SUMMARY

Natural product biosynthetic pathways are replete with enzymes repurposed for new catalytic functions. In some modular polyketide synthase (PKS) pathways, a GCN5-related *N*-acetyltransferase (GNAT)-like enzyme with an additional decarboxylation function initiates biosynthesis. Here, we probe two PKS GNAT-like domains for the dual activities of *S*-acyl transfer from CoA to an acyl carrier protein (ACP) and decarboxylation. The GphF and CurA GNAT-like domains selectively decarboxylate substrates that yield the anticipated pathway starter units. The GphF enzyme lacks detectable acyl transfer activity, and a crystal structure with an isobutyryl-CoA product analog reveals a partially occluded acyltransfer acceptor site. Further analysis

indicates that the CurA GNAT-like domain also catalyzes only decarboxylation, and the initial acyl transfer is catalyzed by an unidentified enzyme. Thus, PKS GNAT-like domains are re-classified as GNAT-like decarboxylases. Two other decarboxylases, malonyl-CoA decarboxylase and EryM, reside on distant nodes of the superfamily, illustrating the adaptability of the GNAT fold.

Graphical Abstract

eTOC blurb

Most GCN5-related *N*-acetyltransferase (GNAT) superfamily members catalyze acyltransfer, but some are decarboxylases. Skiba *et al.* show that “GNATs” involved in the biosynthesis of two polyketide natural products catalyze only decarboxylation. They identify GNAT-like decarboxylases on distant nodes of the superfamily, illustrating the adaptability of the GNAT fold.

INTRODUCTION

Named for the founding member, general control non-repressible 5 (GCN5)-related *N*-acetyltransferase (GNAT) (Neuwald and Landsman, 1997), the GNAT superfamily spans all kingdoms of life and is best known for using an acetyl-coenzyme A (CoA) donor to acetylate diverse amine substrates, such as histones, aminoglycoside antibiotics, arylalkylamines, and a variety of other proteins and metabolic intermediates (Figure 1) (Couture and Trievel, 2006; Favrot et al., 2016; Salah Ud-Din et al., 2016). Other GNAT superfamily members use alternative acyl donors, such as myristoyl-CoA (Farazi et al.,

2001), succinyl-CoA (Vetting et al., 2008), or fatty acyl-ACPs (Gould et al., 2004; Van Wagoner and Clardy, 2006; Watson et al., 2002).

Natural product biosynthetic pathways frequently repurpose enzymes found elsewhere in biology for the production of molecules that confer a selective advantage on the producing organism. For example, a GNAT-like enzyme was acquired in polyketide biosynthetic pathways of a variety of bacteria (Figure 2, Figure S3) (Chang et al., 2004; Grindberg et al., 2011; Gu et al., 2007; Kampa et al., 2013; Kellmann et al., 2008; Mattheus et al., 2010; Moebius et al., 2012; Partida-Martinez et al., 2007; Piel, 2002; Piel et al., 2004a; Simunovic et al., 2006; Young et al., 2013), and first identified in sequence analysis of the pederin biosynthetic pathway (Piel et al., 2004b). Pederin and other polyketides are synthesized in a stepwise manner from acyl-CoA building blocks. Intermediates in the modular type I polyketide synthase (PKS) enzyme assembly lines are tethered to ACP domains via the phosphopantetheine (Ppant) cofactor. PKS GNAT-like domains exist in “loading” or initiation modules and are expected to transfer an acetyl-group from acetyl-CoA to the terminal thiol acceptor of the Ppant cofactor of the initiation module ACP (ACP_L). Identification of a putative diphosphate-binding P-loop for acetyl-CoA, which exists in other GNAT family members, suggested that the pederin GNAT-like domain shares the canonical acetyl-CoA binding property of the GNAT fold. Additional GNAT-like domains exist in PKS initiation modules that produce acetyl (Chang et al., 2004; Kampa et al., 2013; Mattheus et al., 2010; Moebius et al., 2012; Partida-Martinez et al., 2007; Piel et al., 2004a), propionyl (Kellmann et al., 2008; Simunovic et al., 2006), isobutyryl (Young et al., 2013), and pivaloyl (Grindberg et al., 2011; Skiba et al., 2018b; Sudek et al., 2007) starter units (Figure 2, Figure S3).

The initial characterization of a PKS GNAT-like domain was for the CurA GNAT in the pathway for the antimetabolic metabolite curacin A, where we reported a slow *S*-acetyl transfer from acetyl-CoA to the CurA ACP_L to generate the acetyl starter unit of curacin A biosynthesis (Gu et al., 2007) (Figure 2A, 2B). Unexpectedly, CurA GNAT also rapidly decarboxylated malonyl (Mal)-ACP or Mal-CoA and thus could form acetyl-ACP directly from Mal-CoA. Decarboxylation represented a new catalytic function for the GNAT superfamily and required His and Thr amino acids (Gu et al., 2007). The apparent dual activities clarified the function of GNAT-like domains in the initiation modules of other PKS systems. This was demonstrated in the saxitoxin pathway, where the SxtA GNAT-like domain (Figure 2C, 2D) also displayed dual activities, including a very weak acyl transfer activity and a decarboxylation activity with preference for methylmalonyl (MeMal)-ACP conversion to propionyl-ACP, the expected saxitoxin starter unit, over Mal-ACP (Chun et al., 2018). In contrast, in apratoxin A and bryostatin biosynthesis (Figure 2E, 2F), the GNAT-like domain is truncated and possesses no detectable decarboxylation or acyl transfer activity (Skiba et al., 2018b; Skiba et al., 2017). In these pathways, a specialized methyltransferase domain catalyzes decarboxylation coupled to methyl transfer, and the initial acyl transfer step to commence apratoxin A biosynthesis requires an enzyme not encoded in the gene cluster such as FabD, the malonyl-acyltransferase of fatty acid biosynthesis (Skiba et al., 2018b).

Biosynthesis of the cytostatic polyketide gephyronic acid begins with the GphF initiation module (Young et al., 2013), which includes methyltransferase (MT), GNAT-like, and ACP domains (MT_L-GNAT_L-ACP_L, Figure 2G). An isobutyryl starter unit is the expected product of the GphF initiation module, in contrast to other characterized GNAT-containing initiation modules which produce acetyl (curacin A) (Gu et al., 2007), propionyl (saxitoxin) (Chun et al., 2018), and pivaloyl (apratoxin, bryostatin) starter units (Skiba et al., 2018b). Isotope labeling studies indicated that the gephyronic acid isobutyryl unit is derived from *S*-adenosylmethionine (SAM) (Young et al., 2013). Previously, we showed that GphF MT_L and other MTs associated with PKS GNAT-like domains are unusual mononuclear-iron-dependent enzymes that catalyze methylation of Mal-ACP to MeMal-ACP or dimethylmalonyl (Me₂Mal)-ACP (Figure 2H) (Skiba et al., 2017). We determined that the carboxylate of Mal-ACP is essential for methyl transfer activity, calling into question the presumed coupling of the acyl transfer and decarboxylation activities of GNAT-like domains. Decarboxylation of Me₂Mal-ACP by the GphF GNAT-like enzyme would result in the predicted isobutyryl starter unit, but the reaction cannot be coupled to malonyl transfer from CoA to ACP (Figure 2H).

Here, we investigate the catalytic function of two GNAT-like domains in polyketide biosynthesis. The GphF and CurA GNAT-like enzymes displayed a strong acyl-group selectivity for their respective decarboxylation substrates. Additional insight into the decarboxylation reaction is provided by a 2.8-Å crystal structure of the GphF GNAT-like domain with the product analog isobutyryl-CoA. No acyl transfer activity was detected for the GphF GNAT-like domain. Given the low rate of acyl transfer compared to decarboxylation for PKS GNAT-like domains (Chun et al., 2018; Gu et al., 2007), their biological function appears to be primarily or exclusively decarboxylation. Thus, the GNAT-like domains in PKS pathways are more appropriately classified as GNAT-like decarboxylases.

RESULTS

GNAT-like enzymes encode strict substrate specificity

We first investigated the decarboxylation activity of the GphF GNAT-like domain. Metal-dependent MT_L domains in PKS initiation modules can produce either a monomethylated (MeMal-ACP) (Chun et al., 2018) or dimethylated (Me₂Mal-ACP) (Skiba et al., 2017) product, which is presumably decarboxylated by the GNAT domain to produce the polyketide starter unit (Figure 2). Thus, the GNAT-like domain may be a gatekeeper, selectively decarboxylating the MT_L product with the pathway-specific number of methyl groups. The structure and pathway annotation of gephyronic acid (Young et al., 2013) as well as initial biochemical characterization (Skiba et al., 2017) indicated that the GphF MT_L converts Mal-ACP to Me₂Mal-ACP via a MeMal-ACP intermediate (Figure 2H). Thus, we tested the GphF GNAT selectivity for Me₂Mal-ACP, MeMal-ACP and Mal-ACP.

Mal-ACP and MeMal-ACP were generated from the respective CoAs via the promiscuous 4'-phosphopantetheinyl transferase Svp (Sánchez et al., 2001). Me₂Mal-ACP was generated enzymatically from MeMal-ACP using AprA MT_L from the apratoxin A initiation module (Skiba et al., 2017). The AprA ACP_L (Grindberg et al., 2011) was used as a surrogate for

GphF ACP_L, which was insoluble. Relative rates of decarboxylation of the ACP-linked substrates were measured using the mass-spectrometry-based Ppant ejection assay (Dorrestein et al., 2006; Meluzzi et al., 2008). GphF GNAT displayed a strong selectivity for decarboxylation of Me₂Mal-ACP relative to MeMal-ACP (100-fold) or Mal-ACP (barely detectable within 48 hours) (Figure 3A, Figure S4). Thus, GphF GNAT requires the action of MT_L prior to decarboxylation and is selective for the Me₂Mal-ACP product over the MeMal-ACP intermediate, thereby priming the gephyronic acid assembly line with the isobutyryl-ACP starter group (Figure 2H).

We were curious to examine whether other PKS GNAT-like domains exhibit a similar degree of substrate selectivity. The CurA GNAT (Gu et al., 2007) is of particular interest as the CurA initiation module includes the vestige of an MT_L (N-terminal lid region formerly known as an adaptor) but lacks the SAM-binding core (Figure 2A), suggesting that CurA evolved from a module containing an MT_L (Skiba et al., 2017). CurA GNAT displayed a modest ~5-fold selectivity for its natural Mal-ACP substrate over MeMal-ACP (Figure 3B), in agreement with our previous report (Gu et al., 2007), and a 500-fold selectivity for Mal-ACP over Me₂Mal-ACP (Figure 3B). Although the selectivity for Mal-ACP over MeMal-ACP is weak, it is unlikely to result in mispriming with a propionyl-ACP starter unit as many bacteria, including the *Moorea producens* cyanobacterial producer of curacin A, lack a gene for propionyl-CoA carboxylase (Lombard and Moreira, 2011) and do not produce MeMal-CoA at levels sufficient for secondary metabolite biosynthesis.

GphF GNAT Structure and Active Site

In order to understand the substrate selectivity of PKS GNAT-like domains for decarboxylation, we solved crystal structures of the GphF GNAT free enzyme (2.6 Å) and a binary complex with an isobutyryl-CoA product mimic (2.8 Å, Figure 4, Table 1). GphF GNAT displays the conserved GNAT fold comprised of a central β-sheet flanked by α-helices with a V-shaped Ppant-binding cleft between parallel strands β4 and β5 (Figure 4A) (Vetting et al., 2005). A characteristic “bulge” in β4 (GphF Leu588) disrupts the hydrogen bonding scheme of the central β-sheet, thereby creating the active site cleft (Figure 4B). The Ppant site includes a characteristic phosphate-binding loop (GphF 597–602 between β4 and α3, Figure 5), which is part of conserved “motif A” of the GNAT superfamily (Figure 1) (Neuwald and Landsman, 1997). Relative to GNAT *N*-acetyltransferases, PKS GNAT-like domains are distinguished by a helical insertion in GNAT motif B, following β5 (αC, αD) (Figure 4A, Figure 5).

At the substrate entrance, the isobutyryl-CoA Ppant threads along the open edge of strand β4 where it splays away from β5 (Figure 4A). The thioester is positioned at the base of the V-shaped cleft near the conserved Thr/Ser and His residues (GphF Ser626, His660; CurA Thr355, His 389), which are essential for decarboxylation by CurA GNAT (Figure 6) (Gu et al., 2007). The catalytic His of GphF and CurA GNAT resides on helix α4 at the same topological location as a Tyr that is essential for acetyl transfer in serotonin *N*-acetyltransferase (Hickman et al., 1999). A distal binding pocket for acceptor substrates in canonical GNAT acyltransferases lies beyond the V-shaped cleft on the opposite side of the β-sheet from the catalytic His and Thr/Ser. In PKS GNAT-like domains, the pocket includes

conserved Trp and Arg side chains (GphF Trp520, Arg675; CurA Trp 249, Arg404). However, access for acceptor substrates through the distal end of the GphF pocket is restricted by His571 (Figure S5A). The analogous residue in CurA GNAT (Cys300) is less bulky, and the distal pocket would be accessible to a Ppant substrate (Figure S5B). In some PKS GNAT-like enzymes, even larger aromatic side chains at this position would seemingly block access for acceptor substrates (Figure 5).

GNAT Catalysis

The function of active-site residues and the basis for the observed substrate selectivity of GphF and CurA GNAT domains (Figure 3) was probed via site-directed mutagenesis using Me₂Mal-, MeMal- and Mal-ACP substrates (Figure 6). Like the CurA GNAT (Gu et al., 2007), the conserved active site His (GphF His660) and Ser/Thr (GphF Ser626) are essential for decarboxylation of both Me₂Mal-ACP and MeMal-ACP by GphF GNAT (Figure 5, Figures 6A, 6B). In contrast to the high levels of activity with Me₂Mal-ACP, no decarboxylation of Mal-ACP was detected in a 24-hour incubation for wild-type GphF GNAT or any variant. Substitutions to the conserved Arg (GphF R675E and R675K) in the acyl pocket resulted in substantially reduced product formation (Figures 6A, 6B). Analogous substitutions in CurA Arg404 were similarly deleterious (Figures 6C and 6D), validating a role for the conserved Arg in decarboxylation. We conclude that the positively charged Arg interacts with the carboxylate of Me₂Mal- or Mal-ACP, given the order-of-magnitude reduction in product formation for the charge-reversal substitutions (GphF R675E and CurA R404E) and the substantial decrease for the more conservative substitutions (GphF R675K and CurA R404K). The Arg675 guanidinium is well positioned to interact with the carboxylate of the Me₂Mal-ACP substrate, based on the binary complex of the GphF GNAT with the isobutyryl-CoA product mimic (Figure S5C). The essential active site His and Thr/Ser are optimal candidates to stabilize an enolate intermediate formed during decarboxylation and to re-protonate the carbanion upon collapse of the enolate, as previously proposed (Figure S5D) (Gu et al., 2007).

We next examined amino acids in the Ppant binding cleft and acyl group pocket that differ in GphF and CurA GNAT in order to identify the basis for the differing substrate selectivity. The essential Thr side chain in the decarboxylation site of PKS GNAT-like enzymes (CurA Thr355) is more common than Ser (GphF Ser626) (Figure 5, Figures 6B, 6D). Among GNAT-like domains in pathways where the natural product is known, only the GphF initiation module produces an isobutyryl starter group. Reasoning that the smaller active site Ser may provide more space to accommodate dimethylmalonyl than the bulkier Thr, we produced GphF S626T and CurA T355S, but these substitutions had only modest effects on decarboxylation of all substrates and did not influence the selectivity for Me₂Mal-ACP by the GphF GNAT or Mal-ACP by the CurA GNAT (Figures 6A, 6C). We made several additional reciprocal substitutions at amino acid positions in the active site and substrate pocket in either or both enzymes (GphF H690Y, CurA Y419H; GphF R597Q, CurA Q326R; GphF R627L, CurA L356R; GphF H571C). All but GphF R627L, which was insoluble, yielded stable protein, but none altered the substrate selectivity of either enzyme (Figure 6).

GphF GNAT does not catalyze acyl transfer

The distal acyl-binding pocket of the CurA GNAT extends from the V-shaped cleft to the surface of the protein and was proposed to accommodate the Ppant of the ACP acyl acceptor in CurA GNAT (Gu et al., 2007). However, access through the distal end of the GphF pocket is partially blocked by His571 (Figure S5A,C). We also noted that amino acids in the distal pocket are among the least conserved in PKS GNAT-like domains, which is not consistent with a common Ppant pocket for ACP acceptors. Together with the low levels of malonyl or acetyl transfer for previously characterized PKS GNAT-like domains in CurA (Gu et al., 2007) and SxtA (Chun et al., 2018), this led us to investigate the acyltransferase activity of the GphF and CurA GNATs.

The proposed reaction scheme for the GphF initiation module requires the transfer of malonate from CoA to ACP prior to the methylation reactions by MT_L . This ensures that the resulting Me_2Mal product is non-diffusible and available for further processing by subsequent enzymes in the gephyronic acid pathway. GphF GNAT is a candidate to provide the malonyl transfer step as it was unable to decarboxylate malonyl-ACP prior to methylation by GphF MT_L (Figure 2h). However, we detected extremely low levels of malonyl transfer activity by GphF GNAT, unlike the consistently high levels of Me_2Mal -ACP decarboxylation.

For both GphF GNAT and MT_L -GNAT, the consistently low levels of acyl transfer activity varied among apparently identical preparations, suggesting that the observed activity may be due to a contaminating enzyme from the *E. coli* expression host. Previously, contaminating components of the highly active *E. coli* fatty acid biosynthetic machinery were shown to transfer malonyl from CoA to PKS ACPs (Florova et al., 2002). To separate GphF GNAT (pI 7.3) from the *E. coli* fatty acid synthase enzymes most likely to support acyl transfer (FabD (pI 5.0) and FabH (pI 5.1)), we added an additional ion exchange chromatography step to the purification protocol. The stringently purified GphF GNAT retained a high rate of Me_2Mal -ACP decarboxylation but did not support acyl transfer to ACP from a panel of acyl-CoA donors, including Mal-CoA and isobutyryl-CoA (Figure 7A, Figure S6). Thus, we conclude that the GphF GNAT-like enzyme is not an acyltransferase.

The lack of acyl transfer activity for GphF GNAT prompted us to reinvestigate CurA GNAT acyl transfer, which was nearly 800-fold slower than decarboxylation (Gu et al., 2007). We performed additional affinity chromatography and size exclusion purification steps and found that the multistep-purified CurA GNAT had five-fold diminished acyl transfer activity compared to the single-step purified enzyme used previously (Gu et al., 2007) (Figure 7B, Figure S7). The multistep-purified enzyme retained rapid decarboxylation activity (Figure S8).

To determine whether contaminating enzymes from the *E. coli* heterologous host could contribute to the observed acyltransferase activity for the PKS GNAT-like domains, we carried out a mock purification of *E. coli* proteins from cells bearing an empty expression vector. The cytosolic extract enriched by the Ni-NTA affinity step was concentrated and subjected to acyl transfer assays with the CurA ACP (Figure S8). The enriched *E. coli* protein mixture catalyzed transfer of both acetyl and malonyl from CoA to CurA ACP in a

concentration-dependent manner at rates faster than the multi-step purified CurA GNAT, but the mixture of *E. coli* proteins had no detectable decarboxylation of Mal-ACP (Figure 8A, Figure S8). The malonyl and acetyl transfer activity of *E. coli* proteins is evidence that contaminants in preparations from single-step Ni-NTA purification were responsible for both acyltransfer reactions.

As PKS GNAT-like domains possess only decarboxylation activity, an additional enzyme must catalyze the initial malonyl transfer step to initiate both gephyronic acid and curacin biosynthesis in the producing organisms. FabD is an attractive candidate to provide this step for PKS initiation modules containing a GNAT-like decarboxylation domain, as shown in the apratoxin A biosynthetic pathway (Skiba et al., 2018b). We tested this possibility with the *Moorea bouillonii* FabD, which is 97% identical to FabD from the curacin A producer *M. producens*. Recombinant *M. bouillonii* FabD was ~40,000-fold more effective in malonyl transfer from CoA to CurA ACP than was the CurA GNAT (65% transfer in 20 min with 25 nM FabD compared to 8% transfer in 4 hours with 10 μ M GNAT, Figure 7B, Figure 8B, Figure S7).

DISCUSSION

PKS GNAT-like domains are decarboxylases

This study demonstrates that the GNAT-like domain in the PKS loading module for gephyronic acid biosynthesis is a highly selective Me₂Mal-ACP decarboxylase and that it lacks acyl transfer activity. Based on the results for the myxobacterial GphF GNAT_L and the cyanobacterial CurA GNAT_L, decarboxylation is the primary role of GNAT-like enzymes in PKS initiation modules. The rate of acyl transfer is non-existent or suspiciously low for these GNAT-like domains compared to their decarboxylation rates (Gu et al., 2007) and can be reduced further by additional purification steps (Figure 7B). Furthermore, the previously proposed binding site for the Ppant of the CurA ACP acyl acceptor (Gu et al., 2007) is partially occluded in GphF and may be fully occluded in other PKS GNAT-like domains (Figure 5, Figure S5). Thus, the PKS GNAT-like domain is more appropriately designated as a GNAT-like decarboxylase. Decarboxylation by these enzymes requires conserved His and Thr/Ser residues. We further demonstrated the importance of an active site Arg in decarboxylation by both cyanobacterial and myxobacterial GNAT-like decarboxylases; this amino acid is conserved among GNAT-like decarboxylases from PKS initiation modules with known biosynthetic products (Figure 5, Figure 6).

Our results indicate that the extremely slow and variable malonyl transfer activity of the GNAT-like decarboxylase or the MT_L-GNAT didomain is due to a contaminant from the *E. coli* expression host, as additional purification steps of the GNAT-like decarboxylases decreased acyl transfer activity but did not alter the rate of decarboxylation (Figure 7, Figure S8). Previously, the detection of an *E. coli* contaminant refuted a “self-loading” ability of PKS ACPs (Florova et al., 2002). We found that unidentified *E. coli* cytosolic proteins enriched by Ni-NTA resin support both malonyl and acetyl transfer from CoA to a PKS ACP. An obvious malonyl transferase candidate is *E. coli* FabD of fatty acid biosynthesis, and acetyl transfer activity has been detected in *E. coli* FabH (Tsay et al., 1992).

In PKS initiation modules containing GNAT-like decarboxylases, we propose that the ACP_L is primed with malonyl by a standalone malonyl-acyltransferase that may not be encoded in the PKS gene cluster. FabD, the malonyl-acyltransferase from fatty acid biosynthesis, is an obvious candidate, as it supported rapid malonyl acyl transfer to AprA ACP_L (Skiba et al., 2018b) and CurA ACP_L (Figure 8B), as well as other PKS ACPs (Florova et al., 2002; Kumar et al., 2003). Some GNAT-like domains exist in so-called *trans*-AT PKS pathways, where a standalone acyltransferase (AT) provides building blocks at all extension steps in the pathway. A *trans*-AT could catalyze the initiating acyl transfer step in such pathways (Kampa et al., 2013; Mattheus et al., 2010; Moebius et al., 2012; Partida-Martinez et al., 2007; Piel, 2002; Piel et al., 2004a; Simunovic et al., 2006).

Starter-unit biosynthesis for several polyketide natural products is rationalized by the understanding of the decarboxylase function of GNAT-like PKS domains and by sequence analysis of the loading modules (Figure S3). After malonyl acyl transfer to the ACP domain, initiation modules that contain no MT_L, such as CurA (Figure 2A) and those of the pederin (Piel, 2002), onnamide (Piel et al., 2004a) and bongkrekeic acid (Moebius et al., 2012) pathways, or those that contain a defunct and apparently vestigial MT_L, such as the rhizoxin (Partida-Martinez et al., 2007), batumin (Mattheus et al., 2010) and nosperin (Kampa et al., 2013) pathways, proceed directly to decarboxylation by the GNAT-like decarboxylase, yielding an acetyl starter unit. Initiation modules with an active MT_L domain catalyze a pathway-specific number of methyl transfers prior to decarboxylation by the GNAT-like domain, yielding an isobutyryl starter unit for gephyronic acid (Young et al., 2013) and a propionyl for saxitoxin (Kellmann et al., 2008) and myxovirescin (Simunovic et al., 2006). In yet another twist of nature, the GNAT-like variant in the apratoxin (Grindberg et al., 2011) and bryostatin (Sudek et al., 2007) pathways is inactive, and a second MT domain performs coupled methylation and decarboxylation, yielding a pivaloyl starter unit (Skiba et al., 2018b). In the pathways with active methyltransferase domains, methylation of Mal-ACP rather than Mal-CoA is essential, as MeMal and Me₂Mal are precious resources that must be sequestered by the PKS enzyme assembly line. The high degree of substrate selectivity of the GNAT-like decarboxylase limits the production of an incorrect starter unit, which may stall at subsequent biosynthetic steps or lead to an incorrect product. The crystal structures and mutagenesis studies of the GphF and CurA GNAT-like decarboxylases did not reveal the basis for the observed acyl group selectivity.

PKS GNAT-like decarboxylases within the GNAT superfamily

The PKS GNAT-like decarboxylases, as well as many aminoglycoside *N*-acetyltransferases and the histone acetyltransferases (HATs), belong to a large protein family (Pfam PF00583, “Acetyltransf_1”), (El-Gebali et al., 2019) within the even larger “*N*-acetyltransferase-like” superfamily (Pfam clan CL0257, Figure S1). GNAT-like domains in polyketide pathways are not the only decarboxylases in the GNAT superfamily. Although studied for decades (Hayaishi, 1955), the catalytic domain of Mal-CoA decarboxylase (MCD) was identified as a member of the GNAT superfamily only when a crystal structure revealed strong similarity to the CurA GNAT-like domain (Figure 1) (Aparicio et al., 2013; Froese et al., 2013). In mammals, MCD modulates levels of Mal-CoA and in some cases can promote the use of MeMal-CoA in fatty acid biosynthesis, leading to tissue-specific production of multimethyl-

branched fatty acids (Kim and Kolattukudy, 1978). Disruption of the gene encoding MCD causes the genetic disorder malonic aciduria (Sacksteder et al., 1999). Bacterial genes for MCD are linked to those for a Mal-CoA synthetase and malonate transporter (An and Kim, 1998). Located on a remote island (PF05292, “MCD”) within the *N*-acetyltransferase-like superfamily clan (Figure S1), MCD catalyzes decarboxylation, lacks acyl transfer activity, has very low sequence identity (~10%) to *N*-acyltransferase members of the GNAT superfamily, and is conserved from bacteria to mammals (An and Kim, 1998; Kim and Kolattukudy, 1978). Despite this distant evolutionary relationship, the GNAT-like domains of PKS initiation modules and the MCD decarboxylases (An and Kim, 1998; Aparicio et al., 2013; Froese et al., 2013) are mechanistically alike. The essential His and Ser/Thr residues are in topologically identical positions on the identical folds of the PKS GNAT-like decarboxylases and MCD catalytic domains (Aparicio et al., 2013; Froese et al., 2013). By reference to the CurA GNAT, analogous His and Ser residues were implicated in MCD decarboxylation (Froese et al., 2013).

Another biosynthetic enzyme for polyketide initiation resides on a distant branch (PF13523, “Acetyltransf_8”) of the *N*-acetyltransferase-like superfamily tree (clan CL0257) (Figure S1). The malonyl- and methylmalonyl-CoA decarboxylase EryM from *Saccharopolyspora erythraea* [also known as SACE_1304 or Mcd (Lazos et al., 2010; Oliynyk et al., 2007; Robbel et al., 2011)] is essential for the production of both the macrolide antibiotic erythromycin (Hsieh and Kolattukudy, 1994) and the siderophore erythrochelin (Lazos et al., 2010). EryM is encoded in an otherwise defunct biosynthetic gene cluster (*npsI*) that is remote from both the erythromycin and erythrochelin clusters. The multifunctional EryM decarboxylates methylmalonyl-CoA to generate a propionyl-CoA starter unit for erythromycin biosynthesis (Hsieh and Kolattukudy, 1994). Remarkably, in erythrochelin biosynthesis, EryM both decarboxylates malonyl-CoA and transfers acetyl to δ -*N*-hydroxy-L-ornithine (Lazos et al., 2010; Robbel et al., 2011). The C-terminal domain of EryM was recognized as a member of the GNAT superfamily based on sequence similarity to other GNATs (Lazos et al., 2010; Neuwald and Landsman, 1997; Robbel et al., 2011). The sequence identity to PKS GNAT-like domains (8–15%) is too low for reliable homology modeling, but it is highly similar (36% identity) to the structurally characterized *N*-acyltransferase MbtK (Rv1347c) for biosynthesis of the mycobactin siderophore in *Mycobacterium tuberculosis* (Card et al., 2005; Krithika et al., 2006). MbtK and the GNAT-like domain of EryM do not contain His and Ser/Thr residues in analogous locations to the amino acids essential for catalysis by the PKS GNAT-like decarboxylases or MCD. Instead MbtK, EryM and a number of unannotated EryM homologs contain conserved His and Glu(Asp) amino acids (Figure S2). In MbtK, these amino acids are critical for long-chain fatty acyl transfer from ACP to lysine N⁶ (Frankel and Blanchard, 2008; Krithika et al., 2006; McMahon et al., 2012). The His and Glu(Asp) map to the V-shaped Ppant binding pocket, but are on the opposite side of the central β -sheet relative to the catalytic residues of the PKS GNAT-like decarboxylases and MCD. Therefore, EryM relies on alternative decarboxylation mechanism. This is a remarkable example of independent evolution of catalytic activities on a fold.

The enormous *N*-acetyltransferase-like superfamily (> 280,000 members), including the histone acetyltransferases (HAT) of epigenetic regulation and the aminoglycoside *N*-

acetyltransferases, is classically recognized for the GNAT fold and for acetylation of a diverse set of substrates from an acetyl-CoA donor (Dyda et al., 2000). Our work on GNAT-like enzymes in polyketide biosynthesis illuminates additional chemical reactivity within the superfamily. In polyketide initiation modules, the GNAT fold has been co-opted for selective decarboxylation of Mal-ACP, MeMal-ACP, or Me₂Mal-ACP with a strict substrate selectivity that ensures synthesis of the correct natural product. The identical catalytic machinery is employed by these PKS GNAT-like decarboxylases and by MCD, although their sequences are highly diverged. Interestingly, another branch of the GNAT superfamily includes the bifunctional decarboxylase / acyltransferase EryM of erythromycin and erythrochelin biosynthesis (Hsieh and Kolattukudy, 1994) and the fatty acyltransferase of mycobactin biosynthesis. EryM lacks the residues required for decarboxylation by MCD and the PKS GNAT-like decarboxylases, indicating that the superfamily harbors members with an alternative decarboxylation mechanism. Additional uncharacterized decarboxylase members of the GNAT superfamily may currently be misannotated as acyltransferases. Overall, the common feature of many GNAT acyltransferases and decarboxylases is the ability to bind the pantetheine moiety of CoA or ACP at the characteristic V-shaped Ppant binding pocket in the central β -sheet and to stabilize a thioester enolate common to the acyltransfer and decarboxylation reactions on CoA-or ACP-linked substrates. The broad substrate scope and varied catalytic functions of the GNAT fold provide a fascinating example of divergent enzymatic evolution and provoke interest into the evolutionary origin of the superfamily.

STAR METHODS

LEAD CONTACT AND MATERIALS AVAILABILITY

Requests for resources and reagents should be directed to and will be fulfilled by the Lead Contact, Janet Smith (JanetSmith@umich.edu). All plasmids generated in this study are available from the Lead Contact with a Materials Transfer Agreement.

EXPERIMENTAL MODEL AND SUBJECT DETAILS

E. coli BL21(DE3) was used for heterologous expression of all proteins in this study.

METHOD DETAILS

Construct Design—DNA encoding the GphF GNAT was amplified from a partial *gphF* clone provided by Richard Taylor (Notre Dame University) and inserted into pMCSG7 (Stols et al., 2002) by ligation independent cloning (LIC) to create the expression plasmid for GphF GNAT (residues 498–705, GenBank [KF479198.1](#); pMAS/APS340). A cDNA encoding the CurA ACP (residues 444–521, GenBank [AEE88289.1](#)) was amplified from a cosmid library (Chang et al., 2004) and inserted into pMCSG7 via LIC to create pMAS/APS442. All *gphF* site-directed mutants (Supporting Information Table 2) were introduced into pMAS340 using the QuickChange protocol (Stratagene). All primers are listed in Table S1. All constructs and mutations were verified by Sanger sequencing at the University of Michigan DNA Sequencing Core.

Protein Expression and Purification—*Escherichia coli* strain BL21(DE3) was transformed with plasmids encoding GphF GNAT and CurA GNAT (residues 219–439, GenBank [AEE88289.1](#) in pMCSG7) (Gu et al., 2007). Transformed cells were grown in 0.5 L of TB media at 37°C supplemented with 100 µg mL⁻¹ ampicillin to an OD₆₀₀=1–2, cooled to 20°C for 1 hr, and induced with 200 µM IPTG for 18 hr. Cell pellets were resuspended in 35 mL Tris buffer A (50 mM Tris pH 7.4, 300 mM NaCl, 10% (v/v) glycerol, 20 mM imidazole), 0.1 mg mL⁻¹ lysozyme, 0.05 mg mL⁻¹ DNase, and 2 mM MgCl₂, incubated on ice for 30 min, lysed by sonication, and cleared by centrifugation (38,760 × g, 15–30 min, 4°C). The supernatant was filtered and loaded onto a 5 mL HisTrap column (GE Healthcare) or 5 mL of Ni-NTA resin (Qiagen) equilibrated with Tris buffer A. After washing with 10 column volumes of Tris buffer A, proteins were eluted with a 5–100% gradient of Tris buffer B (50 mM Tris 7.4, 300 mM NaCl, 10% glycerol, 400 mM imidazole) over 10 column volumes. Single-step purified CurA GNAT was dialyzed into Tris Buffer A for acyl transfer assays. Proteins used for decarboxylation assays and crystallization were further purified by size exclusion chromatography (HiLoad 16/60 Superdex S75) in Tris buffer C (50 mM Tris pH 7.4, 150 mM NaCl, 10% glycerol).

GphF GNAT used for acyl transfer assays was dialyzed into 50 mM BisTris pH 6.5, 20 mM NaCl, 10% glycerol (BisTris buffer A) and loaded on a HiTrap Q anion exchange column (GE Healthcare) equilibrated with BisTris buffer A. GphF GNAT was collected from the Q column flow through and buffer exchanged into Tris buffer C via size exclusion chromatography (HiLoad 16/60 Superdex S75).

A multistep purification was used for CurA GNAT intended for acyl transfer assays. Cell pellets were resuspended in 5 mL Tris buffer D (100 mM Tris pH 7.9, 300 mM NaCl, 10% glycerol, 15 mM imidazole) per 1 g cell pellet with 4 mg DNase, 10 mg lysozyme, and 4 mM MgCl₂ and incubated on ice for 30 min. Cells were lysed by three passes through an Avestin EmulsiFlex-C3 homogenizer and cleared by centrifugation (30,000 × g, 30 min, 4°C). The supernatant was filtered and loaded onto a 5 mL HisTrap column equilibrated with Tris buffer D. Protein was eluted with a gradient of 30–300 mM imidazole. The His-tag was cleaved by overnight incubation with tobacco etch virus (TEV) protease (1:30 ratio of TEV protease: CurA GNAT with 2 mM DTT) and dialyzed into Tris buffer D. The digested protein was passed over a second 5 mL HisTrap column. Tag-free CurA GNAT was collected from the flow through and further purified by size exclusion chromatography (HiLoad 16/60 Superdex S200) in Tris buffer D.

GphF MT1-GNAT (residues 2–696, GenBank [KF479198.1](#)) used for acyl transfer assays was purified as described previously (Skiba et al., 2017) and then diluted into Hepes buffer A (50 mM Hepes pH 7.4, 15 mM NaCl, 10% glycerol). GphF MT1-GNAT was then loaded onto a HiTrap Q Column equilibrated with Hepes buffer A, washed with 10 column volumes of Hepes buffer A and eluted with a 0.15–1 M linear gradient of NaCl over 20 column volumes. GphF MT-GNAT was buffer exchanged into Hepes buffer B (50 mM Hepes pH 7.4, 150 mM NaCl, 10% glycerol) via size exclusion chromatography (HiLoad 16/60 Superdex S200).

AprA apo-ACP (residues 1058–1138, GenBank [WP_075900460](#)) was produced and purified as described previously (Skiba et al., 2017). A trace metals mix was included in the growth medium to inhibit addition of the phosphopantetheinyl post translational modification by endogenous *E. coli* enzymes (Skiba et al., 2018a). CurA ACP (residues 444–519, GenBank [AEE88289.1](#)) was produced and purified identically to AprA ACP. *M. bouillonii* FabD (residues 1–298, GenBank [WP_075905309.1](#)) (Skiba et al., 2018b) and AprA MT1-ΨGNAT (residues 2–629, GenBank [WP_075900460](#)) (Skiba et al., 2017) were produced and purified as described previously.

Production of Acyl-ACPs—AprA and CurA holo-, malonyl- (Mal-), and methylmalonyl- (MeMal-)ACPs were produced by incubating 180 μM apo-ACP with 20 μM *Streptomyces verticillus* phosphopantetheinyl transferase (SVP) (Sánchez et al., 2001), and ~0.65 mM CoA, Mal-CoA, or MeMal-CoA in 50 mM Tris pH 7.4, 150 mM NaCl, 10% glycerol, 20 mM MgCl₂ for 4 hr at 30°C. The ACP was purified from the reaction mixture by size exclusion chromatography (HiLoad 16/60 Superdex S75) equilibrated with Tris buffer E (100 mM Tris pH 7.4, 250 mM NaCl, 5% glycerol, 5 mM tris(2-carboxyethyl)phosphine (TCEP).

As dimethylmalonyl (Me₂Mal)-CoA is not commercially available, AprA MT1 (Skiba et al., 2017) was used to convert the AprA and CurA MeMal-ACPs to the Me₂Mal-ACPs. Reaction mixtures for AprA ACP (~3 mL total in 130 μL aliquots) containing 300 μM AprA MeMal-ACP, 150 μM AprA MT1-ΨGNAT and 6 mM *S*-adenosylmethionine (SAM) in 50 mM Hepes pH 7.4, 150 mM NaCl, 3 mM Fe(NH₄)₂(SO₄)₂ were incubated 5.5 hr at 30°C. Reaction mixtures for CurA ACP (~4 mL total in 50 μL aliquots) containing 150 μM CurA MeMal-ACP, 150 μM AprA MT1-ΨGNAT and 6 mM SAM in 50 mM Hepes pH 7.4, 150 mM NaCl, 3 mM Fe(NH₄)₂(SO₄)₂ were incubated for 6 hr at 30°C. Me₂Mal-ACPs were purified from the reaction mixtures by size exclusion chromatography (HiLoad 16/60 Superdex S75) equilibrated with Tris buffer E. Intact protein mass spectra coupled with the Ppant ejection assay (Dorrestein et al., 2006; Meluzzi et al., 2008) was used to validate the conversion of MeMal-ACP to Me₂Mal-ACP.

Enrichment of Non-specific Ni-NTA Binders—Empty pMCSG7 expression vector (Stols et al., 2002) was transformed into *E. coli* BL21(DE3), expressed and purified as described for the GphF and CurA GNAT above. His elution fractions that would typically contain the GNAT were collected, concentrated 20 fold in a 3 kDa cutoff concentrator and dialyzed into Tris Buffer A to remove imidazole.

Decarboxylation Enzyme Assays—As GphF ACP_L could not be produced in soluble form, AprA ACP_L from the apratoxin A biosynthetic pathway (Grindberg et al., 2011) was used as a surrogate ACP. Reaction mixtures (80–100 μL) containing 100 μM AprA Mal-, MeMal-, or Me₂Mal-ACP and 10 μM GphF GNAT in 50 mM HEPES pH 7.4, 150 mM NaCl were incubated at 30°C. 10 μL of the reaction mixture was collected at various time points and quenched with 1% (v/v) formic acid. 0.25 μL of reaction mixtures were subjected to LC/MS analysis.

Reaction mixtures (10 μ L) containing 100 μ M AprA acyl-ACP and 10 μ M GphF GNAT variants in 50 mM HEPES pH 7.4, 150 mM NaCl were incubated at 30°C for 5 min (Me₂Mal-ACP), 8 hr (MeMal-ACP), or 24 hr (Mal-ACP). Reactions were quenched with 1% (v/v) formic acid. 0.25 L of reaction mixtures were subjected to LC/MS analysis.

Reaction mixtures (80–100 μ L) containing 100 μ M CurA Mal-, MeMal-, or Me₂Mal-ACP and 10 μ M CurA GNAT in 50 mM HEPES pH 7.4, 150 mM NaCl were incubated at 30°C. 10 μ L of the reaction mixture was collected at various time points and quenched with 1% (v/v) formic acid. 0.1 μ L of reaction mixtures were subjected to LC/MS analysis.

Reaction mixtures (10 μ L) containing 100 μ M CurA acyl-ACP and 10 μ M CurA GNAT variants in 50 mM HEPES pH 7.4, 150 mM NaCl were incubated 6 hr (Me₂Mal-ACP), 7.5 min (MeMal-ACP), or 3 min (Mal-ACP). Reactions were quenched with 1% (v/v) formic acid. 0.1 L of reaction mixtures were subjected to LC/MS analysis.

Acyl Transfer Enzyme Assays—Acyl transfer reaction mixtures (70 μ L) containing 100 μ M AprA or CurA holo-ACP, 10 μ M CurA GNAT or GphF GNAT, 0.85 mM of Mal-, MeMal-, acetyl-, propionyl-, or isobutyryl-CoA in 50 mM Hepes pH 7.4, 150 mM NaCl were incubated at 30°C. At various time points 10 μ L aliquots were removed and quenched with 1% (v/v) formic acid. 0.25 μ L of GphF GNAT reactions and 0.1 μ L of CurA GNAT reactions were used for LC/MS analysis.

GphF MT_L-GNAT acyl transfer reaction mixtures (70 μ L) containing 100 μ M AprA holo-ACP, 10 μ M GphF MT_L-GNAT, 0.85 mM of Mal-CoA, 0.54 mM SAM, 50 mM Hepes pH 7.4, 150 mM NaCl, 0.5 mM FeH₈N₂O₈S₂ were incubated at 30°C. At various time points 10 μ L aliquots were removed and quenched with 1% (v/v) formic acid. 0.25 μ L of the reaction mixtures were subjected to LC/MS analysis.

M. bouillonii FabD reaction mixtures (120 μ L) containing 100 μ M CurA holo-ACP, 25 nM FabD, and 0.85 mM Mal-CoA in 50 mM Hepes 7.4, 150 mM NaCl were incubated at 30°C. At various time points 10 μ L aliquots were removed and quenched with 1% (v/v) formic acid. 0.1 μ L of the reaction mixtures were subjected to LC/MS analysis.

Reaction mixtures (120 μ L) with *E. coli* proteins from the mock purification contained 0.5 or 1 mg mL⁻¹ *E. coli* proteins, 100 μ M CurA holo-ACP, and 0.87 mM of Mal-CoA or acetyl-CoA in 50 mM Hepes 7.5, 150 mM NaCl and were incubated at 30°C. 10 μ L of the reaction mixture was collected at various time points and quenched with 1% (v/v) formic acid. 0.1 μ L of the reaction mixture was subjected to LC/MS analysis.

LC-MS Analysis—An Agilent Q-TOF 6545 was used to analyze reaction mixtures using the phosphopantetheine (Ppant) ejection method (Dorrestein et al., 2006; Meluzzi et al., 2008). Samples underwent reverse phase HPLC (Phenomenex Aeris widepore C4 column 3.6 μ M, 50 \times 2.10 mm) in H₂O with 0.2% (v/v) formic acid at a flow rate of 0.5 mL min⁻¹. Protein was eluted over a 4 min linear gradient of 5–100% acetonitrile with 0.2% (v/v) formic acid. Samples were subjected to the following conditions: fragmentor voltage, 225 V; skimmer voltage, 25 V; nozzle voltage, 1000 V; sheath gas temperature, 350 °C; drying gas temperature, 325 °C. Data were processed using MassHunter Qualitative Analysis Software

(Agilent). The relative abundances of Ppant ejection fragments for substrates and products were used to calculate the percent of total ACP species. In acyl transfer reactions with active GNAT domains, abundances of intact and decarboxylated acyl-ACP species were combined to calculate percent acyl group transfer.

Protein Crystallization and Structure Determination—GphF GNAT (residues 498–705, with additional N-terminal His-tag) was crystallized at 20°C by sitting drop vapor diffusion from a 2:1 μL mixture of protein stock (20.7 mg mL^{-1} GphF GNAT in Tris buffer C) and reservoir solution (30 – 35% PEG 3350, 0.23 – 0.30 M ammonium acetate, 0.10 M Bis-tris HCl pH 5.5). Crystals of thin-blade morphology grew overnight, often in clusters, and could be divided into apparently single crystals for data collection. Crystals were cryoprotected with well solution supplemented with 15% glycerol and flash cooled in liquid N_2 . For the isobutyryl-CoA complex, crystals were soaked with 2.5 mM isobutyryl-CoA for 24 hr prior to harvesting.

Diffraction data were collected at 100 K on GM/CA beamline 23ID-B at the Advanced Photon Source (APS) at Argonne National Laboratory (Argonne, IL). Data were processed using XDS (Kabsch, 2010). The thin-blade morphology of the crystals limited the data quality. Diffraction patterns were streaky and moderately anisotropic (diffraction limit for GphF GNAT: $d_{\min} = 3.3 \text{ \AA}$ along a^* , and 2.6 \AA along b^* and c^* ; isobutyryl-CoA complex: $d_{\min} = 5.0 \text{ \AA}$ along a^* and 2.8 \AA along b^* and c^*). Probing the crystal with a 10- μm beam in raster cells did not identify local regions with better spot shapes or lower anisotropy. The structure of GphF GNAT was solved by molecular replacement using Phaser (McCoy et al., 2007) through the Phenix Software Suite (Adams et al., 2010) with CurA GNAT (2REE) (Gu et al., 2007) as the starting model. Crystals of the isobutyryl complex were isomorphous with crystals of the free enzyme. Chain A contained clear density for isobutyryl-CoA, whereas density in Chain B indicated multiple positions for the CoA product analog. Iterative rounds of model building and refinement were carried out using Coot (Emsley and Cowtan, 2004) and Phenix.refine (Afonine et al., 2012) with automated translation/liberation/screw group selection. Structures were validated with MolProbity (Chen et al., 2010), and structure figures were prepared with PyMol (Schrodinger, 2015). Sequence alignments were prepared using Clustal (Larkin et al., 2007) through Jalview (Waterhouse et al., 2009). The map of GNAT families was generated in the Pfam server (El-Gebali et al., 2019).

QUANTIFICATION AND STATISTICAL ANALYSES

All biochemical assays were performed in triplicate. Error bars represent standard deviation of the mean.

DATA AND SOFTWARE AVAILABILITY

Atomic coordinates and structure factors have been deposited in the Protein Data Bank for GphF GNAT-like decarboxylase (PDB 6MFC) and the isobutyryl-CoA complex of GphF GNAT-like decarboxylase (PDB 6MFD).

Highlights:

GNAT superfamily catalyzes decarboxylation in addition to acyltransfer

A GNAT-like enzyme initiates biosynthesis of some polyketide natural products

Polyketide synthase GNAT-like enzymes catalyze only decarboxylation

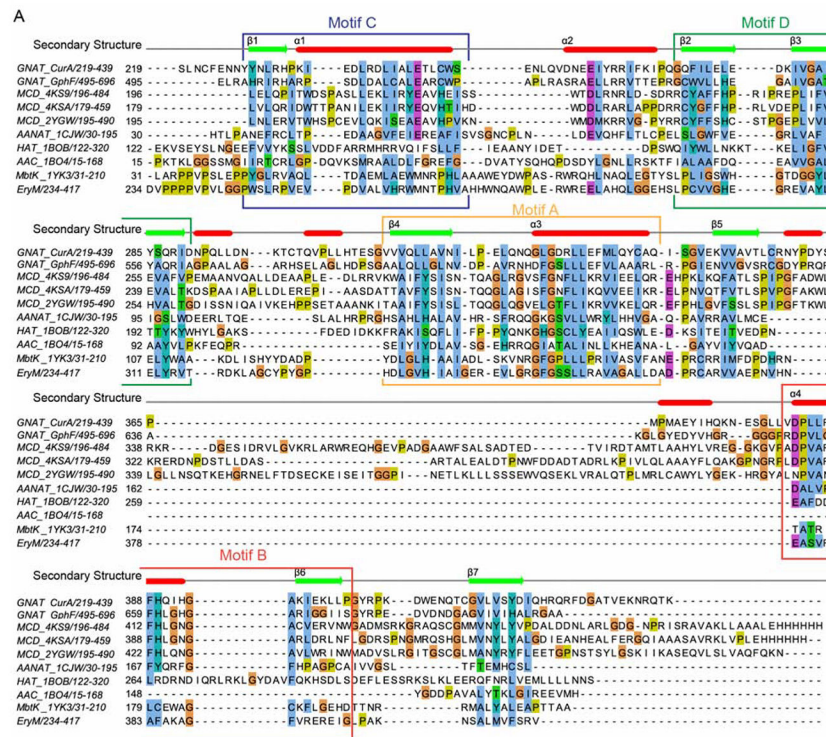

Figure 1. 3D structures of GNAT superfamily members. **(A)** Structure-based sequence alignment of PKS GNAT-like domains, malonyl-CoA decarboxylase (MCD), and *N*-acetyltransferases (See also Figure S1). Structural motifs A-D of the GNAT fold are outlined in colored boxes (Neuwal and Landsman, 1997). The CurA GNAT secondary structure is displayed above the alignment. PKS GNAT-like domains and MCD contain an insertion within motif B. Protein abbreviations: Gph-gephyronic acid, PDB 6MFC; Cur-curacin A, 2REE (Gu et al., 2007); *Cupriavidus metallidurans* MCD, 4KS9 (Froese et al., 2013); *Rhodospseudomonas palustris* MCD, 4KSA (Froese et al., 2013); *Homo sapiens* MCD, 2YGW (Froese et al., 2013); serotonin *N*-acetyltransferase AANT, 1CJW (Hickman et al., 1999); histone acetyltransferase HAT 1BOB (Dutnall et al., 1998); aminoglycoside 3-*N*-acetyltransferase AAC, 1BO4 (Wolf et al., 1998); *M. tuberculosis* *N*-acetyltransferase MbtK, 1YK3 (Card et al., 2005), *Saccharopolyspora erythraea* *N*-acetyltransferase/decarboxylase EryM. (See also Figure S2.) Structures of GNAT superfamily members **(B)** serotonin *N*-acetyltransferase AANT, **(C)** *C. metallidurans* MCD, and **(D)** CurA.

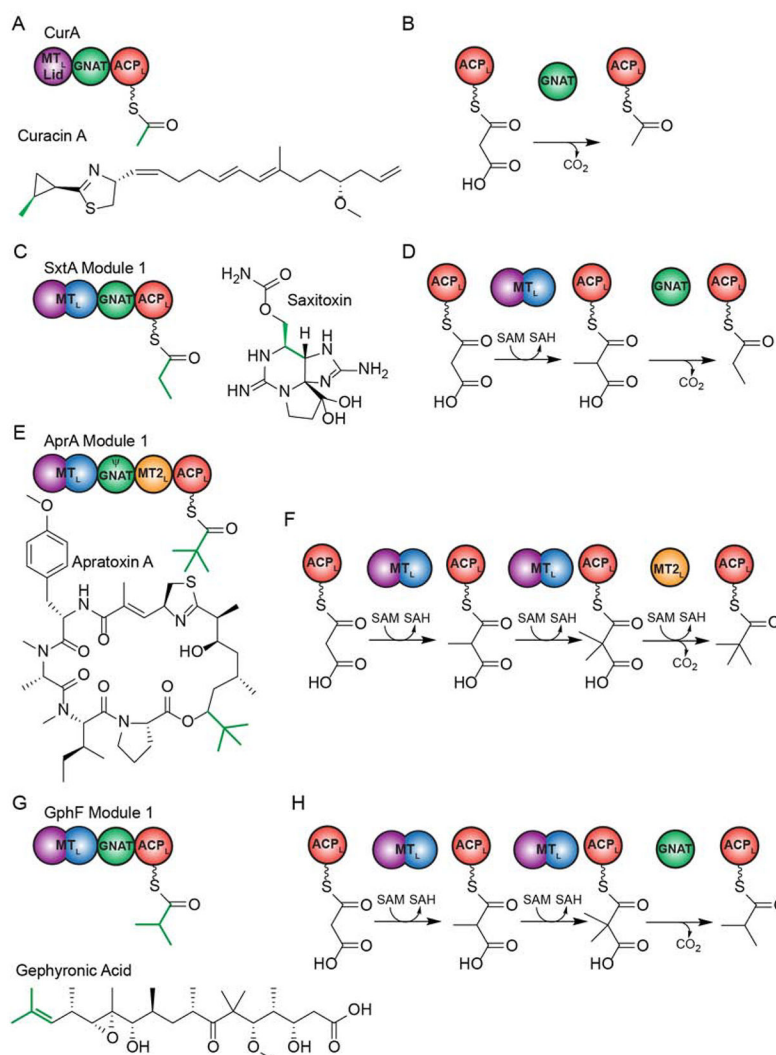

Figure 2. GNAT-like enzymes in curacin A, saxitoxin, apratoxin A, and gephyronic acid biosynthesis. (A) CurA initiation module for an acetyl starter unit (green). (B) CurA Mal-ACP decarboxylation. (C) SxtA initiation module for a propionyl starter unit. (D) SxtA Mal-ACP methylation and MeMal-ACP decarboxylation. (E) AprA initiation module for a pivaloyl starter unit. (F) AprA Mal-ACP dimethylation and coupled Me₂Mal-ACP decarboxylation/methylation. (G) GphF initiation module for an isobutyryl starter unit. (H) GphF Mal-ACP dimethylation and Me₂Mal-ACP decarboxylation. (See also Figure S3.)

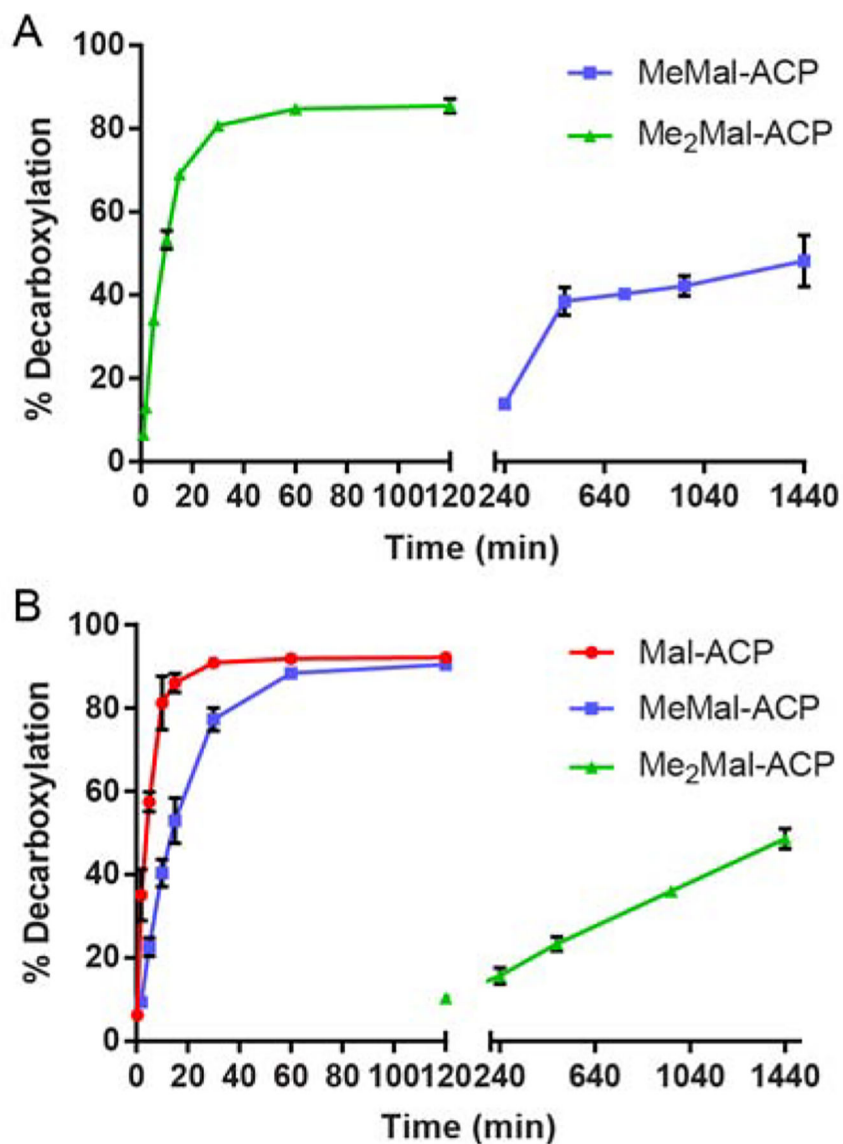

Figure 3. GphF and CurA GNAT decarboxylation activity. Decarboxylation of acyl-ACP substrates by (A) GphF GNAT and (B) CurA GNAT. Activity was monitored via the Ppant ejection assay (Dorrestein et al., 2006; Meluzzi et al., 2008). Error bars represent triplicate experiments and, in some cases, are too small to be visible. GphF GNAT did not decarboxylate Mal-ACP in a 48-hour reaction time (See also Figure S4).

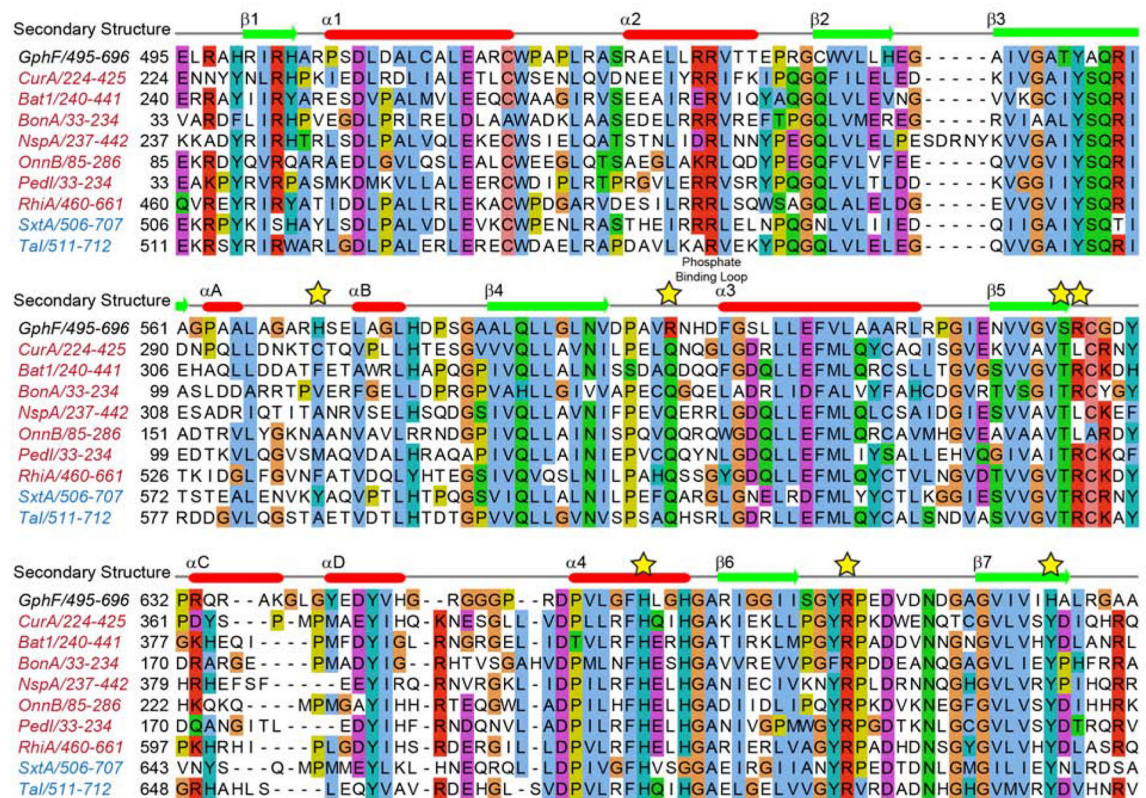

Figure 4.

(A) GphF GNAT structure. The protein is colored as a rainbow from blue (N-terminus) to red (C-terminus), shown in stereo. Isobutyryl-CoA (ball-and-stick form with atomic colors: gray C, red O, blue N, yellow S) binds to a V-shaped cleft between $\beta 4$ (green) and $\beta 5$ (yellow). (B) Characteristic GNAT β -bulge in $\beta 4$, rendered as sticks in this stereo image with coloring as in (A). The β -bulge is at the base of the V-shaped cleft between $\beta 4$ (green) and $\beta 5$, and places the α -carbons of Leu558 and Gly559 on the same face of the β -sheet. The view is from the opposite face of the β -sheet as in (A). (See also Figure S5).

**Figure 5.**

Sequence alignment of GNAT-like domains from PKS pathways for natural products of known structure. All GNAT-like domains occur in presumed initiation modules. Only GphF is predicted to produce an isobutyryl starter unit; initiation modules with propionyl starter units are in blue and those with acetyl starter units in red. The GphF GNAT secondary structure annotation is displayed above the alignment. Amino acids subjected to mutagenesis are starred. Protein abbreviations (GenBank accession codes: Gph-gephyronic acid, [KF479198.1](#); Cur-curacin A, [AEE88289.1](#); Bat-batumin, [WP_052451043.1](#); Bon-bongkrekeic acid, [AFN27480.1](#); Nsp-nosperin, [ADA69237.1](#); Onn-onnamide, [AAV97870.1](#); Ped-pederin, [AAR19304.1](#); Rhi-rhizoxin, [WP_013435483.1](#); Sxt-saxitoxin, [WP_009343302.1](#); Ta-myxovirescin A, [WP_011553948.1](#)).

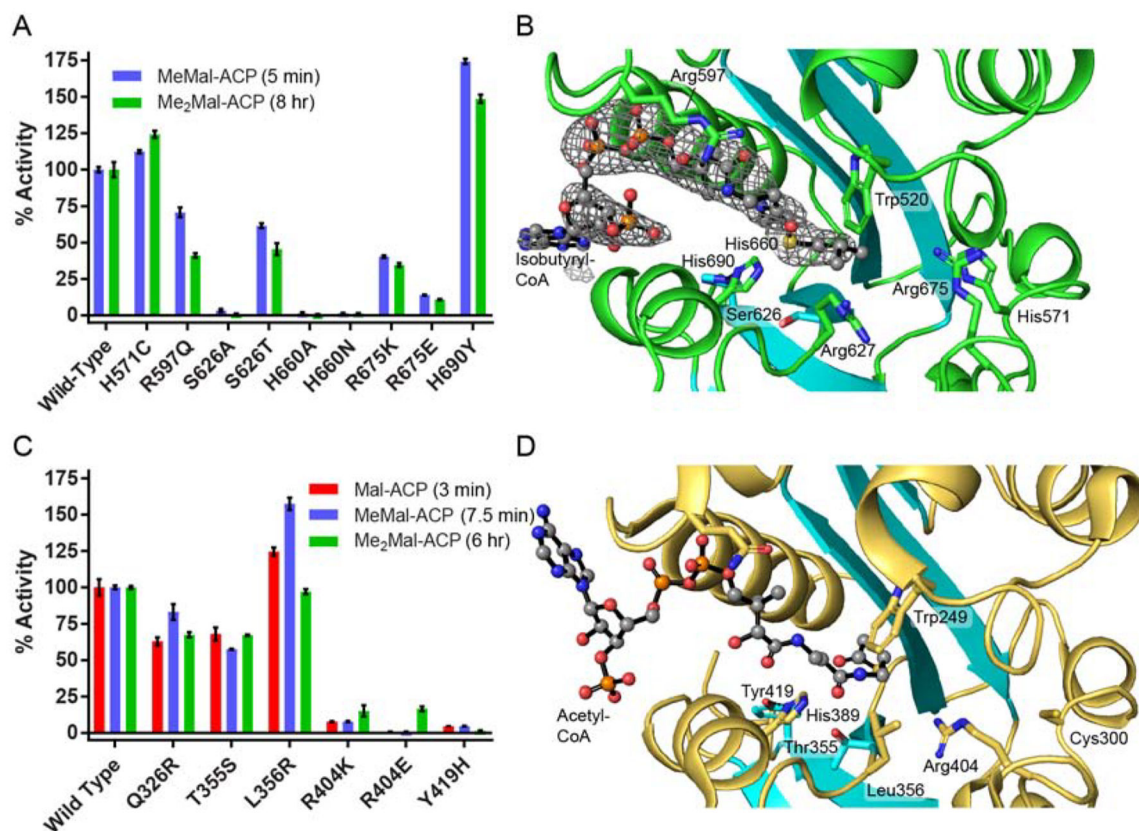

Figure 6. Probing decarboxylation via site directed mutagenesis. (A) GphF GNAT decarboxylation reactions. Activity is normalized to wild-type levels at 5 minutes (MeMal-ACP) and 8 hours (Me₂Mal-ACP) (Figure 3). (B) GphF GNAT active site with bound isobutyryl-CoA. Fo-Fc omit density for isobutyryl-CoA is shown in gray mesh at 3 σ contour. Ser626 and His660 are the catalytic amino acids. (C) CurA GNAT decarboxylation reactions. Activity is normalized to wild-type levels at 6 hours (Me₂Mal-ACP), 7.5 minutes (MeMal-ACP), and 3 minutes (Mal-ACP) (Figure 3). (D) CurA GNAT active site with bound acetyl-CoA (Gu et al., 2007). Thr355 and His389 are the catalytic amino acids. Error bars represent triplicate experiments and, in some cases, are too small to be observed. Bound CoAs are shown in ball-and-stick form. Amino acids subjected to mutagenesis are shown in sticks with atomic coloring. (See also Figure S5.)

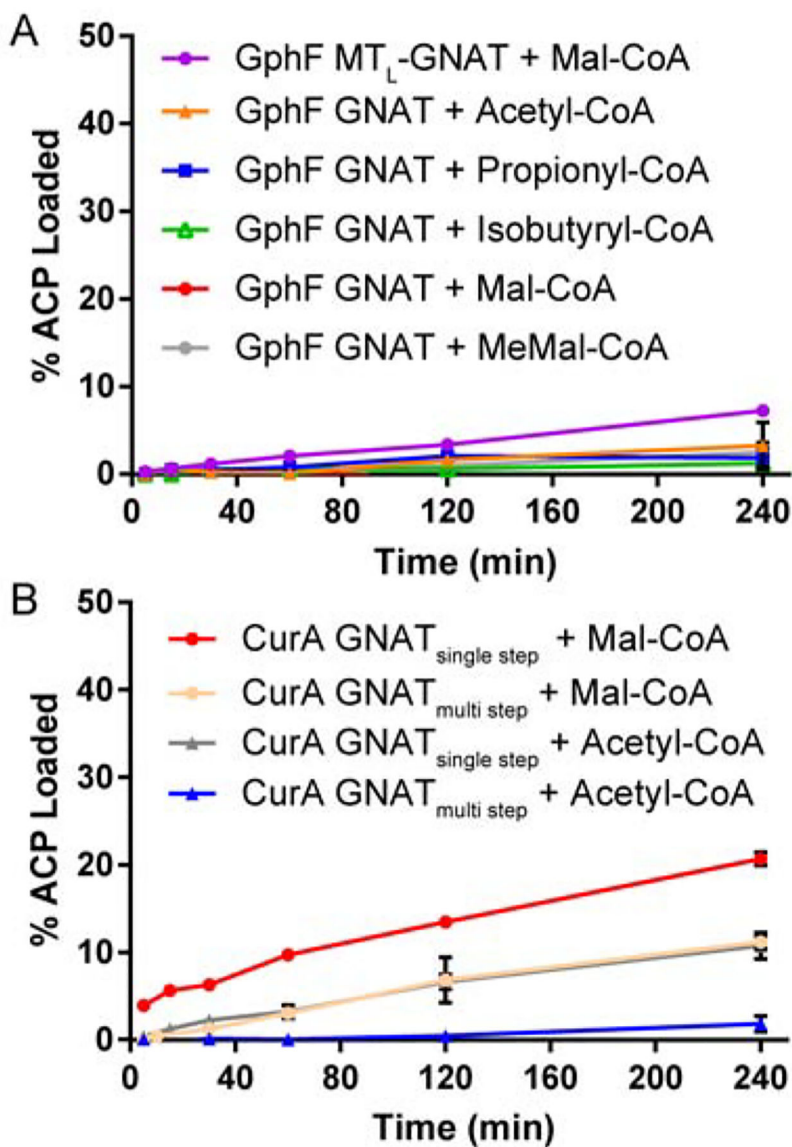

Figure 7. GphF and CurA GNAT acyl transfer assays. **(A)** Time course (4 hr) of 10 μ M GphF GNAT and 10 μ M GphF MT_L-GNAT reactions with acyl-CoAs and AprA holo-ACP. Virtually no acyl group transfer to the ACP was detected with GphF GNAT. GphF MT_L-GNAT supported low levels of malonyl transfer. **(B)** Time course (4 hr) of 10 μ M CurA GNAT reactions with Mal-CoA or acetyl-CoA and CurA holo-ACP. The apparent acyl transfer activity of CurA GNAT preparations diminished with additional purification steps whereas decarboxylation activity was unaffected (See also Figure S8). Activity was monitored via the Ppant ejection assay (Dorrestein et al., 2006; Meluzzi et al., 2008). Error bars represent triplicate experiments and, in some cases, are too small to be observed. (See also Figures S6, S7).

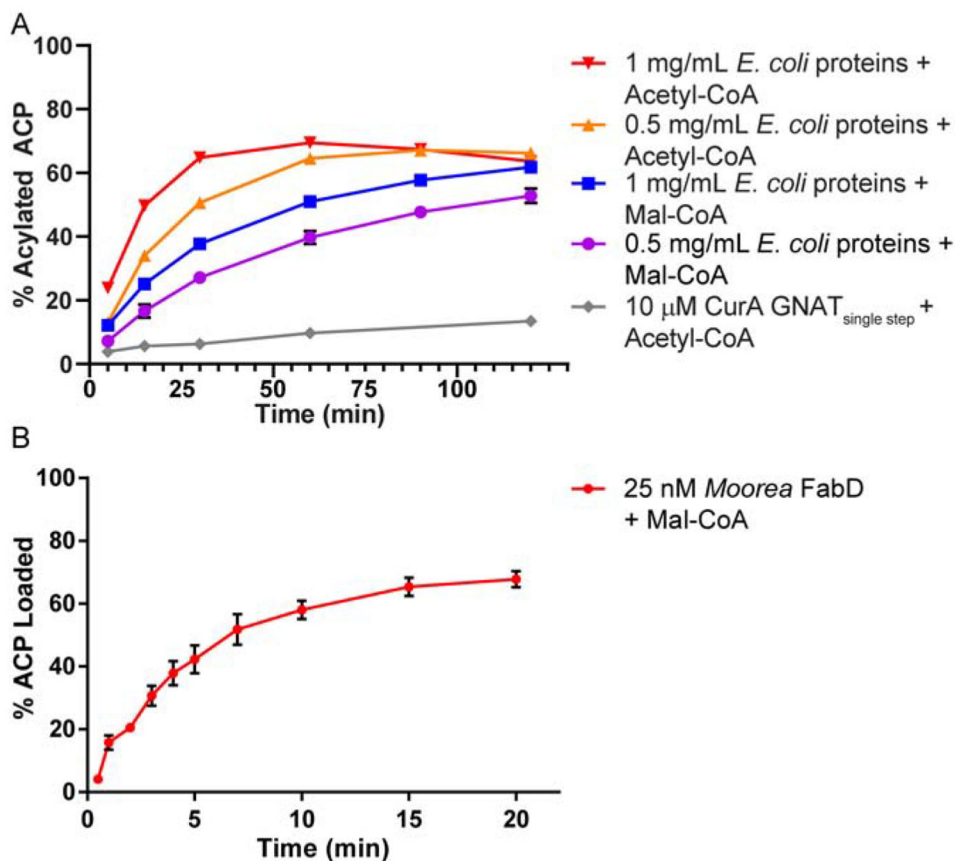

Figure 8. Time courses for acyltransfer by the *E. coli* protein mixture in reactions with CurA holo-ACP, and acetyl-CoA or Mal-CoA and *M. bouillonii* FabD reactions with CurA holo-ACP and Mal-CoA. (A) Acyltransfer by the *E. coli* mixture was concentration dependent. Error bars represent triplicate experiments and, in some cases, are too small to be visible. Acetyl transfer from single-step purified CurA GNAT (Figure 7b) is shown for comparison. (See also Figure S8). (B) 25 nM *M. bouillonii* FabD rapidly transferred malonyl from CoA to CurA ACP (20 min time course) at a 1:4000 molar ratio of FabD to ACP. (See also Figure S7).
