 1.5 fold were further analyzed using the Database for Annotation, Visualization and Integrated Discovery (DAVID) (Huang da, Sherman, and Lempicki 2009; Dennis et al. 2003). Data are presented in a Functional Annotation Chart. The functional annotation chart lists annotation terms and their associated genes under study. Associated genes were subjected to Fisher Exact statistics to avoid over counting duplicated genes. This report includes percent genes and p value. Percent genes is calculated by dividing the genes identified for the arrays by the total number of genes in that category. P value is based on Fisher Exact statistics. The smaller the p value, the more overrepresented the gene is associated with the annotation term. Further analysis of annotated terms were done thru AmiGO (<http://amigo.geneontology.org>) (Blake and Harris 2008). Briefly, each annotated term in question (biological process) was uploaded to the AmiGO website and submitted under terms. This would list the term in question along with similar terms. The term is then viewed in a tree. The tree is similar to a family tree where the term in question is the child and is linked to

a parent term. A graphical view of the tree starts with the term in question (child), which is a part of the next term (parent) which is then a part of the next term (parent of the parent) and so on. The parent is a broader biological process, and the child is a specific example of the broad biological process. As is the case in biology, there is overlap within definitions of broad biological processes, and this results in linking a specific biological process to more than one broad biological process.

Results:

Experimental conditions

In order to study the role of the maternal liver in lactation, we studied age-matched mice that were virgin (V), non-lactating (NL), and lactating. Virgin mice were never mated. Non-lactating mice and lactating mice had two rounds of reproduction (complete pregnancy, complete lactation, weaning) before the current mating for this study. In order to normalize the mice and remove the confounding effects of diet, the mice were fasted.

Verification of microarray data for selected genes by real time PCR (qPCR)

The use of microarrays along with real time PCR have been shown to be powerful tools to identify and validate differentially expressed genes in diverse applications that range from disease models to parturition (Zou et al. 2002; Hassan et al. 2006; Rajeevan et al. 2001). In this study, we validated the microarray expression values of the liver enriched transcription factor hepatocyte nuclear factor 4alpha (HNF4 α) (*Hnf4a*) mRNA and the transcriptional coactivator peroxisome proliferator-activated receptor gamma coactivator-1alpha (Pgc1 α) (*Ppargc1a*) from the livers of virgin (V), non-lactating (NL), and lactating (L) mice by quantifying their mRNA expression by real time PCR (Fig 3.1). Both genes play important roles in liver function and metabolism (Hayhurst et al. 2001; Rhee et al. 2006; Rhee et al. 2003). *Hnf4a* gene expression was higher in the livers of non-lactating mice (NL) compared to virgin mice (V). *Hnf4a* gene expression was also higher in the livers of lactating

mice (L) compared to virgin mice, but was lower than non-lactating mice. *Ppargc1a* (PGC1 α) had a similar expression profile: the gene was up regulated with non-lactation (compared to the virgin state) and up regulated less with lactation.

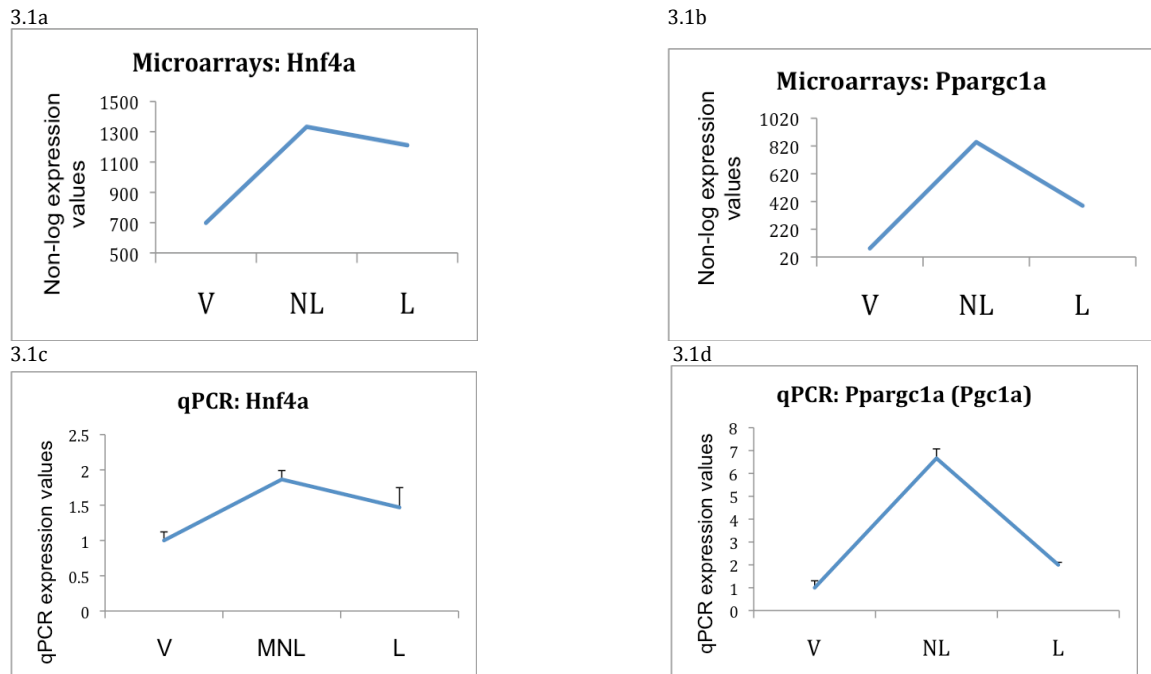

Fig 3.1 Verification of HNF4 α (*Hnf4a*) and PGC1 α (*Ppargc1a*) microarray data by quantitative real time PCR (qPCR)

Gene expression profiles of *Hnf4a* (Panel 3.1a) or *Ppargc1a* mRNA (Panel 3.1b) in livers of virgin (V, n=4), non-lactating (NL, n=4) and lactating (L, n=4) mice as determined by microarray analysis. mRNA of *Hnf4a* and *Ppargc1a* were quantified by real time PCR (qPCR) (Panel 3.1c and Panel 3.1d) (n_V=4, n_{NL}=4, n_L=4). For qPCR primers, refer to materials and methods and Table 1.

Prolactin is the major hormone responsible for lactation (Ostrom 1990; Svennersten-Sjaunja and Olsson 2005). The actions of prolactin are mediated by the prolactin receptor (PRLR). There are four forms of PRLR, three short forms and one long form. The long form is predominantly found in the mammary gland, while the short forms are predominant in the liver, although all forms are present in both

tissues (Jahn *et al.* 1997). The long form of prolactin receptor activates signaling pathways culminating in milk protein gene transcription (Gouilleux *et al.* 1994; Lesueur *et al.* 1991; Das and Vonderhaar 1995). In order to study the differences in expression, if any, between the short forms and long form of Prlr, we quantified mRNA of the long form of prolactin receptor (Prlr-L) and the short forms of prolactin receptor (Prlr-S1, Prlr-S2, Prlr-S3) in the livers of virgin (V), non-lactating (NL), and lactating (L) mice. The molecular signature of prolactin receptor is as follows: no significant change in gene expression in the livers of non-lactating mice compared to virgin mice, but a noticeable increase in the livers of lactating mice. Real time PCR quantification of mRNA for the long and short isoforms of prolactin receptor showed a similar trend (Fig 3.2a-3.2d).

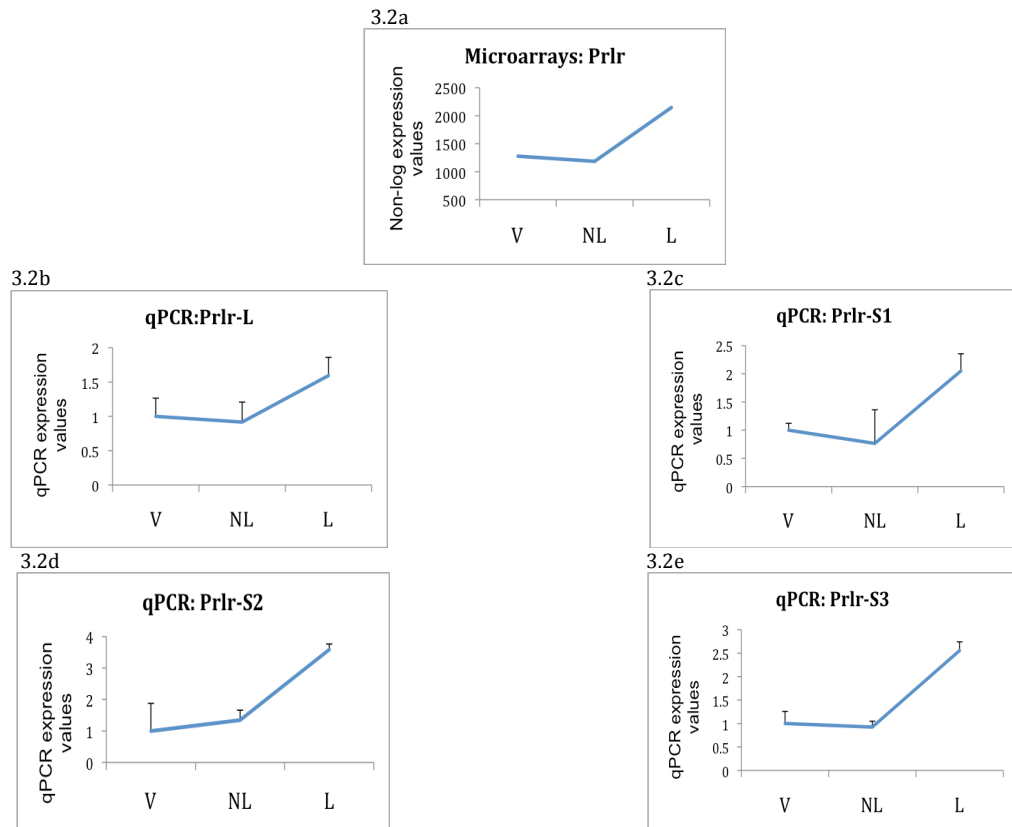

Fig 3.2 Verification of *Prlr* microarray data by quantitative real time PCR (qPCR). The molecular signature of prolactin receptor (*Prlr*) in the livers of virgin (V, n=4), non-lactating (NL, n=4), and lactating (L, n=4) mice was determined by microarray analysis. mRNA of the long isoform of prolactin receptor (*Prlr-L*) and three short isoforms of prolactin receptor (*Prlr-S1*, *Prlr-S2*, *Prlr-S3*) in the livers of virgin (V, n=4), non-lactating (NL, n=4) and lactating (L, n=4) mice were quantified by real time PCR (qPCR).

Number of genes up and down regulated postpartum 1.5-fold or more

In order to obtain a global perspective of the liver during lactation, we examined genes that were up regulated or down regulated at least 1.5-fold in the livers of non-lactating (NL) and lactating (L) mice (Fig 3.3). Liver gene expression values of NL and L mice were compared to liver gene expression values of virgin (V) mice. There were 2552 genes (~ 18%) that were differentially up and down regulated after parturition (Fig 3.3). A total of 1232 genes were up regulated postpartum (~ 8.75%) while total of 1320 genes (~ 9.37%) were down regulated postpartum. (For

tables of genes up regulated or down regulated during lactation or non-lactation, please see Appendix A). There were slightly more genes down regulated at least 1.5-fold postpartum (% genes_{downreg} = 9.37, % genes_{supreg}=8.75, NL vs V or L vs V). A similar percentage of postpartum genes were up-regulated with non-lactation only or with lactation only (% genes_{NLonly}=3.73, % genes_{Lonly}=3.20%). In contrast, there was only a small percentage of genes up regulated under both postpartum conditions (% genes_{common}=1.81%). In comparison, the percentage of postpartum genes down regulated with non-lactation is greater than those with lactation only (% genes_{NLonly}=3.58, % genes_{Lonly}=1.87), while the percentage of common genes down regulated postpartum is similar to genes down regulated with non-lactation only (% genes_{common}=3.93). The large number of genes differentially up regulated or down regulated postpartum (with or without lactation) reflects the profound effect that pregnancy and parturition have on the maternal liver. Although our results indicate that a large number of genes that are differentially expressed in currently lactating livers (714, Fig 3.3), we can not discount the effects of past lactation, since our currently non-lactating mice lactated in the past. Although the physiological importance of the maternal liver in pregnancy and lactation has been recognized, few have documented this on the molecular level in a global scale. Ramanathan et al (Ramanathan *et al.* 2008) examined the mammary gland of highly fecund mouse strains during pregnancy and lactation. Casey et al (Casey *et al.* 2009) studied the homeostatic response to lactation in late pregnant (day 20) and early lactation (day 1) (Bell 1995; Bauman 2000). Our study is unique in that we are studying the

maternal liver of virgin, non-lactating, and lactating mice, the latter during peak lactation. The non-lactating state allows us to examine long term effects of lactation because these mice lactated in the past. In this way, we hope to learn more about the role of the maternal liver in lactation, and any long term effects lactation may bring.

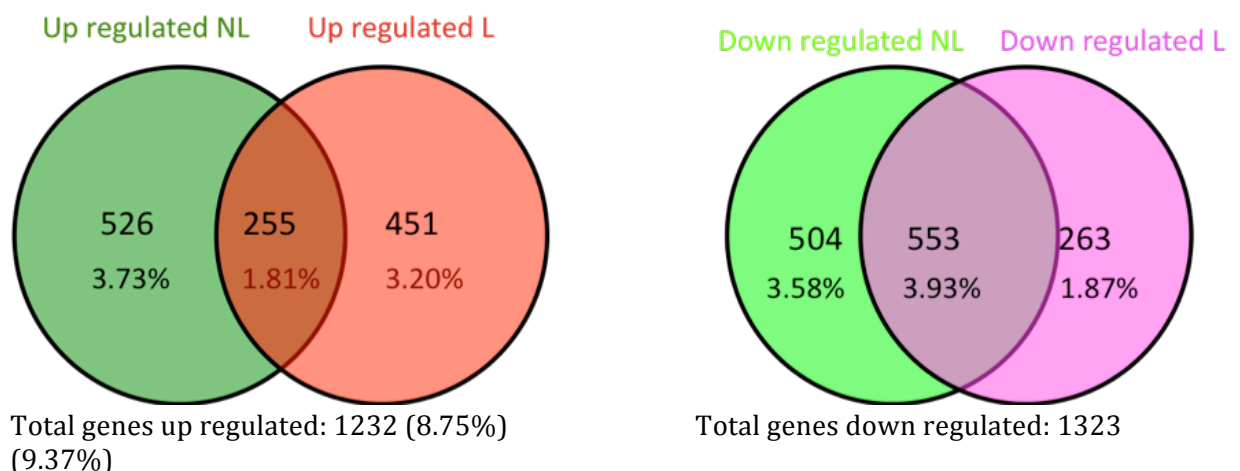

Fig 3.3: Genes up regulated and down regulated during lactation and non-lactation
 Non-log values of relative gene expression of genes during lactation or non-lactation were compared to relative gene expression in virgins. Venn diagrams were created by copying and pasting a list of genes that were up regulated or down regulated at least 1.5-fold (compared to virgins) during lactation or non-lactation to the VENNY website (<http://bioinfogp.cnb.csic.es/tools/venny/index.html>, created by Juan Carlos Oliveros), an interactive tool for comparing lists by using Venn diagrams. NL = non-lactating, L = lactating.

Overrepresented Biological Processes when genes are differentially expressed at least 1.5-fold with lactation only

There are many biological processes that are affected during reproduction as a consequence of the up regulation and the down regulation of genes. In order to understand the role of the maternal liver in lactation, we used gene ontology to analyze biological processes that occur postpartum when genes are up regulated

(Fig 3.4) or down regulated (Fig 3.5) at least 1.5-fold (compared to the virgin state) with lactation.

The biological processes that are most overrepresented when genes are up regulated during lactation are metabolic processes (Fig 3.4). Some specific examples of metabolic processes include: hormone metabolic process (p value=1.99E-09), cholesterol metabolic process (p value=3.32E-08), and lipid metabolic process (p value=1.50E-04), catabolic process (p value=1.36E-02), and electron transport (p value=2.21E-02). Another overrepresented broad biological process when genes are up regulated during lactation is response to stress. Specific examples of response to stress include inflammatory response (p value=2.57E-03), innate immune response (p value=2.06E-02), and response to external stimulus (p value=2.87E-02). A third significant broad biological process is biological regulation. Specific examples of biological regulation include estrogen receptor signaling pathway (p value=1.70E-04), regulation of catalytic activity (p value=2.24E-04), regulation of a molecular function (p value=2.20E-02), regulation of MAP kinase activity (p value=2.53E-02), and regulation of body fluid levels (p value= 4.59E-02). Other overrepresented biological processes include cell cycle process (p value=3.26E-02), and blood coagulation (p value=1.29E-02).

The most enriched biological processes when genes are down regulated with lactation are also metabolic processes (p value= 8.88E-06), although the sub-categories tend to be different from the up regulated genes. For example, cofactor metabolic process (9.14E-03) and cell lipid metabolic process (p value=1.76E-02)

are significantly down but not up with lactation. Another biological process that is overrepresented when genes are down regulated during lactation is localization. Examples of localization include: macromolecule localization (p value = 1.09E-04), protein localization (p value=9.54E-04), and cell localization (p value= 1.65E-02). Other overrepresented biological processes include RNA transport (p value=1.20E-03), response to protein stimulus (p value=1.95E-03), and fatty acid oxidation (p value=4.20E-02).

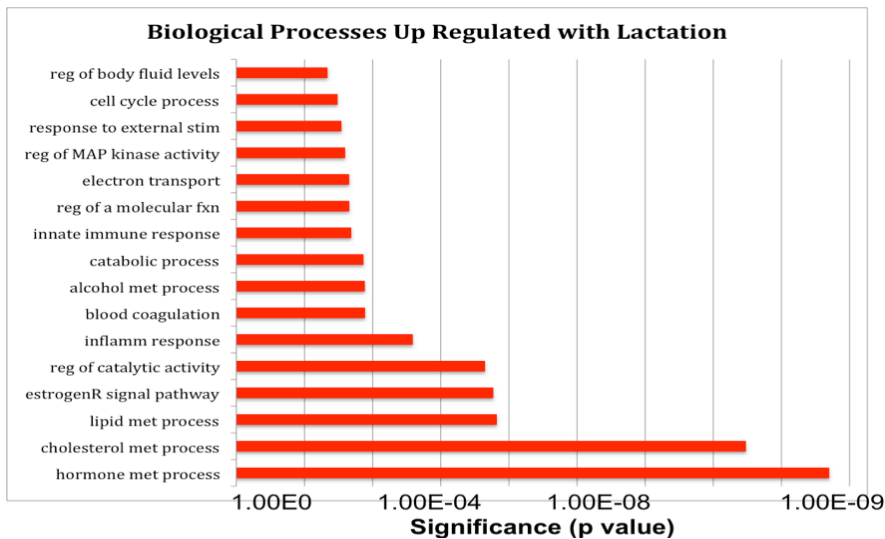

Fig 3.4 Overrepresented biological processes among genes up regulated with lactation only. Gene ontology analysis was used to evaluate the genes that are up regulated at least 1.5-fold in liver genes from lactating mice (compared to virgin mice). See Materials and Methods section for more details.

Fig 3.5 Overrepresented biological processes among genes down regulated with lactation only. Gene ontology analysis was used to evaluate the genes that are down regulated at least 1.5-fold in liver genes from non-lactating mice (compared to virgin mice). See Materials and Methods for more details.

Overrepresented Biological Processes when genes are differentially expressed at least 1.5-fold without lactation (NL) only

We used Gene Ontology to analyze biological processes that are overrepresented when genes are up regulated (Fig 3.6) or down regulated (Fig 3.7) postpartum in non-lactating animals only. This serves as a control for the lactation analysis and provides further insight into the effect of pregnancy and parturition in the maternal liver without the confounding effect of lactation.

Again, metabolic processes were significantly overrepresented in genes that were up regulated in the non-lactating mice. Specific examples include: macromolecule metabolic process (p value=5.92E-17), gene expression (p value=4.89E-14), protein

metabolic process (p value=5.31E-07), RNA splicing (p value=8.63E-05), and DNA metabolic process (p value=2.96E-04). Additional biological processes that were overrepresented are cellular processes, localization, biological regulation, and developmental processes. Specific examples of cellular processes include: cellular component organization and biogenesis (p value=8.37E-07), chromatin modification (p value=3.40E-06), cellular process (p value=8.23E-06), organelle organization and biogenesis (p value=1.19E-04), and cell cycle cell (p value=6.07E-04). Specific examples of localization include: RNA transport (p value=2.14E-05), nuclear transport (p value=8.98E-04), and protein transport across a membrane (p value= 2.15E-03). Specific examples of biological regulation and developmental processes include the negative regulation of biological process (p value=2.76E-03) and cell development (p value=1.33E-02).

Fig 3.6 Overrepresented biological processes among genes up regulated with non-lactation. Gene ontology analysis was used to evaluate the genes that are up regulated at least 1.5-fold in liver genes from non-lactating mice (compared to virgin mice). See Materials and Methods section for more details.

Finally, there were several biological processes that were significantly overrepresented in the genes down regulated postpartum without lactation (non-lactation) (Fig 3.7). The most significant category is immune system process/response to stress, including adaptive immune response (p value = 7.07E-04) and T cell proliferation (p value=8.11E-04).

Fig 3.7 Overrepresented biological processes among genes down regulated with non-lactation. Gene ontology analysis was used to evaluate the genes that are up regulated at least 1.5-fold in liver genes from non-lactating mice (compared to virgin mice). See Materials and Methods section for more details.

Gene expression profiles of transcription factors

In order to shed light on the mechanisms responsible for all the changes in gene expression during pregnancy and lactation, we looked at the gene expression profiles of liver enriched transcription factors and co-activators (Fig 3.8). Expression of these genes in maternal livers from non-lactating (NL) or lactating mothers were compared to those from livers of age-matched virgin females. Several

liver enriched transcription factor genes were up regulated postpartum. Hepatocyte nuclear factor 4alpha (*Hnf4a*), CCAAT/enhancer binding protein beta (*Cebpb*), retinoid X receptor beta (*Rxb*), forkhead box P1 (*Foxp1*), forkhead box O1 (*Foxo1*), forkhead box A3 (*Foxa3*), and the co-activator peroxisome proliferative activated receptor gamma coactivator 1 alpha (*Ppargc1a* or *Pgc1a*) all had similar expression profiles: expression increased robustly postpartum but less so with lactation (Fig 3.8a-3.8g). This is consistent with the greater numbers of genes up regulated in the non-lactating samples (781 genes) compared to the lactating samples (706 genes). *Hnf4a* (*HNF4α*) gene expression increased 1.90-fold with non-lactation, and 1.73-fold with lactation (Fig 3.8a). This is in line with the postpartum increase in HNF4α protein expression that we observed in chapter 2 (Fig 2.11). *Cebpb* (*C/EBP/β*) gene expression increased 2.29-fold with non-lactation and 1.74-fold with lactation (Fig 3.8b). *Rxb* gene expression increased 1.83-fold with non-lactation and 1.56-fold with lactation (Fig 3.8c). *Foxp1* gene expression increased 3.16-fold with non-lactation and 1.82-fold with lactation (Fig 3.8d). *Foxo1* gene expression increased 2.14-fold with non-lactation and 1.54-fold with lactation (Fig 3.8e). *Foxo3a* gene expression increased 2.36-fold with non-lactation and 2.21-fold with lactation (Fig 3.8f). Finally, the co-activator PGC1α (*Ppargc1a*) increased 10.37-fold with non-lactation and 4.76-fold with lactation (Fig 3.8g).

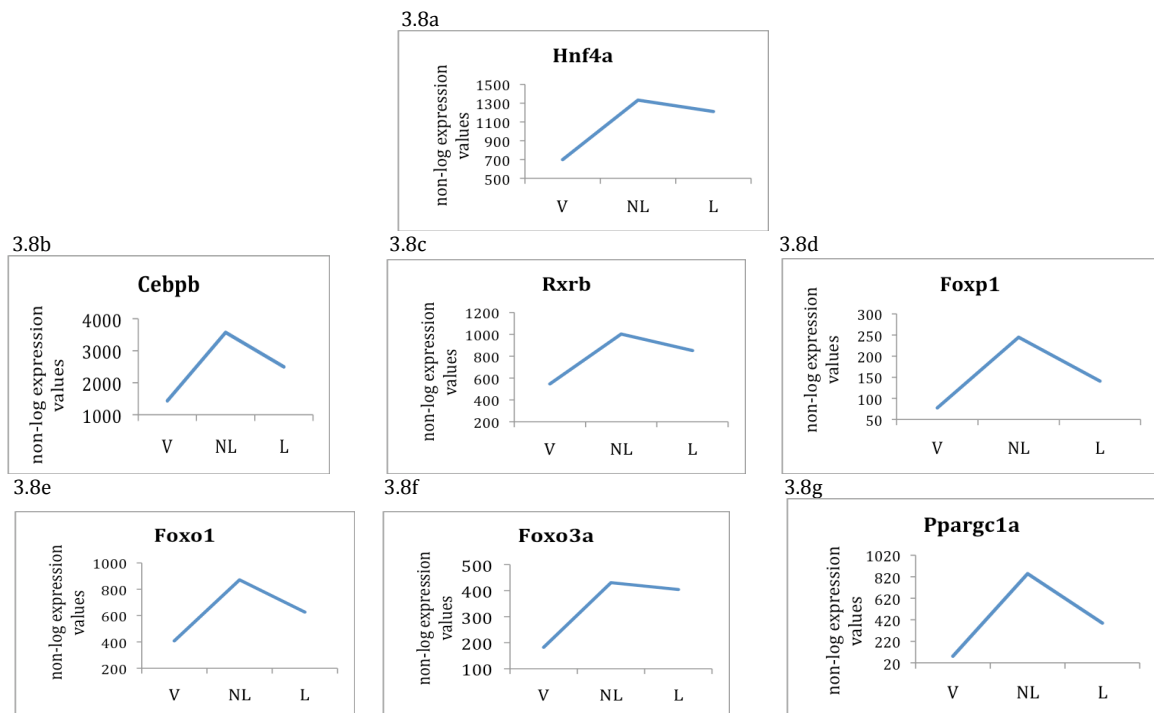

Fig 3.8 Molecular signatures of liver enriched transcription factor genes that are up regulated postpartum. Microarray data was analyzed using GC Robust Multi-Array Average (GCRMA) background adjustment and quantile normalization on probe-level data sets with R software (<http://www.bioconductor.org>). Genes that were differentially expressed at least 1.5-fold compared to virgin expression values were analyzed. From this group of genes, genes that had expression values >100 (non-log) were eliminated. Genes were normalized to GAPDH expression.

We also identified transcription factor genes that were down regulated postpartum. Transcription factor 2 (*Tcf2*), also known as hepatocyte nuclear factor 1 beta (*Hnf1b*), peroxisome proliferator activated receptor gamma (*Pparg*), and one cut domain family member 1 Onecut1, also known as hepatocyte nuclear factor 6 beta (*Hnf6b*) gene expression decreased considerably with non-lactation, and increased slightly with lactation (Fig 3.9a-3.9c). *Hnf1b* gene expression decreased 2.15-fold with non-lactation 2.05-fold with lactation (Fig 3.9a). *Pparg* gene expression decreased 2.33-fold with non-lactation 2.23-fold with lactation (Fig 3.9b). *Hnf6b* gene expression decreased 2.45-fold with non-lactation and 2.06-fold

with lactation (Fig 3.6c). The decrease in expression of these transcriptional activators could be responsible for the down regulation of genes with lactation and with non-lactation (Fig 3.3).

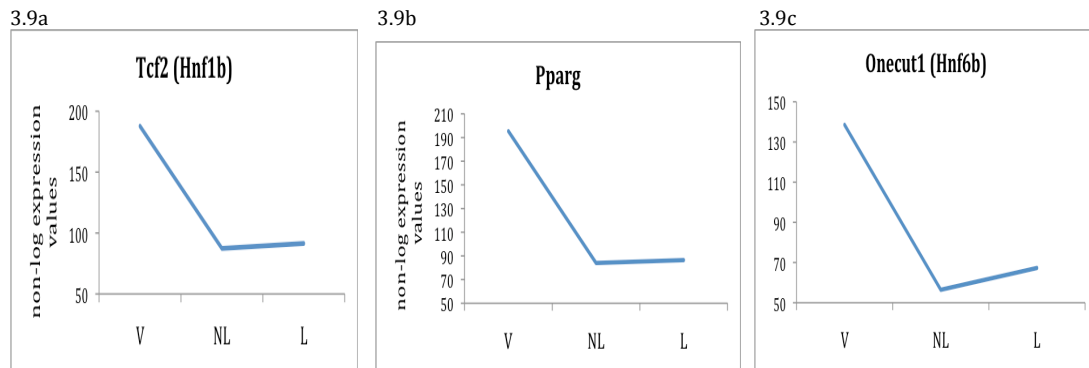

Fig 3.9: Molecular signatures of other liver enriched transcription factors were down regulated postpartum Gene expression profiles from the livers of virgin (V), non-lactating (NL), and lactating (L) mice of the indicated genes as described in Fig 3.8.

Expression profiles of hormone receptor genes

Hormones and their receptors are known to play key roles in lactation (Svennersten-Sjaunja and Olsson 2005). For this reason, we also looked at the postpartum molecular signatures of hormone receptors that were differentially expressed at least 1.5-fold with lactation (Fig 3.10a-3.10c). These hormone receptor genes included leptin receptor (*Lepr*), prolactin receptor (*Prlr*), and growth hormone receptor (*Ghr*). Leptin receptor gene expression increased 2.36-fold with non-lactation but less (1.86-fold) with lactation (Fig 3.10a). In contrast, the lactogenic hormone receptors *Prlr* and *Ghr* exhibited similar expression profiles: a slight decrease with non-lactation (1.09-fold for *Ghr*, and 1.07-fold for *Prlr*), and a

much larger increase with lactation (1.70-fold for *Ghr*, and 1.68-fold for *Prlr*) as one might expect (Fig 3.10b, Fig 3.10c).

Fig 3.10 Postpartum molecular signatures of hormone receptor genes involved in lactation. Gene expression profiles from the livers of virgin (V), non-lactating (NL), and lactating (L) mice of the indicated genes as described in Fig 3.8.

Expression profiles of growth factors genes

Growth factors play an important role in lactation. For this reason, we examined the gene expression profiles of several growth factors and/or receptors that have been implicated in lactation in the maternal liver. Several growth factors were differentially up regulated postpartum (Fig 3.11a-3.11c). Insulin-like growth factor 1 (*Igf1*), epidermal growth factor receptor (*Egfr*), and insulin-like growth factor binding protein 1 (*Igfbp1*) were all up regulated postpartum in the non-lactating samples. *Igf1* and *Egfr* genes also had further up regulation under lactation. *Igf1* gene expression increased 1.18-fold with non-lactation and 1.69-fold with lactation (Fig 3.11a) while *Egfr* increased 1.75-fold with non-lactation and 2.23-fold with lactation (Fig 3.11b). *Igfbp1* exhibited a different expression profile: an up regulation with non-lactation (2.48-fold), but less of an up regulation with lactation (1.64-fold). In contrast, transforming growth factor alpha (*Tgfa*), transforming

growth factor beta induced (*Tgfb1*), and insulin-like growth factor binding protein 7 (*Igfbp7*) genes were significantly down regulated postpartum, but less so with lactation. *Tgfa* gene expression decreased 1.74-fold with non-lactation and 1.58-fold with lactation (Fig 3.12a). *Tgfb1* gene expression decreased 1.80-fold with non-lactation and 1.51-fold with lactation (Fig 3.12b). Finally, *Igfbp7* gene expression decreased 1.74-fold with non-lactation and 1.64-fold with lactation (Fig 3.12c).

Fig 3.11: Growth factor/receptor genes are differentially up regulated postpartum
Gene expression profiles from the livers of virgin (V), non-lactating (NL), and lactating (L) mice of the indicated genes as described in Fig 3.8.

Fig 3.12: Growth factor genes are differentially down regulated postpartum
Gene expression profiles from the livers of virgin (V), non-lactating (NL), and lactating (L) mice of the indicated genes as described in Fig 3.8.

Expression profiles of pregnancy genes

A successful pregnancy contributes to a successful lactation, both of which are important in achieving the goal of reproduction. For this reason, we looked at gene expression profiles of genes that play a role in the maintenance of pregnancy (Bethin *et al.* 2003). Cluster of differentiation 14 (*Cd14*), Prostaglandin F receptor (*Ptgfr*), Prostaglandin-endoperoxide synthase 1 (*Ptgs1*) also known as Cytochrome C oxidase 1 (*Cox1*), LIM domain containing preferred translocation partner in lipoma (*LPP*) genes were all up regulated postpartum as expected. *Cd14* gene exhibited the following expression profile: a marked up regulation with non-lactation (11.97-fold), but less up regulation with lactation (10.30-fold) (Fig 3.13a). In contrast, *Ptgfr*, *Cox1*, and *Lpp* were all up regulated with non-lactation and further up regulated with lactation (Fig 3.13b-3.13d). *Ptgfr* gene had the highest expression fold-change of all 17,000 genes during non-lactation and lactation: 43.47-fold increase with non-lactation and 55.94-fold with lactation (Fig 3.10c). *Cox1* and *Lpp* genes had much more modest changes: *Cox1* increased 1.19-fold with non-lactation and 1.58-fold with lactation (Fig 3.13d), while *Lpp* increased 1.44-fold with non-lactation and 1.71-fold with lactation (Fig 3.13e).

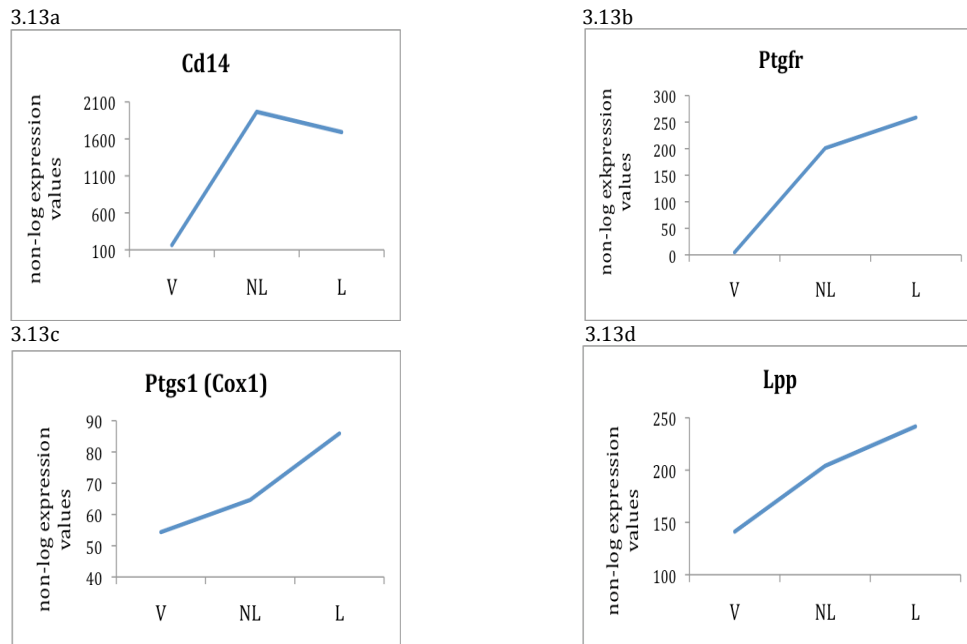

Fig 3.13: Pregnancy genes are up regulated postpartum
Gene expression profiles from the livers of virgin (V), non-lactating (NL), and lactating (L) mice of the indicated genes as described in Fig 3.8.

Gene expression profiles of other lactation genes

Genes involved in lactation have been characterized extensively in mammary gland studies (Lemay et al. 2007; Naylor et al. 2005; Rudolph et al. 2007; Anderson et al. 2007; Ramanathan et al. 2008). In contrast, relatively little is known about the expression of those genes associated with lactation in the maternal liver. Some lactation genes were down regulated postpartum (Fig 3.14), while others were up regulated postpartum (Fig 3.15). Phospholipid scramblase 1 (*Plscr1*) and Proviral integration site 1 (*Pim1*) genes share similar expression profiles: a large decrease in expression with non-lactation and slightly less of a decrease with lactation. *Plscr1* gene expression decreased 2.40-fold with non-lactation, and 2.17-fold with lactation

(Fig 3.14a). *Pim1* decreased 1.76-fold with non-lactation and 1.71-fold with lactation (Fig 3.14b).

Fig 3.14 Lactation genes are down regulated postpartum in the maternal liver. Gene expression profiles from the livers of virgin (V), non-lactating (NL), and lactating (L) mice of the indicated genes as described in Fig 3.8.

Other genes that play a role in lactation were up regulated postpartum, just as they were in the mammary gland. These include Casein kinase 1 delta (*Csnk1d*), Suppressor of cytokine signaling 3 (*Socs3*), Phospholipase C epsilon 1 (*Plce1*), Signal transducer and activator of transcription 5B (*Stat5b*) (Fig 3.15a-d). *Csnk1d* gene had the following expression profile: up regulation with non-lactation (1.66-fold) and further up regulation with lactation (2.08-fold) (Fig 3.15a). *Socs3*, *Plce1*, and *Stat5b* genes exhibited similar expression profiles: an increase with non-lactation, and less of an increase with lactation. *Socs3* increased 3.26-fold with non-lactation, and 1.93-fold with lactation (Fig 3.15b). *Plce1* increased 1.81-fold with non-lactation, and 1.75-fold with lactation (Fig 3.15c). *Stat5b* increased 3.36-fold with non-lactation, and 3.15-fold with lactation (Fig 3.15d).

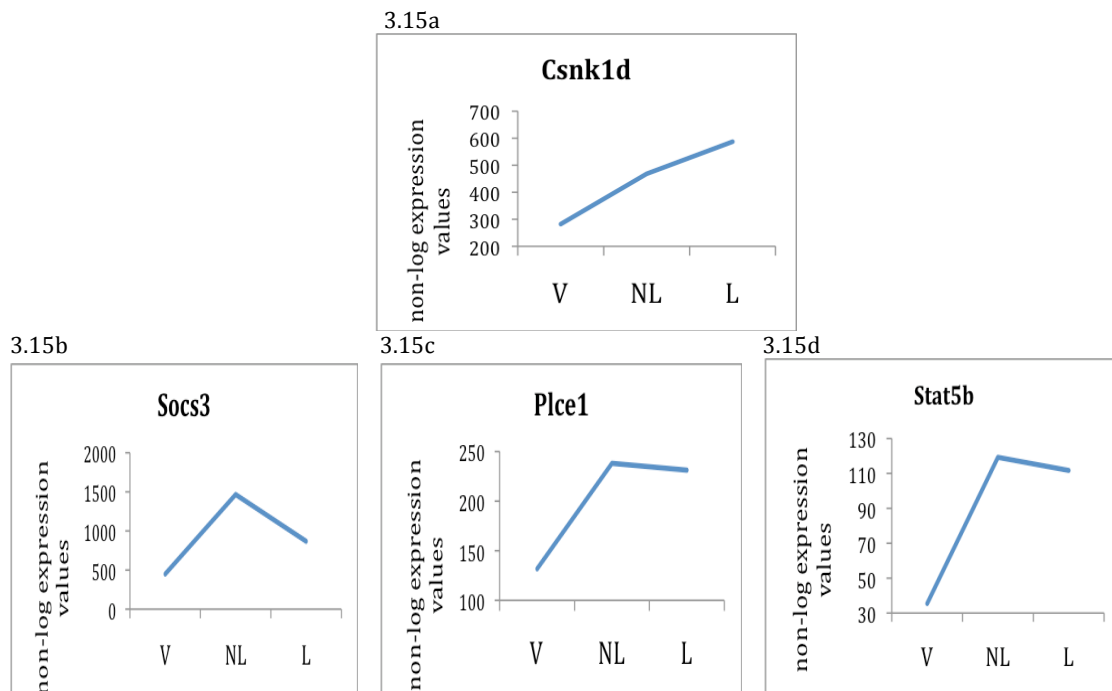

Fig 3.15: Lactation genes are up regulated postpartum in the maternal liver
Gene expression profiles from the livers of virgin (V), non-lactating (NL), and lactating (L) mice of the indicated genes as described in Fig 3.8.

Lipogenic genes are up regulated with lactation

Fatty acids, as components of triglycerides in particular, are an important component of milk (Vernon 2005). In order to understand the role the liver plays in fatty acid metabolism during lactation, we looked at the gene expression profiles of lipogenic genes. Sterol regulatory element binding factor 1 (SREBP1c) is a master regulator of fatty acid or cholesterol synthesis (Sun et al. 2007; Brown et al. 2002). The SREBP1c gene (*Srebf1*) gene decreased slightly with non-lactation (1.11-fold) but increased with lactation (1.9-fold) (Fig 3.16a). Stearoyl-Coenzyme A desaturase 1 (*Scd1*) and thyroid hormone responsive SPOT14 homolog (*Thrsp*) genes exhibited similar expression profiles: a decrease with non-lactation and an increase with

lactation. *Scd1* gene expression increased 1.71-fold with non-lactation and 5.27-fold with lactation (Fig 3.16b). *Thrsp* gene expression increased 1.69-fold with non-lactation and 4.96-fold with lactation (Fig 3.16c). *Lpin1* (*Lpin1*) gene expression, on the other hand, increased significantly with non-lactation (3.76-fold) but less so with lactation (2.82-fold) (Fig 3.16d). All told, these lipogenic genes are up regulated postpartum, $\frac{3}{4}$ of which are further increased with lactation. This suggests that the liver is synthesizing more lipids during lactation.

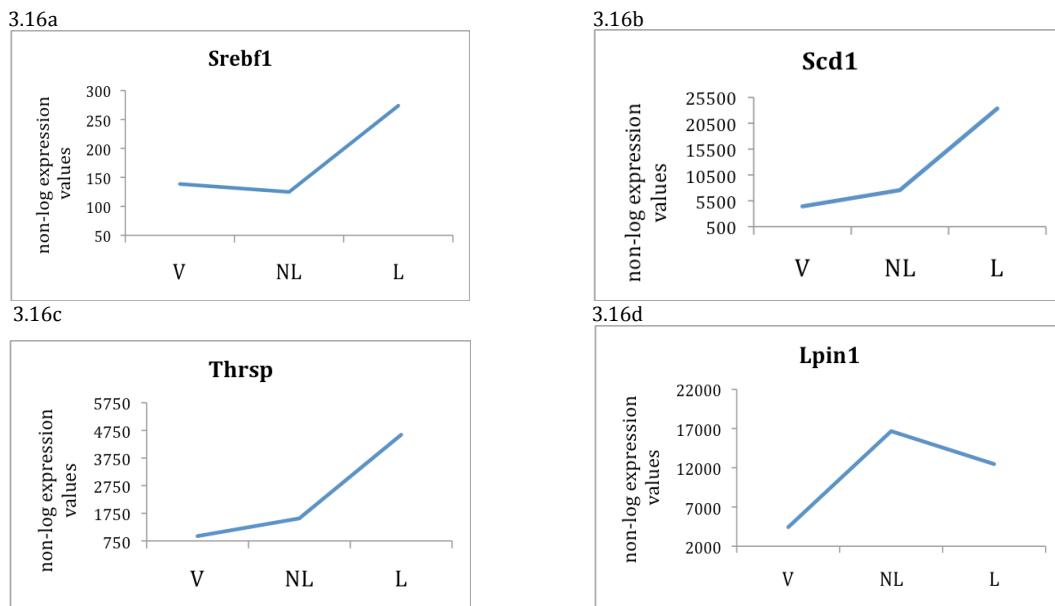

Fig 3.16 Lipogenic genes are up regulated postpartum. Gene expression profiles from the livers of virgin (V), non-lactating (NL), and lactating (L) mice of the indicated genes as described in Fig 3.8.

Expression profiles of genes involved in triglyceride secretion

Our current study has shown that one of the consequences of lactation is an elevation of plasma triglycerides (Fig 2.10). For this reason, we looked at the expression profiles of genes involved in triglyceride secretion. Genes that play a

role in triglyceride secretion include apolipoprotein E (*ApoE*), lipoprotein lipase (*Lpl*), and very low density lipoprotein receptor (*Vldlr*). *Lpl* is the key enzyme in triglyceride hydrolysis in triglyceride-rich lipoproteins such as very low density lipoproteins (VLDL). During lipolysis, lipoproteins are broken down and enriched with the apolipoprotein Apo E, whose remnants are taken up by receptors that recognize Apo E. An example of such a receptor is VLDLR. VLDLR therefore binds triglyceride-rich lipoproteins via Apo E. Transgenic studies have shown that increased *ApoE* expression results in increased triglyceride secretion and that in the liver, increased *ApoE* expression results in the mobilization of hepatic triglycerides. In our study, *ApoE* is up regulated postpartum with non-lactation (1-fold) and up regulated further with lactation (1.13-fold) (Fig 3.17a). *Lpl*, on the other hand, is down regulated with non-lactation (1.74-fold) but down regulated less with lactation (1.34-fold); the net fold change between lactation and non-lactation is a 2.33-fold increase (Fig 3.17b). *Vldlr* has a similar expression profile. Although *Vldlr* is down regulated with non-lactation, it is up regulated with lactation; the net fold change between lactation and non-lactation is 2.27 (Fig 3.17c). These results indicate that there is a net increase in genes involved in triglyceride transport in the lactating liver.

Gene expression profiles from the livers of virgin (V), non-lactating (NL), and lactating (L) mice of the indicated genes as described in Fig 3.8.

Expression profile genes involved in fatty acid transport

Since fatty acid transport genes play an important role in the trafficking of fatty acids (Furuhashi and Hotamisligil 2008), we looked at the expression profiles of several genes involved in fatty acid transport (Fig 3.18a-3.18d). Liver fatty acid binding protein (*Fabp1*), intestinal fatty acid binding protein (*Fabp2*), Solute carrier family 27 member 4, also known as fatty acid transfer protein 4 (*Slc27a4*), and fatty acid translocase/Cd36 (*Cd36*) all share the same expression profile: a decrease with non-lactation and a further decrease with lactation. *Fabp1* gene expression decreased 1.29-fold with non-lactation and 1.56-fold with lactation (3.18a). *Fabp2* gene expression decreased 1.67-fold with non-lactation and 2.46-fold with lactation (Fig 3.18b). *Slc27a4* gene expression decreased 1.07-fold with non-lactation and a

1.47-fold with lactation (Fig 3.18c). Finally, *Cd36* gene expression decreased 1.39-fold with non-lactation and 2.52-fold with lactation (Fig 3.18d). All told, there is a significant decrease in the expression of genes involved in moving fatty acid into the maternal liver during lactation.

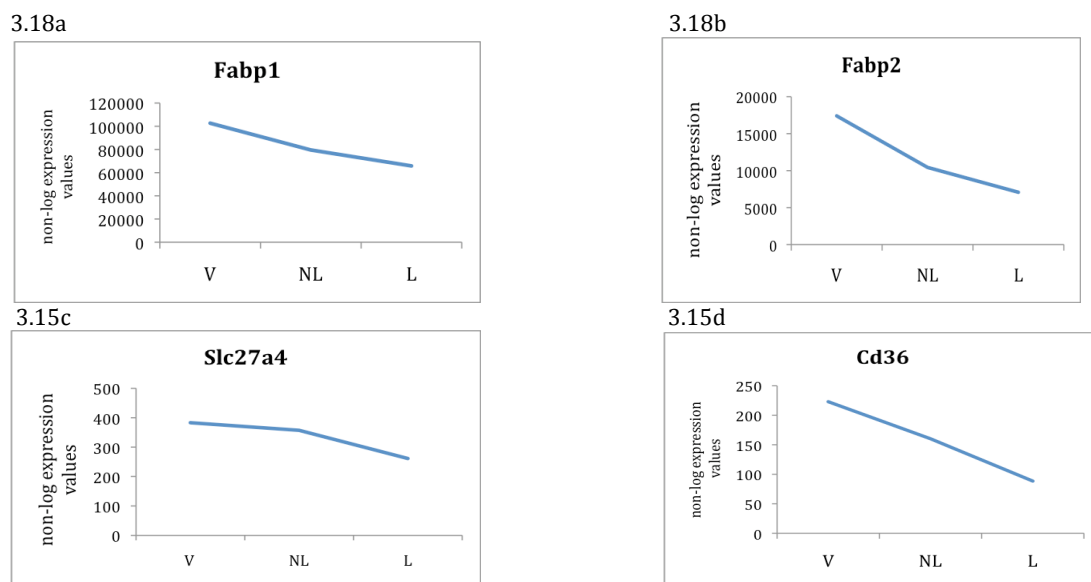

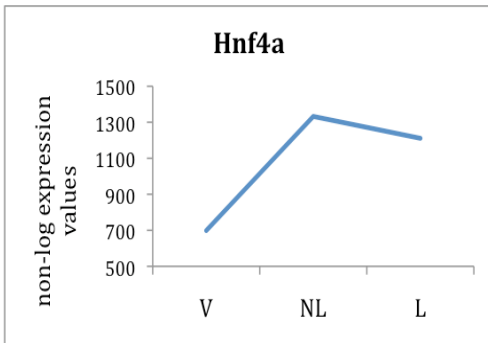

Fig 3.18 Fatty acid transport genes are down regulated postpartum
Gene expression profiles from the livers of virgin (V), non-lactating (NL), and lactating (L) mice of the indicated genes as described in Fig 3.8.

Expression profiles of HNF4 α and some of its targets

HNF4 α is a master regulator of hepatic lipid metabolism (Hayhurst et al. 2001; Bolotin, Schnabl, and Sladek 2009). The postpartum molecular signature of the HNF4 α gene (*Hnf4a*) is an induction during non-lactation, and less induction with lactation (Fig 3.8). In order to understand the role of HNF4 α in the maternal liver during lactation, we looked at the expression profiles of some of its target genes. Apolipoprotein A1 (*Apoa1*), apolipoprotein B (*Apob*), and phosphoenolpyruvate

carboxykinase 1 (*Pck1/Pepck*) genes all had similar expression profiles: increased expression with non-lactation and less of an increase with lactation. *Apoa1* gene expression increased 1.12-fold with non-lactation and 1.10-fold with lactation. *Apob* gene expression increased 1.56-fold with non-lactation and 1.3-fold with lactation. *Pck1* gene expression increased 1.24-fold with non-lactation and 1.17-fold with lactation.

Discussion

Establishing our microarray system

The goal of this study is to understand the role the liver plays in lactation. We have employed gene expression profile analysis (microarray) in order to give us a global perspective of the maternal liver during lactation. In order to have confidence in our results, we verified the postpartum molecular signatures of select genes with quantitative real time PCR (qPCR). We chose to verify the postpartum molecular signatures of HNF4 α and its co-activator PGC1 α (*Ppargc1a*), since they have been shown previously to play roles in liver metabolism (Rhee *et al.* 2006). We also chose to verify the molecular signature of the prolactin receptor (*Prlr*) because it mediates the effects of prolactin, a hormone that is essential for lactation, at least in the mammary gland (Svennersten-Sjaunja and Olsson 2005). And indeed, the postpartum molecular signatures of the liver enriched transcription factor HNF4 α , and its co-activator PGC1 α , were validated by qPCR (Fig 3.1a-3.1d). The same is true for the long and short isoforms of prolactin receptor (Fig 3.2a-3.2e). As hypothesized, prolactin receptor expression was increased during lactation. In addition, our data show a few of the genes involved in lactation that are up regulated in the mammary gland during lactation are also up regulated in the liver with lactation.

These results validate key aspects our microarray data.

Overall Effects in Gene Expression During Lactation

Lactation elicits many maternal adaptations as a means to meet the demands of the highly activated mammary gland and the suckling pups. For this reason, we looked at the number and percentage of genes that were differentially expressed postpartum with or without lactation (Fig 3.3). The percentage of genes that were up regulated with non-lactation was similar to that of genes that were up regulated with lactation. Although the animals in this study were not pregnant at the time of sacrifice, the postpartum non-lactating state represents the post-pregnant condition because the lactating group (L) and the non-lactating group (NL) had both undergone pregnancy, the only difference is the occurrence or non-occurrence of lactation. Since pregnancy and lactation are closely tied, then the similarity in the percentage of up regulated genes with or without lactation is as expected. There were more genes differentially down regulated (9.37%, Fig 3.3) compared to genes that were differentially up regulated (8.75%, Fig 3.3) postpartum. The percentage of genes that were differentially up regulated with lactation was nearly double that of genes that were differentially down regulated with lactation. This would reflect a highly active liver during lactation, perhaps in order to meet the many demands that lactation imposes on the nursing mother.

We next used Gene Ontology analysis to examine the biological processes that were overrepresented postpartum with or without lactation. The diversity in significant biological processes among genes that are either up regulated or

down regulated with lactation or with non-lactation demonstrate the complexity of lactation, which could result in some of the maternal adaptations we noted in Chapter 2 as consequences of lactation. Some of the most notable examples are biological processes that involve lipid metabolism and the immune system (Fig 3.4 – 3.7)

The most overrepresented biological process with lactation and with non-lactation is metabolic process (Fig 3.4 and Fig 3.6). The over representation of lipid, cholesterol, and hormone metabolism among genes up regulated with lactation reflects an increase in the metabolic activity of the liver, especially in regard to high energy substrates such as lipids that are required to meet the needs of the mammary gland, and ultimately, the suckling pups.

Immune Response During Lactation

It is of interest to note that biological processes that involve the immune system (i.e. inflammatory response, innate immune response) are highly represented in the lactating state among genes that are differentially up regulated (Fig 3.4), while biological processes that involve the immune system (e.g. adaptive immune response, T cell proliferation, regulation of T cell activation, innate immune response) are over represented among genes that are differentially down regulated in the non-lactating state (Fig 3.7).

There are many hormones involved in lactation, and these hormones may also play a role in the immune system during reproduction. For example, the molecular

signature of growth hormone receptor (*Ghr*) (slight decrease with non-lactation and a much larger increase with lactation, Fig 3.10c) in our study may provide an explanation for the difference in immune response processed with lactation and non-lactation. In addition to promoting growth, growth hormone has a positive influence on the immune system (Kelly *et al.* 1991). Several studies have shown that growth hormone stimulates T cell and B cell proliferation and immunoglobulin synthesis (Morrhaye *et al.* 2009). The increase in *Ghr* gene expression during lactation may be an explanation of the increased immune response during lactation and could explain why genes involved in T cell proliferation are not down regulated as they are in the non-lactating condition. In contrast, in the non-lactating state, genes involved in the immune response tend to be down regulated (Fig 3.7). Examples of these are innate immune response and acute inflammatory response. Lower immune response during pregnancy is a way to provide a means for the maternal immune system to tolerate the fetus (Tincani *et al.* 2009). For example, it has been suggested that thrombotic/inflammatory processes often accompany recurrent pregnancy loss (Kwak-Kim, Yang, and Gilman-Sachs 2009). Human breast milk, on the other hand, contains leukocytes and other factors that have antimicrobial effects (Jackson and Nazar 2006; Goldman 1993), suggesting a stimulated immune system. Studies have shown that the adaptive immune system of the nursing mother can provide passive protection to the suckling newborn by passing on antibodies through the mother's milk (Wilson and Butcher 2004; Holmgren *et al.* 1976; Stoliar *et al.* 1976). In contrast, lower immune response

during non-lactation that continued from the pregnant state that serves to protect the trophoblast from maternal immunity, and hence, maintain pregnancy.

Weight Loss During Lactation

A noticeable consequence of lactation in our study was significant weight loss in fasted, currently lactating animals (Fig 2.2, 2.3). This could be due to the mobilization of fat stores, or enhanced lipolysis of adipose tissue, in order to meet the high energy demands of lactation (Vernon 1989; McNamara 1997; Sumner and McNamara 2007). The significant increase in plasma glycerol, a marker of adipose tissue lipolysis (Judd *et al.* 1998) during lactation (Fig 2.4) and the strong correlation between percent weight lost and high glycerol levels during lactation (Fig 2.5) supports the idea that the rapid weight loss that accompanies lactation is due to the mobilization of fat stores in the body. Growth hormone is lipolytic and may play a role in the rapid weight loss we observed. Reduced growth hormone secretion is associated with obesity (Makimura *et al.* 2009). Growth hormone has been shown to promote lipid mobilization (Savastano *et al.* 2009; Rhoads *et al.* 2004). The molecular signature of the growth hormone receptor gene (*Ghr*) in our study is as follows: down regulation with non-lactation and an up regulation with lactation. This would suggest an elevation of growth hormone action with lactation, which would result in an increase in lipolysis (mobilization of fat stores), and could explain the rapid weight loss that accompanies lactation.

Increased Liver Mass with Lactation

Another consequence of lactation is an increase in liver mass (Fig 2.6a, 2.6b). The increased liver mass may be the result of increased food intake during lactation (Speakman and Krol 2005; Naya et al. 2008), a parameter that was not measured in our study. The increase in liver weight may also be due to hypertrophy and not hyperplasia. Dunphy et al (Dunphy, Snell, and Clegg 1992), for example, demonstrated that hepatic proliferation does not occur during lactation. In this case, one would expect to see elevated levels of hormones that promote growth, such as growth hormone and prolactin. Our data show similar postpartum molecular signatures for the receptors of these hormones, growth hormone receptor (*Ghr*) and prolactin receptor (*Prlr*): a decrease in gene expression with non-lactation and a dramatic increase in gene expression with lactation (Fig 3.10b, Fig 3.10c). Transgenic mice overexpressing growth hormone develop hepatocellular megaly (Quafe et al 1989; Wolf et al 1993). Prolactin, on the other hand, has also been shown to increase cell number in liver regeneration in rats (Olazabal et al. 2009), but it likely has many more functions which contribute to hypertrophic responses. In addition, transforming growth factor alpha (*Tgfa*), a factor that has been shown to promote hepatocyte proliferation (Sato et al. 2006) is down regulated postpartum (Fig 3.12b). In addition antigen identified by monoclonal antibody Ki-67 (*Mki67*), a marker of cellular proliferation, is down regulated with non-lactation and further down regulated with lactation (data not shown). Taken together, our data suggest that the increase in liver mass during

lactation is a consequence of the up regulation of growth promoting hormone genes (growth hormone receptor and prolactin receptor), which promote hypertrophy, and not due to cell proliferation (down regulation of *Tgfa* and *Mki67*).

Lipid Metabolism During Lactation

Genes involved in lipid metabolic processes were significantly overrepresented among genes up regulated during lactation. Lipids such as fatty acids are important components of milk, a majority of which is in the form of triglycerides (Anderson *et al.* 2007). The liver, the mammary gland, and adipocytes are the main sources of lipids during lactation (Vernon *et al.* 2002; Barber *et al.* 1997). During times of stress, very high rates of lipolysis can occur, resulting in the availability of free fatty acids (FFA) in the blood. The liver then takes up the FFA and esterifies them to triglycerides which are then secreted back into the circulation as very low density lipoproteins (VLDL) (Vernon *et al.* 2002; Vernon 2005). *In vivo* and microarray data from our current study support this scenario. First, there is the rapid weight loss that accompanies lactation, when the animal is fasting, which suggests an increase in lipolysis, which would then increase free fatty acids available to the liver (Fig .2, 2.3). Second, several genes that are involved in the synthesis of triglycerides are up regulated postpartum: *Srebf1*, *Scd1*, *Thrsp*, and *Lpin1* (Fig 3.16a-d). This would suggest an increase in triglyceride synthesis in the maternal liver of lactating mice. Third, plasma triglyceride levels are elevated with lactation (Fig 2.7). In addition, genes involved in triglyceride secretion are up regulated with lactation

(Fig 3.17). Taken together, the increase in plasma triglyceride levels and the stimulation of genes involved in triglyceride secretion suggests that the liver synthesizes triglycerides which are then secreted into the blood. Hepatic triglyceride levels are reduced with lactation (Fig 2.8). The lipogenic genes *Srebf1*, *Scd1*, and *Lpin1* have been shown to play important roles in triglyceride synthesis (Sun et al. 2007; Miyazaki and Ntambi 2003; Finck and Kelly 2006). It is of interest to note that although *Lpin1* is up regulated with non-lactation, the degree of up regulation is less with lactation. Finck et al (Finck and Kelly 2006) have shown that stimulation of *Lpin1* in the liver suppressed hepatic lipogenesis and TG secretion, and increased hepatic TG storage. This could explain the decrease in hepatic TG storage and the increase in TG secretion that we observed during lactation when compared to non-lactation. In addition, Im et al (Im et al. 2009) show that *Srebf1* plays a role in regulating the partitioning of lipids in hepatocytes. The liver has the ability to either oxidize the fatty acids it derives from adipose tissue or synthesize these same fatty acids into triglycerides. A deficiency in *Srebf1* leads to an unbalanced partitioning of fatty acids, favoring fatty acid oxidation resulting in an excess amount of ketone bodies and less triglyceride for storage. Consistent with this model is a decrease in the expression of fatty acid oxidation genes with lactation.

Taken together, our data implies an increase in growth hormone with lactation and this results in an increase of adipose tissue lipolysis, which leads to increased free fatty acids in the circulation. The liver is then able to utilize the free fatty acids

to synthesize triglycerides. A decrease in *Lpin1* gene expression that accompanies lactation up regulates lipogenic genes, including *Srebf1*. The decrease in *Lpin1* expression also results in an up regulation of genes involved in triglyceride secretion. As a result, there is a decrease in hepatic storage and an increase in plasma triglyceride levels with lactation, exactly what we observed. In addition, the increase in *Srebf1* expression pushes the liver to favor triglyceride production, and not fatty acid oxidation.

Regulatory Factors in Lactation

A growing body of evidence suggests that the metabolic changes that occur as a consequence of lactation result in better health for the mother (Stuebe *et al.* 2005; Schwarz *et al.* 2009). A closer examination of microarray data from our current study may give us clues on how lactation brings about a healthier maternal profile. Several liver enriched transcription factors, including C/EBP β , PGC1 α , and HNF4 α , share similar postpartum molecular signatures: an up regulation of gene expression with non-lactation and less up regulation with lactation (Fig 3.8). Several studies suggest that a decrease in *Cebpb* expression with lactation may lessen the incidence of diabetes. Dhahbi *et al.* (Dhahbi *et al.* 2003) showed that C/EBP b levels are increased in Streptozotocin induced diabetes (SID). PGC1 α is a co-activator of several transcription factors that regulates lipid and metabolic pathways in the liver (Lin, Handschin, and Spiegelman 2005; Spiegelman and Heinrich 2004). Type 1 and Type 2 diabetes models have shown an increase in hepatic *Pgc1a* expression

and activity (Herzig *et al.* 2001; Rhee *et al.* 2003). Therefore, a decrease in the up regulation of *Pgc1a* suggests that lactation lowers the incidence of diabetes in nursing mothers. The liver enriched transcription factor hepatocyte nuclear factor 4alpha (HNF4 α) has been linked to diseases such as diabetes and atherosclerosis. Its postpartum molecular signature is as follows: an up regulation with non-lactation and less of an up regulation with lactation. Some of its targets, including PEPCCK (*Pck1*) and Apolipoprotein B (*Apob*) have similar postpartum molecular signatures (Fig 3.19). An increase in PEPCCK results in an increase in gluconeogenesis (Rosella *et al.* 1993). An increase in gluconeogenesis is associated with diabetes (Magnusson *et al.* 1992; Consoli *et al.* 1989). Apo B is the major protein component of low density lipoproteins (LDL) and is involved in the transport of lipids and cholesterol (Mahley *et al.* 1984). High levels of LDL in the circulation are associated with diabetes and heart disease (Therond 2009). Our data would suggest that the lower levels of HNF4 α (*Hnf4a*) and its targets (*Pck1* and *Apob*) during lactation may lead to less of an incidence of diabetes and heart disease. However, HNF4 α is known to directly regulate hundreds of genes in hepatocytes (Bolotin *et al.* 2009), the majority of which are involved in metabolism and homeostasis. Therefore, it is likely to play a very complex role in the maternal liver.

Not all transcription factors are up regulated postpartum. PPAR γ (*Pparg*) is down regulated with lactation (Fig 3.9b). A study by Schadinger *et al.* (Schadinger *et al.* 2005) shows that an up regulation of *Pparg2* induces lipid accumulation in hepatocytes, and it does so by stimulating pathways regulating de novo lipid

synthesis, and this ultimately results in hepatic steatosis (fatty liver). This would suggest that the down regulation of *Pparg* during lactation may lower the incidence of accumulating triglycerides in the liver. Suppressor of cytokine signaling 3 (*Socs3*), a gene that plays a role in lactation in the mammary gland (Le Provost *et al.* 2005), is up regulated with non-lactation and up regulated less with lactation (Fig 3.15b). Ukeki et al (Ueki, Kadowaki, and Kahn 2005) have shown that *Socs3* overexpression in liver causes insulin resistance and hepatic steatosis. Howard et al (Howard *et al.* 2004), on the other hand, showed that *Socs3* knock out mice are protected from diet induced obesity. Our data would therefore suggest that, the differential expression of these genes may promote weight loss and lessen hepatic triglyceride storage in the lactating mouse.

Conclusions

Our data show that there are many genes that are differentially up regulated and down regulated postpartum. This would reflect the complexity of pregnancy, parturition, and lactation, and the profound effects they have on the maternal liver. The differential up regulation and down regulation of genes during lactation brings about maternal adaptations to satisfy the energetic needs of the lactating mammary gland and suckling pups. Examples include, hepatic hypertrophy (increase in liver weight), increased immune response, and increased circulating triglyceride levels. Other consequences of the differential gene expression during lactation include rapid weight loss upon fasting and decreased hepatic triglyceride storage, which may be due to The liver, therefore, is highly active metabolically in currently lactating mice. It also plays a role in supplying the triglycerides that the lactating mammary gland needs by perhaps utilizing the free fatty acids and synthesizing these into triglycerides, which it then secretes into the circulation. It is interesting to note that maternal physiological and metabolic changes such as rapid weight loss upon fasting and decreased hepatic triglyceride storage may suggest improved maternal health during lactation. In our study, these trends are only apparent in currently lactating animals. Although human studies point to lactation as providing long term beneficial effects for the lactating mother, in our mouse study, the beneficial trends that we observe may not extend to long term effects because the non-lactating mice exhibit different trends from the lactating mice. Studies involving mice in the post-lactating state (weaning) and mice that have gone

through pregnant but never lactated may help us tease out the role of the maternal liver in lactation.

Chapter 4

Conclusions

Chapter 4

Conclusions:

The Big Picture

Lactation is a complex process that requires various hormones whose presence or absence result in the orchestration of different metabolic activities of various maternal organs in order to meet the energy demands of the lactating mammary gland (Dunphy, Snell, and Clegg 1992; Vernon 2005). The liver is a highly active organ that plays an important role in this process. We used *in vivo* experimentation and bioinformatics in order to get a global picture of the liver in an attempt to further understand the role it plays in lactation. We chose to examine peak lactation (lactation day 10-12) because we thought we would see the most dramatic effects at this time. We also chose to compare the livers of lactating mice to virgin and non-lactating mice. Out of a total of ~ 14000 gene probe sets, 2552 genes were up regulated (~ 18%) postpartum (with lactation and without lactation) (Fig 3.3). This is a tremendous percentage and shows pregnancy and parturition have a profound effect on the liver. Lactation by itself also has significant effects on the maternal liver, since 714 genes or ~ 5% are differentially up regulated or down regulated. Taken together, pregnancy, parturition, and lactation greatly affect the maternal liver.

Gene Ontology

Gene Ontology analysis sheds some light on the consequences of the differential regulation of genes with or without lactation, by identifying the biological processes that are overrepresented when genes are up regulated or down regulated. The most overrepresented biological processes that occur when genes are differentially up regulated in lactating mice are different from the most overrepresented biological processes that occur when genes are differentially up regulated in non-lactating mice (Fig 4.1). For example, the biological processes that accompany lactation when genes are up regulated include hormone metabolism and cholesterol metabolism. The same can be said for the most overrepresented biological processes when genes are differentially down regulated in lactating mice or in non-lactating mice (Fig 4.1). Examples include macromolecular metabolism and DNA metabolism. Significantly enriched biological processes when genes are down regulated with lactation include metabolic processes, macromolecular localization and protein localization. The diversity in these biological processes emphasize the complexity of pregnancy and lactation.

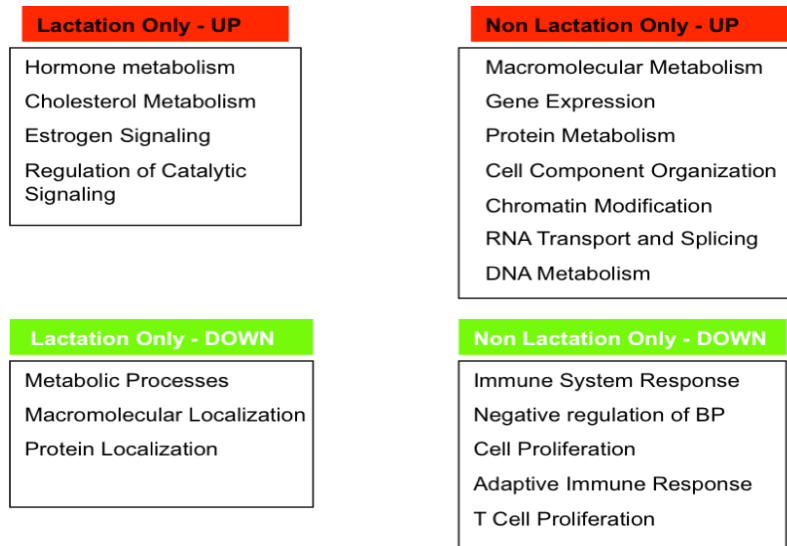

Fig 4.1

Shown are the most over represented Biological Processes ($<1.0E-3$) in each of the indicated categories from the expression profiling array results. All samples are compared to virgin controls. See Fig 3.3 for details.

In vivo data and gene expression profiling data

Chapter 2 documents the many maternal adaptations that occur in order to meet the many demands of lactation. These include the capacity for rapid and significant weight loss (Fig 2.2, Fig 2.3), an increase in plasma glycerol levels (Fig 2.4), an increase in maternal liver weight (Fig 2.6), an increase in plasma triglyceride levels (Fig 2.8), and a decrease in hepatic triglyceride levels (Fig 2.9). In order to examine these maternal adaptations further, we employed gene expression profiling analysis in Chapter 3. Gene expression profiling data reveal differential up regulation or down regulation of different categories of genes. Notable categories include transcription factors (Fig 3.8, Fig 3.9), hormone receptors (Fig 3.10), genes involved in lipogenesis (fig 3.16), and genes involved in triglyceride secretion (Fig 3.17). These categories contribute to the complex processes that occur during lactation which result in the many maternal adaptations that we observed. For example,

rapid weight loss upon fasting during lactation may come as a result of an increase in growth hormone. The increase in growth hormone receptor gene expression during lactation suggests an increased sensitivity to circulating growth hormone. Growth hormone has been shown to increase the mobilization of fat stores (lipolysis) (Savastano et al. 2009; Rhoads et al. 2004). The increase in lipolysis also leads to an increase in free fatty acids in the blood. The up regulation *Scd1* and *Srebfl*, for example, results in the partitioning of fatty acids in the liver towards triglyceride synthesis (as opposed to fatty acid oxidation), and results in an increase of triglyceride secretion (Ntambi and Miyazaki 2003; Im et al. 2009). Added evidence is supported by the up regulation of *Lpl*, *ApoE*, and *Vldlr* during lactation, genes involved in triglyceride secretion. The increase in triglyceride secretion leads to elevated plasma triglyceride levels, that provide the triglycerides that the mammary gland needs in order to make milk to sustain the suckling pups. The secretion of triglycerides leads to a decrease in hepatic triglyceride storage. This is consistent with our *in vivo* result of decreased hepatic triglyceride levels in livers of lactating mice (Fig 2.8), the latter further corroborated with histological staining (Fig 2.9). Taken together, this would suggest that the liver is highly active during lactation. It also provides evidence that the liver plays an important role in synthesizing and providing triglycerides to the lactating mammary gland.

Lactation and its effects on maternal health

A growing body of evidence from human studies suggests that lactation brings about metabolic changes that contribute to a unique maternal profile that promotes the prevention of metabolic diseases. For example, gluconeogenesis is associated with diabetes (Magnusson et al. 1992). HNF4 α is required in PGC1 α mediated gluconeogenesis during fasting (Rhee et al. 2003). Our data show HNF4 α and PGC1 α sharing the same postpartum molecular signature: an increase in gene expression with non-lactation, and less of an increase in gene expression with non-lactation. In addition, PEPCK (*Pck1*) gene expression has a similar postpartum molecular signature. Taken together, our microarray data suggests that there is less gluconeogenesis with lactation. Although a decrease in gluconeogenesis might suggest lower potential risk for developing diabetes, there is no apparent hyperglycemia in our mice, since glucose levels were similar for all three conditions. What is apparent in our mouse model is the weight loss upon fasting that comes with current lactation, which could protect the currently lactating mouse against obesity, while the mouse is lactating.

Lactation, metabolic syndrome, and long term effects

Recent studies suggest that the maternal health benefits gained from lactation may have long term effects. For example, Gunderson et al (Gunderson 2009) (gunderson et al 2009) show that women who nursed their babies for a short amount of time significantly lowered their risk for developing metabolic syndrome

many years later. What's more, the risk for developing metabolic syndrome later in life is lowered the longer a woman breastfeeds. This study verifies other studies (Ram et al. 2008; Pirkola et al. 2009; Davis and Olson 2009) that point to the long term effects of lactation on maternal health. This sounds very promising. In order to further this promising outcome of lactation, we looked at weaned mice. These mice had at least 2 successful rounds of reproduction, having gone through a full term pregnancy, parturition, lactation, weaning (removal of suckling pups after 21 days of lactation), and were sacrificed at least 21 days post weaning. We looked at circulating triglyceride levels and hepatic triglyceride levels of weaned mice (Fig 4.2, Fig 4.3)

In contrast to the increase in plasma triglyceride levels that we saw in lactating mice, the plasma triglyceride levels of weaned mice significantly decreased (compared to lactating mice), or went back to virgin levels (Fig 4.2). A similar trend is apparent with hepatic triglyceride levels. Recall that hepatic triglyceride levels decreased with lactation. Hepatic triglyceride levels of weaned mice significantly increased, compared to lactating mice (Fig 4.3). Hepatic triglyceride levels of weaned mice were not significantly different from that of virgin and non-lactating mice. These data suggest that the increase in plasma triglycerides and decrease in hepatic triglyceride storage are transient.

Our results would suggest that the increase in plasma triglycerides that accompanied lactation is a transient phenomenon. Perhaps this was a way for the lactating mother to provide energy to the lactating mammary gland. In our system,

however, the lactating mice were also fasting. This is a confounding factor. Perhaps the fasting aspect increased the need for lipolysis (mobilization of fat stores), and, in the process, increased the need to secrete more triglycerides into the circulation for the mammary gland. Recall too that the time point we chose was peak lactation, where the maternal mouse was continuously lactating, the pups were continuously suckling, and so there was a dramatic need for triglycerides, an energy source. The same can be said for hepatic triglyceride levels. During lactation, there is decreased lipogenesis in adipocytes, and increased lipogenesis in the liver (Vernon 2005). It has been shown that lipogenesis in adipocytes increases when pups are taken away from the lactating mother (Vernon 1989). Perhaps in this weaned condition, the liver still synthesizes triglycerides but lessens its secretion.

In our model, the trends we saw such as increased triglyceride secretion and decreased hepatic triglyceride storage are transient. Although our model examines long term effects of lactation through the non-lactating condition, it would be of interest to examine the long term effects of pregnancy alone on the maternal liver. This study would require mice that have gone through pregnancy but have never lactated. This would enhance our understanding of the role of the liver in reproduction.

Fig 4.2: Postpartum plasma triglyceride levels (TG) of weaning mice significantly decrease (compared to levels of lactating mice).

Plasma triglyceride (TG) levels of virgin (V, blue bar, n=10), non-lactating (NL, green bar, n=10), and lactating (L, red bar, n=4). Materials and methods section in chapter 2 for details. * = NL vs V or L vs V; # = L vs NL; ^ = W vs L; * or # or ^, $p < 5.00E-02$; ** or ## or ^^, $p < 5.00E-04$.

Fig 4.3: Hepatic triglyceride levels return to virgin and non-lactating levels with weaning.

Triglycerides (TG) from livers of virgin (V, blue bar, n=9), non-lactating (NL, green bar, n=9), and lactating (L, red bar, n=4). See materials and methods section in chapter 2 for details. * = NL vs V or L vs V; # = L vs NL; ^ = W vs L; * or # or ^, $p < 5.00E-02$; ** or ## or ^^, $p < 5.00E-04$.

The Role of the Liver in Lactation

Our results show a highly active maternal liver during lactation. The sheer number of genes that are induced in the liver of lactating mice can attest to this. In addition, there is an increase in liver mass. An increase in liver mass has been associated with an increase in liver metabolism (Grigor et al. 1982; Reynolds et al.

2004). The up regulation of certain genes, such as growth hormone receptor (*Ghr*) and prolactin receptor (*Prlr*), mediators of hormones that play important roles in lactation, may contribute to an increase in liver mass. Our data does not exhibit cell proliferation since *Tgfa*, a factor that promotes hepatocyte proliferation, and Ki-67 (*Mki67*), a marker of cell proliferation is down regulated during lactation.

The liver is an important player in lipid metabolism (Grigor et al. 1982; Hayhurst et al. 2001; Bolotin, Schnabl, and Sladek 2009; Sladek and Seidel 2001). Lipid metabolism is a highly overrepresented biological process in lactation.

Triglycerides, in particular, provide the energy needed by the lactating mammary gland. Our microarray data shows an increase in lipogenic genes (*Scd1* and *Srebfl*) that prefer triglyceride synthesis over fatty acid oxidation. Genes that are involved in triglyceride secretion (*ApoE*, *Vldl*, *Lpl*) are stimulated in the liver of lactating mice. Together, this results in an increase of triglyceride synthesis and triglyceride secretion in the liver, the consequences of which are increased circulating triglycerides and decreased hepatic triglyceride storage. Our data also show evidence of a decrease in gluconeogenesis, despite the fasting state of the lactating mouse, as suggested by the decrease in the up regulation of *Hnfa*, *Pgc1a*, and PEPCCK (*Pck1*), all important players in gluconeogenesis.

In summary, during lactation, we see a highly metabolically active liver, as evidenced by hepatic hypertrophy. Our data also suggest that the liver supplies the major source of energy to the lactating mammary gland. Some consequences of lactation include rapid weight loss upon fasting, a decrease in gluconeogenesis, an

increase in plasma triglycerides, and a decrease in hepatic triglyceride storage, but these trends are transient. The benefits to the mother brought on by lactation are only beneficial during lactation in the mouse. Further studies involving mice that have gone through pregnancy but have never lactated will enhance our understanding on the role the liver plays in lactation.

Table 3: Genes down regulated at least 1.5-fold in lactating mice.
Abbreviations: affyID: annotated files from Affymetrix that identifies probeset
IDs for genes on its chips. fcVvsL: the fold change of genes in lactating mice
compared to virgin mice, in non-log form.

affyid	Gene Symbol	fcVvsL

Table 5 : Genes down regulated at least 1.5-fold in non- lactating mice
Abbreviations: affyID: annotated files from Affymetrix that identifies
Probeset IDs for genes on its chips. fcVvsNL: the fold change of genes
in non- lactating mice compared to virgin mice, in non-log form.
