## Abstract

We present a shape recovery technique in  $2D$  and  $3D$  with specific applications in modeling anatomical shapes from medical images. This algorithm models extremely corrugated structures like the brain, is topologically adaptable, and runs in  $O(N \log N)$  time where  $N$  is the total number of points in the domain. Our technique is based on the level set shape recovery scheme introduced in [14, 15] and the fast marching method in [22] for computing solutions to static Hamilton-Jacobi equations.

**Index Terms:** Hamilton-Jacobi Equation, Eikonal Equation, Shape Recovery, Shape Modeling, Medical Image Analysis, Level Sets

## 1 Introduction

In many medical applications such as cardiac boundary detection and tracking, tumor volume quantification etc., accurately extracting shapes in  $2D$  and  $3D$  from medical images becomes an important task. These shapes are implicitly present in noisy images and the idea is to construct their boundary descriptions. Visualization and further processing like volume computation is then possible. In this paper, we present a fast shape modeling technique with specific applications in medical image analysis.

Active contour models [7] and surface models [27] have been used by many researchers to segment objects from medical image data. These models are based on deforming a trial shape towards the boundary of the desired object. The deformation is achieved via solving Euler-Lagrange equations which attempt to minimize an energy functional. As an alternative, implicit surface evolution models have been introduced by Malladi, Sethian, and Vemuri [14, 15]; readers are also referred to Caselles *et al.* [3] for a related effort. In these models, the curve and surface models evolve under an implicit speed law containing two terms, one that attracts it to the object boundary and the other that is closely related to the regularity of the shape.

One of the challenges in shape recovery is to account for changes in topology as the shapes evolve. In the Lagrangian perspective, this can be done by reparameterizing the curve once every few time steps and to monitor the merge/split of various curves based on some criteria; see [18]. However, some problems still remain in 3D where the issue of monitoring topological transformations calls for an elegant solution. In [14, 15], the authors have modeled anatomical shapes as propagating fronts moving under a curvature dependent speed function [21]. They adopted the level set formulation of interface motion due to Osher and Sethian [19]. The central idea here is to represent a curve as the zero level set of a higher dimensional function; the motion of the curve is then embedded within the motion of the higher dimensional surface. As shown in [19], this approach offers several advantages. First, although the higher dimensional function remains a function, its zero level set can change topology, and form sharp corners. Second, a discrete grid can be used together with finite differences to devise a numerical scheme to approximate the solution. Third, intrinsic geometric quantities like normal and curvature of the curve can be easily extracted from the higher dimensional function. Finally, everything extends directly to moving surfaces in three dimensions.

In order to isolate shapes from images, an artificial speed term has been synthesized and applied to the front which causes it to stop near object boundaries; see [14, 15] for details. In [4, 8], this work has been improved by adding an additional term to the governing equa-

tion. That work views the object detection problem as computation of curves of minimal (weighted) distance. The extra term is a projection of an attractive force vector on the curve normal. Subsequently the level set based schemes for shape recovery have been extended to 3D in [10, 5] and geometric measurements from detected anatomical shapes were made in [16]. Finally, interested readers are referred to [8, 25, 28, 13, 16] for closely related efforts.

One drawback of the level set methodology stems from computational expense. By embedding a curve as the zero-level set of a higher dimensional function, we have turned a two-dimensional problem into a three-dimensional one. Reducing the added computational expense without sacrificing the other advantages of level set schemes has been the focus of some recent work. Tube or narrow-band methods both in 2D and 3D have been developed and used in [6, 15, 1, 10]. The main idea of the tube method is to modify the level set method so that it only affects points close to the region of interest, namely the cells where the front is located. Another way to reduce the complexity of level set method is adaptive mesh refinement. This is precisely what Milne [17] has done in his thesis. The basic idea here is to start with a relatively coarse grid and adaptively refine the grid based on proximity to the zero level set or at places with high curvature. In both these cases it is possible to reduce computational expense from  $O(M^3)$  to  $O(M^2)$  per time step in the case of a moving surface, where  $M$  is the number of points in each coordinate direction. Multi-scale implementation has also been considered as a possibility for fast solution of the level set equation [28].

In this paper, we solve the shape modeling problem by using the fast marching methods devised recently by Sethian [22, 23] and extended to a wider class of Hamilton-Jacobi equations in [2]. The marching method is a numerical technique for solving the Eikonal equation, and results from combining upwind schemes for viscosity solutions of Hamilton-Jacobi equations, narrow-band level set methods, and a *min*-heap data structure. It results in a time complexity of  $O(N \log N)$ , where  $N$  is the total number of points in the domain. The rest of this paper is organized as follows: section 2 introduces the fast marching method; section 3 explains shape recovery with the marching method and how it ties together with the level set

method [15, 10]; section 4 presents some results in  $2D$  and  $3D$ . We note that an abbreviated version of this paper was reported in Malladi and Sethian [9].

## 2 The Fast Marching Method

We now briefly discuss the fast marching algorithm introduced in [22], which we shall need for shape recovery. Let  $\Gamma$  be the initial position of a hypersurface and let  $F$  be its speed in the normal direction. In the level set perspective, one views  $\Gamma$  as the zero level set of a higher dimensional function  $\psi(x, y, z)$ . Then, by chain rule, an evolution equation for the moving hypersurface can be produced [19], namely

$$\psi_t + F(x, y, z) |\nabla\psi| = 0, \quad (1)$$

Consider the special case of a monotonically advancing surface, i.e. a surface moving with speed  $F(x, y, z)$  that is always positive (or negative). Now, let  $T(x, y, z)$  be the time at which the surface crosses a given point  $(x, y, z)$ . The function  $T(x, y, z)$  then satisfies the equation

$$|\nabla T| F = 1; \quad (2)$$

this simply says that the gradient of arrival time is inversely proportional to the speed of the surface. Broadly speaking, there are two ways of approximating the position of the moving surface; iteration towards the solution by numerically approximating the derivatives in Eqn. 1 on a fixed Cartesian grid, or explicit construction of the solution function  $T(x, y, z)$  from Eqn. 2. Our marching algorithm relies on the latter approach.

For the following discussion, we limit ourselves to a two-dimensional problem. Using the correct “entropy” satisfying [21, 19] approximation to the gradient, we are therefore looking for a solution in the domain to the following equation:

$$[\max(D_{i,j}^- T, 0)^2 + \min(D_{i,j}^+ T, 0)^2 + \max(D_{i,j}^- T, 0)^2 + \min(D_{i,j}^+ T, 0)^2]^{1/2} = 1/F_{i,j}, \quad (3)$$

where  $D^-$  and  $D^+$  are backward and forward difference operators. Since the above equation is in essence a quadratic equation for the value at each grid point, we can iterate until

convergence by solving the equation at each grid point and selecting the largest possible value as the solution. This is in accordance with obtaining the correct viscosity solution.

## 2.1 The Algorithm

The key to constructing the fast algorithm is the observation that the upwind difference structure of Eqn. 3 means that information propagates from smaller values of  $T$  to larger values. Hence, the algorithm rests on building a solution to Eqn. 3 outwards from the smallest  $T$  value. Motivated by the methods in [1, 15], the “building zone” is confined to a narrow band around the front. The idea is to sweep the front ahead in an upwind fashion by considering a set of points in the narrow band around the current front, and to march this narrow band forward. We explain this algorithmically:

To illustrate, imagine that one wants to solve the Eikonal equation on an  $M$  by  $M$  grid on the unit box  $[0, 1] \times [0, 1]$  with right-hand-side  $F_{i,j} > 0$ ; furthermore, we are given an initial set  $T = 0$  along the top of the box.

### 1. Initialize

- (a) (Alive Points): Let *Alive* be the set of all grid points at which the value of  $T$  is fixed. In our example,  $Alive = \{(i, j) : i \in \{1, \dots, M\}, j = M\}$ .
- (b) (Narrow Band Points): Let *NarrowBand* be the set of all grid points in the narrow band. For our example  $NarrowBand = \{(i, j) : i \in \{1, \dots, M\}, j = M - 1\}$ , also set  $T_{i,M-1} = dy/F_{i,j}$ , where  $dy$  is the spatial step size along  $y$  axis.
- (c) (Far Away Points): Let *FarAway* be the set of all the rest of the grid points  $\{(i, j) : j < M - 1\}$ , set  $T_{i,j} = \infty$  for all points in *FarAway*.

### 2. Marching Forwards

- (a) Begin Loop: Let  $(i_{\min}, j_{\min})$  be the point in *NarrowBand* with the smallest value for  $T$ .

- (b) Add the point  $(i_{\min}, j_{\min})$  to *Alive*; remove it from *NarrowBand*.
- (c) Tag as neighbors any points  $(i_{\min} - 1, j_{\min})$ ,  $(i_{\min} + 1, j_{\min})$ ,  $(i_{\min}, j_{\min} - 1)$ ,  $(i_{\min}, j_{\min} + 1)$  that are not *Alive*; if the neighbor is in *FarAway*, remove it from that set and add it to the *NarrowBand* set.
- (d) Recompute the values of  $T$  at all neighbors according to Equation (3), solving the quadratic equation given by our scheme.
- (e) Return to top of Loop.

For more general initial conditions, and for a proof that the above algorithm produces a viable solution, see [2, 24].

## 2.2 The Min-Heap Data Structure

An efficient version of the above technique relies on a fast way of locating the grid point in the narrow band with the smallest value for  $T$ . We use a variation on a heap algorithm (see Segdewick [20]) with back pointers to store the  $T$  values.

Specifically, we use a min-heap data structure. In an abstract sense, a min-heap is a “complete binary tree” with a property that the value at any given node is less than or equal to the values at its children. In practice, it is more efficient to represent a heap sequentially as an array by storing a node at location  $k$  and its children at locations  $2k$  and  $2k + 1$ . From this definition, the parent of a given node at  $k$  is located at  $\lfloor \frac{k}{2} \rfloor$ . Therefore, the root which contains the smallest element is stored at location  $k = 1$  in the array. Finding the parent or children of a given element are simple array accesses which take  $O(1)$  time.

We store the values of  $T$  together with the indices which give their location in the grid structure. Our marching algorithm works by first looking for the smallest element in the *NarrowBand*; this `FindSmallest` operation involves deleting the root and one sweep of `DownHeap` to ensure that the remaining elements satisfy the heap property. The algorithm proceeds by tagging the neighboring points that are not *Alive*. The *FarAway* neighbors are added to the heap using an `Insert` operation and values at the remaining points are

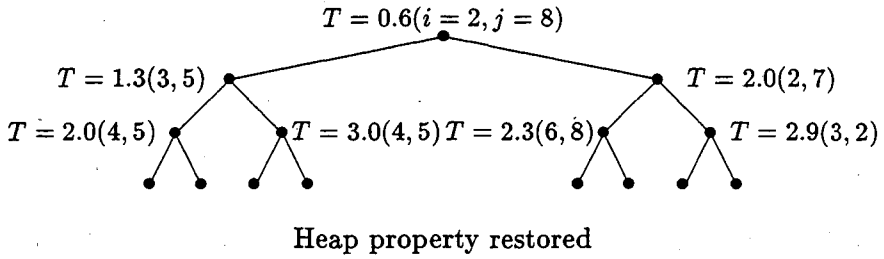

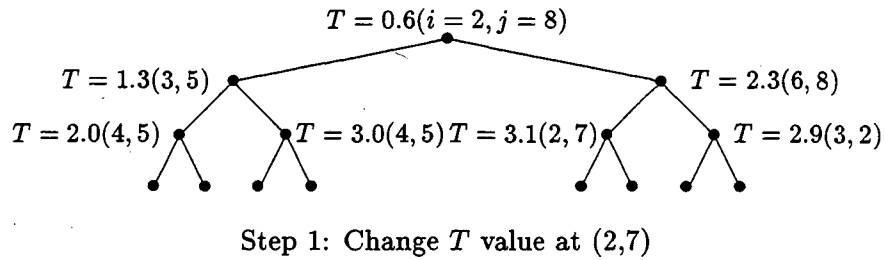

Figure 1: Heap structure and the UpHeap operation

updated using Equation 3. Insert works by increasing the heap size by one and trickling the new element upward to its correct location using an UpHeap operation. Lastly, to ensure that the updated  $T$  values do not violate the heap property, we need to perform a UpHeap operation starting at that location and proceeding up the tree.

The DownHeap and UpHeap operations (in the worst case) carry an element all the way from root to bottom or vice versa. Therefore, this takes  $O(\log M)$  time assuming there are  $M$  elements in the heap. It is important to note that the heap which is a complete binary tree is always guaranteed to remain balanced. This leaves us with the operation of searching for the *NarrowBand* neighbors of the smallest element in the heap. We make this  $O(1)$  in time by

maintaining back pointers from the grid to the heap array. Without the back pointers, the above search takes  $O(M)$  in the worst case. The example in Fig. 1 shows the heap structure as the value at location  $(2, 7)$  changes from 3.1 to 2.0.

### 3 Shape Recovery from Medical Images

Given a noisy image function  $I(\mathbf{x})$ ,  $\mathbf{x} \in \mathcal{R}^2$  for a 2D image and  $\mathbf{x} \in \mathcal{R}^3$  in 3D, the objective in shape modeling is to extract mathematical descriptions of certain anatomical shapes contained in it. We are interested in recovering boundary representation of these shapes with minimal user interaction. In general, our approach consists of starting from user-defined “seed points” in the image domain and to grow trial shape models from these points. These surfaces are made to propagate in the normal direction with a speed  $F(\mathbf{x})$ .

Shape recovery is possible if we synthesize a special image-based speed function which is defined as a decreasing function of image gradient  $|\nabla I(\mathbf{x})|$ . The image-based speed function, say  $k_I$ , controls the outward propagation of an initial surface (an interior point or a set of interior points) such that the shape model stops in the vicinity of shape boundaries. Mathematically this procedure corresponds to solving a static Hamilton-Jacobi equation (see Eqn. 1) which, when recast in the arrival time framework, is

$$|\nabla T(\mathbf{x})| = \frac{1}{k_I}. \quad (4)$$

The speed function defined as

$$F(\mathbf{x}) = k_I(\mathbf{x}) = e^{-\alpha|\nabla G_{\sigma} * I(\mathbf{x})|}, \quad \alpha > 0, \quad (5)$$

has values very close to zero near high image gradients, i.e., possible edges. False gradients due to noise can be avoided by applying a Gaussian smoothing filter or more sophisticated edge-preserving smoothing schemes (see [11, 12, 13, 10, 26]).

As an example, we consider the problem of reconstructing the entire cortical structure of the human brain from a dense MRI data set. The data is given as intensity values on a

256 × 256 × 124 grid. We start by defining “seed” points in the domain. The value of  $T$  at these points is set to zero and the initial heap is constructed from their neighbors. The fast marching algorithm in 3D is then employed to march ahead to fill the grid with time values according to Eqn. 2. We visualize various stages of our reconstruction by rendering particular level surfaces of the final time function  $T(x, y, z)$ . These stages are shown in Fig. 2. The corrugated structure shown in Fig. 2(f) is our final shape. In the Fig. 4(a)-(d), we render the same  $\{T(x, y, z) = 0.75\}$  surface from different perspectives. Finally, in Fig. 4(e), we slice the surface parallel to the  $xy$  plane and superimpose the resulting contours on the corresponding image (see Fig. 4(f)). The timings for various stages of calculation on a Sun SPARC 1000 machine are shown in Fig. 3.

With this model, the surface does not always stop near the shape boundary unless the speed values are very close to zero. More often than not, there are variations in the gradient along the object boundary which can cause the shape to “over-shoot”. In large part, the definition of Eqn. 5 ensures that the speed  $F$  goes to zero rapidly and minimizes the over-shoot effect. However, to be further accurate, we now follow the ideas in [14, 15, 4, 10] and outline how additional constraints can be imposed on the surface motion.

### 3.1 Level set method

First, note that the shape model is represented implicitly as a particular level set of a function  $\psi(\mathbf{x})$  defined in the image domain. As shown in section 2, an evolution equation can be written for the function  $\psi$  such that it contains the motion of the surface embedded in it. Let the surface move under a simple speed law  $F = 1 - \epsilon K$ , where  $K(\mathbf{x})$  is the curvature and  $\epsilon > 0$ . The constant component of  $F$  causes the model to seek object boundaries and the curvature component controls the regularity of the deforming shape. Geometric quantities like surface normal and curvature can be extracted from the higher dimensional function  $\psi$ ; for example

$$K = \frac{\psi_{xx}\psi_y^2 - 2\psi_x\psi_y\psi_{xy} + \psi_{yy}\psi_x^2}{(\psi_x^2 + \psi_y^2)^{3/2}} \quad (6)$$

(a)  $\{T(x, y, z) = 0.01\}$

(b)  $\{T(x, y, z) = 0.035\}$

(c)  $\{T(x, y, z) = 0.075\}$

(d)  $\{T(x, y, z) = 0.125\}$

(e)  $\{T(x, y, z) = 0.25\}$

(f)  $\{T(x, y, z) = 0.75\}$

Figure 2: Evolutionary sequence showing the brain reconstruction.

Grid Size	Time to Load Speed File	Time to Propagate Surface	Total Time
256 × 256 × 124	8.61 secs	74.92 secs	83.53 secs

Figure 3: Timing for Marching to  $T=0.75$ : Sun SPARC 1000

in 2D and in 3D the mean curvature is given by the expression

$$K = \frac{\psi_{xx}(\psi_y^2 + \psi_z^2) + \psi_{yy}(\psi_x^2 + \psi_z^2) + \psi_{zz}(\psi_x^2 + \psi_y^2) - 2\psi_{xy}\psi_x\psi_y - 2\psi_{yz}\psi_y\psi_z - 2\psi_{zx}\psi_z\psi_x}{(\psi_x^2 + \psi_y^2 + \psi_z^2)^{3/2}}. \quad (7)$$

The driving force that molds the initial surface into desired anatomical shapes comes from two image-based terms. The first one is similar to Eqn. 5 and the second term attracts the surface towards the object boundaries; the latter term has a stabilizing effect especially when there is a large variation in the image gradient value. Specifically, the equation of motion is

$$\psi_t + g_I(1 - \epsilon K)|\nabla\psi| - \beta\nabla P \cdot \nabla\psi = 0. \quad (8)$$

where,

$$g_I(\mathbf{x}) = \frac{1}{1 + |\nabla G_\sigma * I(\mathbf{x})|}. \quad (9)$$

The second term  $\nabla P \cdot \nabla\psi$  denotes the projection of an (attractive) force vector on the surface normal. This force which is realized as the gradient of a potential field (see [4])

$$P(\mathbf{x}) = -|\nabla G_\sigma * I(\mathbf{x})|, \quad (10)$$

attracts the surface to the edges in the image; coefficient  $\beta$  controls the strength of this attraction.

In this work, we adopt the following two stage approach when necessary. We first construct the arrival time function using our marching algorithm. If a more accurate reconstruction is desired, we treat the final  $T(\mathbf{x})$  function as an initial condition to our full model. In other words, we solve Eqn. 8 for a few time steps using explicit finite-differencing with  $\psi(\mathbf{x}; t = 0) = T(\mathbf{x})$ . This too can be done very efficiently in the narrow band framework [15, 1]. Finally, the above initial condition is a valid one since the surface of interest is a particular level set of the final time function  $T$ .

## 4 Results

In this section, we present some shape recovery results from  $2D$  and  $3D$  medical images using the two-stage procedure we described in the previous section. We begin by defining seed points inside the region of interest; in most cases one mouse click will suffice. The value of  $T(\mathbf{x})$  at these points is set to zero and the initial heap in order to start the marching method is constructed from their neighbors. We then employ the marching method to march until a fixed time or until the size of heap doesn't change very much between two successive time increments. This ends stage #1 of our scheme. We pass the final  $T(\mathbf{x})$  function as the initial state to Eqn. 8 which is then solved for a few time steps. In  $2D$ , this whole procedure takes less than a second on a typical Sun SPARC workstation and to recover a  $3D$  shape, the method executes in few tens of seconds.

First, we present some results in  $2D$ . In Fig. 5(a), we show a  $256 \times 256$  image of the thoracic region along with the user-defined seed point inside the liver cross-section. The marching method is run until  $T(x, y) = 0.90$ ; Fig. 5(b) depicts the level set  $\{T = 0.75\}$ . This function is then treated as the initial state to our full method, Eqn. 8, and the final shape, the level set  $\{\psi = 0.75\}$ , is shown in Fig. 5(c). In Figs. 5(d)-(f), we show the same sequence with the same parameters to reconstruct the shape of left ventricle from a different image. Finally, in Figs. 5(g)-(i), we show the final shapes of left ventricle cross-sections from three other images.

In the next set of figures, we present examples in  $3D$ . Figure 6 shows the reconstruction of spleen from a  $3D$  CT image of size  $256 \times 256 \times 64$ . We begin by initializing stage # 1 with a set of mouse clicks in the image domain; see Fig. 6(a). As we did before in Fig. 2, we render various isosurfaces of the final time function  $T(x, y, z)$ . Note that the shading model and colors used are purely artificial and have no relation to the real organ. The time function  $T$  is passed as an initial state to the level set shape recovery equation which is then solved for a few steps in a narrow-band around the level surface  $\{\psi = 0.1\}$ . The result is shown in Fig. 6(e). As shown in Fig. 6(d), the level surface  $\{T = 0.1\}$  that marks the end of

stage # 1, is noisy and is stopped a little further away from the object boundary compared to the final reconstruction in Fig. 6(e). This is because the speed function in Eqn. 5 falls to zero rapidly. To check the fidelity of the surface, we slice it parallel to the  $xy$  plane and superimpose the resulting contour on the corresponding image slice; see Fig. 7. Finally, in Fig. 8 we show two views of reconstructed shapes of liver, heart chambers, and the spleen from  $256 \times 256 \times 64$  medical images.
