This version: September 2002

Abstract: Eighty five percent of Italian men aged 18-33 live with their parents. In this paper we use micro data from the Bank of Italy Survey of Households' Income and Wealth from 1989 to 1998 to explain this remarkably high rate of cohabitation. We argue that Italian parents like to live with their children and a rise in their income makes it possible for them to offer their children higher consumption in exchange for their presence at home. Children prefer to live on their own but are willing to exchange some independence for extra consumption. We test the predictions of the model by estimating the effect of parental income on the probability that children live with their parents. The key econometric issue is the endogeneity of parental income. In order to identify the causal effect of parental income on children's living arrangements we use changes in parents' retirement age induced by the 1992 reform of the Italian social security as an instrument for parental income. By raising retirement age, this reform forced some fathers to remain in the labor market longer than the cohort immediately preceding them, therefore raising their income. Our instrumental variable estimates indicate that a rise in parents' income significantly raises the children's propensity to live at home: a \$500 increase in annual parental income results in a 3 to 3.5 percentage point rise in the proportion of children living with their parents.

1. Introduction

Young Italian men are considerably more likely to live with their parents than are their European and American counterparts. Eighty five percent of Italian men aged 18-33 live with their parents. In contrast, only 35% of American men of the same age live with their parents (Table 1). The percentage is only slightly higher for French, German and British men. Even among the other Southern European countries, rates of cohabitation are still lower than they are in Italy.

In this paper we analyze the economic determinants of the living arrangements of young Italian men. Obvious explanations for the high fraction of cohabiting Italians are the high youth unemployment rate and housing costs. While we do not rule out the importance of these two factors, we focus on an alternative, less obvious explanation. We argue that a rise in parental income makes it possible for parents to offer their children higher consumption in exchange for their presence at home. We formalize this intuition within the framework of a simple bargaining model between parents and children based on the assumption that cohabitation is a 'good' for parents and a 'bad' for children. In support of this assumption, data from the World Values Survey show that Italian parents are systematically happier if their children live at home while the opposite happens in the US. The model predicts that among selfish parents, all else equal, an increase in parental income results in an increase in transfers to cohabiting children, thereby raising the probability that children live with their parents.

We test this hypothesis using data from the individual records of the Bank of Italy Survey of Households' Income and Wealth (SHIW) for 1989 to 1998.¹ The key econometric problem in estimating the effect of parental income on the children's propensity to cohabit is the potential endogeneity of parental income. Parental income is likely endogenous because of the endogeneity of

¹ Because of data limitations, we focus on living arrangements of men. The instrumental variable is in most cases not available for women.

parental labor supply (parents of unemployed children may decide to work more in order to support their cohabiting children) or altruistic behavior of children (if parents suffer negative income or health shocks, their children may invite their parents to live with them). An additional problem arises because data on parental income are available only for cohabiting children. As with most existing household data sets, our data lack information on parental income for non-cohabiting children.

To address the problems of endogeneity and lack of parental income, we use a two-sample instrumental variable strategy (Angrist and Krueger, 1995). Under a reasonable exclusion restriction, the two-sample IV estimator generates a consistent estimate of the effect of parental income on children living arrangements.

Specifically, our instrumental variable strategy is based on the increase in normal retirement age mandated by the 1992 reform of social security. The change in the retirement law forced some cohorts of parents to stay in the labor force longer than they would have stayed otherwise, thereby significantly increasing their disposable income with respect to previous cohorts. Because our instrument is based on a change in retirement *eligibility*, not on the actual retirement decision, it is arguably exogenous with respect to other determinants of living arrangements. In support of this, we show that the instrument is orthogonal to many observable predetermined characteristics of parents and children.

To obtain the two-sample IV estimator, we first estimate the effect of changes in parental pension eligibility on the probability that children live at home. We then derive the IV estimates by dividing this coefficient by the estimated effect of pension eligibility on parental income. A feature of the reform is that retirement age increased over time (from 60 at the beginning of the period to 64 at the end). This is useful, because it allows to control for unrestricted father age effects. Identification comes from the interaction of father age and year of the mandated changes. A useful characteristic of the SHIW dataset is that it provides information on the age of parents (a key component of our instrumental variable) for both cohabiting and non-cohabiting children. This

allows us to circumvent the problem arising from the lack of information on parental income for non-cohabiting children.

Instrumental variables estimates suggest that parents' income is an important determinant of their children's propensity to live at home. A 1 million lira increase in annual parental income (approximately \$500) raises the probability of cohabiting by 3 to 3.5 percentage points. The estimates are robust to controls for local labor and housing market conditions, standard socio-economic characteristics, such as parents' education and children's age and school enrollment. Our findings are inconsistent with the hypothesis that parents behave altruistically toward their children.

Previous research has focused on youth labor market conditions as the primary determinants of living arrangements. For example, Card and Lemieux (2000) find that poor labor market conditions in Canada explain why the fraction of youth living with their parents has increased in Canada relative to the U.S. in recent years. In contrast, the role of parental transfers in determining living arrangements has received much less attention. The number of studies that empirically document the effect of parental income on living arrangements is surprisingly limited.²

Our identification strategy, although not perfect, relaxes some of the restrictions imposed by previous studies. In a series of papers that use an identification strategy that is similar to ours, Bertrand, Mullainathan and Miller (2001), Duflo (2000) and Edmonds, Mammen and Miller (2001) exploit a special feature of the South African Pension system to identify the effect of grandparents' income on household composition, and grandchildren labor supply and well-being. Their

² There is remarkably little literature on housing arrangements of young Italians. One exception is Fogli (2000) who proposes an overlapping generation model to study the relationship between family ties and labor market rigidities. Recently Bentolila et al. (2001) propose an empirical test of Fogli's model. Martínez-Granado and Ruiz-Castillo (2002) study the living arrangements decisions of Spanish youths. They jointly model the decisions of working, studying and leaving the parental household, and conclude that endogeneity is empirically important. Rosenzweig and Wolpin (1993, 1994) use an overlapping generation model to explain the living arrangement decisions of young Americans. Although, similarly to us, they explicitly account for the role of parental transfers, differently from us, in their model cohabitation is a bad for both parents and children.

A related stream of literature analyzes the effect of pension and welfare transfers on living arrangements. Costa (1997) and McGarry and Shoeni (2000) study the effect of pensions on living arrangement decisions of the elderly. Recently Bitler, Gelbach and Hoynes (2001) study the effect of the US welfare reforms of the 1990s on the living arrangements of children and women.

instrumental variable is based on differences in pension entitlement across age groups. Since their data consist of a single cross section, their identification comes from a comparison of individuals of different ages. In contrast, we have multiple cross-sections, and our instrument is based on *changes* over time and across age groups in pension entitlement, allowing us to control for unrestricted father age effects. Father age is a potentially important determinant of children living arrangements.

Finally, by modeling children's living arrangements as a consumption good, our research adds to the literature on household consumption and the debate on parents' altruism dating back to Becker's (1981) seminal analysis. The existing evidence suggests that the unitarian model of household consumption is rejected by the data. See for example, Del Boca (1997) for evidence based on Italian data.³ Also, direct evidence on intra-vivos transfers from parents to children lends little empirical support to the view that parents are altruistic.⁴ Our results provide further evidence against the notion that parents behave altruistically toward their children.

The rest of the paper is organized as follows. In Section 2 we present a stylized model of living arrangements. In Section 3 we describe the data and present our empirical results. Section 4 concludes.

2. A Simple Model of Living Arrangements

In this Section we present a simple model of children's housing arrangements and present some empirical evidence that supports the basic assumption behind the model. The basic insight of the model is that, conditional on housing costs and children's earnings, a rise in parental income tends to increase the children's propensity to live at home.

We use a bargaining model to describe household consumption decisions. We assume that parents derive some utility from cohabiting with their children while the opposite is true for children.

³ Other examples include, but are not limited to, Deaton, Ruiz-Castillo and Thomas, (1989); Thomas (1990) and Chiappori, Bourguignon, Browning and Lechene (1994).

Parents can transfer money to their children in order to provide an incentive for them to stay at home. We call this transfer the 'bribe'. Depending on their utility function and the value of their income, children might be willing to trade some of their independence for some extra consumption. We begin by ignoring any altruistic motive. Later in the section we allow for parents' altruism towards their offspring and show that the results can be reversed if parents are sufficiently altruistic.

Cohabitation in this game brings a surplus, the foregone children's housing cost. We assume that parents possess all the bargaining power so that they appropriate the whole surplus if they get their children to cooperate. We solve the problem by backward induction. We assume that children decide their living arrangements conditional on the transfers they receive from their parents. Parents then derive the optimal transfer by maximizing their own utility conditional on the children's optimal reaction.

One of the key assumptions of our model is that parents draw utility from their children's presence at home, while children would rather live on their own.⁵ Evidence suggests that this assumption may be reasonable for Italy, but not necessarily for other countries, particularly the US. Table 2 shows the results of an OLS regression of a measure of parental happiness on a dummy variable indicating whether at least one child lives with the parents and a set of covariates. Parents are defined as men aged 40 to 75 and women aged 37 to 72 with children. The coefficient on the cohabitation dummy is reported for the same set of countries as in Table 1. Data are from the World Value Survey 1981-84, which includes the question: "Taking all things together, would you say you are: Not at all happy, Not very happy, Quite happy, Very happy". We classify the possible answers into equally spaced values between zero and one, with "Not at all Happy" being zero and "Very Happy" being one. In the first column of the table we report the results of a regression with basic

⁴ Cox (1990); Altonji, Hayashi and Kotlikoff (1997)

⁵ As suggested by Cox (1990), parents might derive a utility both from services provided by children (care or housecleaning, for example) as well as "more subtle types of service that entails the behavioral constraints associated with attention to parents [...], companionship and conforming to parents' regulations".

controls including family income, parents' gender, parents' age and age squared plus country-specific dummies. In the second column we have included additional controls, namely a full set of dummies for parents' marital status (married, cohabiting, single, divorced or separated and widowed), dummies for their employment status (employed, unemployed, housewife, student, pensioner and other inactive) and a health status variable. According to the estimates in column 1, parents in Italy and Spain seem to be significantly happier if their children live with them, while the opposite is true in the United States. When we introduce further controls in column 2, the coefficient becomes insignificant for Spain, but remains significant and positive for Italy.

Evidence from the same survey also supports our assumption that Italian children, all things equal, are indifferent between living at home and living independently. In Table 3 we present results from a separate regression where the dependent variable is children's happiness. The sample includes males age 18 to 33, consistent with the sample that we use in the empirical part of the paper. The variable of interest here is a dummy variable for whether the child lives with his parents. In all countries, including Italy, the effect of cohabitation is negative, although it tends to become statistically insignificant when all controls are included.

Although our results are only suggestive, it appears that children are indifferent between living at home and living independently in all countries included in this analysis while parents' tastes for cohabitation with children differ between Italy and the rest of the countries in our sample.

2.1 No Altruism

We assume that children's utility is a function of consumption and a term representing the disutility of living at home. Their resources are a function of their income, the compensation they receive from their parents if living at home minus any housing cost they will have to incur if living on their own. Assuming a Stone-Geary utility function, their problem can be written as:

$$\text{Max } \log(CK) - H \log(a_1) \quad \text{s.t. } CK + R(1-H) = YK + b_1H$$

where CK is children's consumption; H is a dummy variable equal 1 if the child is living at home; YK children's income and R their housing costs; b_1 is the compensation for being at home, which either comes in the form of a provision of goods or cash transfers from parents to children; a_1 is the children's marginal disutility of living at home ($a_1 \geq 1$). We have postulated that parents only make transfers to their children if they live at home, a hypothesis that we will remove later when we deal with the altruistic case. We assume that children pay for their own housing costs if they live away from home, while housing costs are borne by parents if children cohabit. We also assume that parents' housing costs remain unchanged if their children move out. Children stay with their parents if the marginal utility of living with their parents is at least equal to the marginal disutility, a_1 :

$$(1) \quad H=1 \quad \text{if} \quad (YK+b_1)/(YK-R) \geq a_1$$

Conditional on the bribe, b_1 , the propensity of children to live with their parents depends inversely on their income, YK, and directly on housing costs, R. (See appendix for the proof).

Parents' budget constraint requires parents' consumption not to exceed their income minus any bribe they pay to cohabiting children. We assume that parents observe their children's preferences, income and housing costs and maximize

$$\begin{aligned} \text{Max } \log(CP)+H \log(c_1) & \quad \text{s.t.} \quad CP=YP-b_1H + kH \\ & \quad \text{s.t.} \quad H=1 \quad \text{if} \quad b_1 \geq (a_1-1)YK - a_1R \end{aligned}$$

where CP is parents' consumption and YP is their income; k denotes scale economies (diseconomies) which accrue to parents from living with their children;⁶ and $c_1 \geq 1$ is the parents' marginal utility of living with their children.⁷ The second constraint is the incentive compatibility constraint.

⁶ The presence of scale economies is reminiscent of Rosenzweig and Wolpin's (1993, 1994) models. There, because of its public nature, housing is a cheaper way for parents to bribe their kids than financial transfers.

⁷ The model should also include parents' housing costs. Since we have assumed that these are borne by parents irrespective of their children's living arrangements and because we have assumed that these are unchanged when children move out of the parental household, parents' housing costs do not affect the children's marginal decision as to whether to live with their parents or not. To simplify the notation, parents' housing costs are not explicitly included in the model.

In equilibrium, parents set b_1 to make children indifferent between living with them and living on their own. Any surplus deriving from reaching an agreement ($R+k$) will then accrue to parents who have all the bargaining power. In equilibrium:

$$(2) \quad H=1 \quad \text{if} \quad k \geq -(c_1-1)/c_1 YP + (a_1-1)YK - a_1R$$

and the optimal transfer is $b_1^* = (a_1-1)YK - a_1R$. (See appendix for the proof). From equation 2 it is clear that in equilibrium the propensity of children to live with their parents depends inversely on their income, YK , and directly on parents' income, YP .

2.2 Altruistic Parents

We have argued that as parents' income increases, they are willing to give up more of their consumption in order to compensate those children who cooperate, thereby increasing the likelihood that their children live with them. We now extend the model to allow for altruistic behavior of parents towards their children. In this case parents transfer some resources to their children irrespective of their living arrangements, although there is an additional transfer if children decide to co-reside. The children's budget constraint is now a function of both the bribe and the altruistic transfer they receive from their parents:

$$\text{Max } \log(CK) - H \log(a_1) \quad \text{s.t. } CK + R(1-H) = YK + b_0 + b_1H$$

where b_0 is the amount of the altruistic transfer and we have assumed again Stone-Geary preferences.

The compensation children want to receive for living with their parents increases as b_0 increases:

$$(3) \quad H=1 \quad \text{if} \quad (YK + b_0 + b_1)/(YK + b_0 - R) \geq a_1$$

From the children's point of view, the altruistic transfer operates as unearned income, so that the probability of living at home depends negatively on the altruistic transfer, b_0 .⁸ The more generous parents are, the higher is the amount children require in order to live at home.

⁸ It is easy to see that (3) is the same as condition (1) where YK has been replaced by $YK + b_0$.

Parents care about their children's welfare and maximize a linear combination of their own utility and the children's utility:

$$\begin{aligned} \text{Max } & \log(CP) + H \log(c_1) + \rho[\log(CK) - H \log(a_1)] \\ \text{s.t. } & CP = YP - b_0 - b_1 H + kH, \\ \text{s.t. } & b_0 \geq 0 \\ \text{s.t. } & H = 1 \quad \text{if } b_1 \geq (a_1 - 1)(YK + b_0) - a_1 R \end{aligned}$$

where ρ is the degree of parents' altruism. The condition $b_0 \geq 0$ restricts altruism to be one-sided.⁹

In order to derive the equilibrium of the game, we assume that parents set b_0 so as to maximize their own utility, conditional on their children living away from home. They will then set b_1 exactly as before. In equilibrium the optimal altruistic transfer is a linear combination of the difference between parents' income and children's income net of housing costs:

$$(4) \quad b_0^* = \max[(\rho YP - YK + R)/(1 + \rho), 0]$$

If parents are sufficiently altruistic ($b_0^* \geq 0$), then

$$(5) \quad H = 1 \quad \text{if} \quad k \geq [-(c_1 - 1)/c_1 + (a_1 - 1)\rho]/(1 + \rho) (YP + YK) - (\rho a_1 + 1/c_1)/(1 + \rho)R$$

and the optimal bribe is $b_1^* = (a_1 - 1)\rho/(1 + \rho)(YP + YK) - (1 + \rho a_1)/(1 + \rho)R$. (See appendix for proofs of equations 4 and 5).

From equation 5 we conclude that if parents are sufficiently altruistic ($b_0^* \geq 0$), the main result of section 2.1 is reversed: in equilibrium a rise in parents' income reduces the children's propensity to live with them. Children of richer parents are less likely to live at home even though their parents would draw some utility from their presence. The reason for this result is that selfish children of altruistic parents only care for the differential paid to them if they live at home (equation 3). Altruistic parents, however, cannot commit to pay a high enough differential to those children who decide to live at home. Children know they will get what they need from their parents whether

they are living with them or not. For $\rho \leq (YK-R)/YP$ equation 5 rewrites as 3 and we are back to the case no altruism.

3. Empirical Evidence

3.1 Data

The goal of this paper is to test the hypothesis that intra-household transfers play an important role in determining the living arrangement decisions of Italian men. We provide a test of our hypothesis by estimating the effect of parents' income on children's living arrangements. The model in the previous section suggests that if parents derive some utility from living with their adult children and are mainly driven by self-interest, increases in parental income should increase the probability of children living with their parents.

We use data from the individual records of the Bank of Italy Survey of Households' Income and Wealth (SHIW) for all the available years starting in 1989 (1989, 1991, 1993, 1995 and 1998). The survey collects detailed information on household composition, including socio-demographic characteristics of its members as well as a rich array of income and labor market information. For each household head, the data also include the year of birth of the father and mother and whether they are still alive.¹⁰ This allows to recover parental age for non-cohabiting children. Data on parental age for cohabiting children can be easily recovered by taking the age of the of the head and his spouse. We ignore living arrangement decisions of women because parental age, on which our instrument is built, is missing for individuals who are not heads of households while living on their own. In most cases household heads are men.

⁹ In principle this model could account for two-sided altruism. If b_0 were set by children in the form of a transfer to their parents, the problem would be written identically with $1/\rho$ being the degree of children's altruism.

¹⁰ This information is only available starting in 1989 and this explains why we restrict our analysis to the 1989-1998 period.

The top panel of Table 4 reports descriptive statistics for children. We define “children” as all men aged 18-33 whose parents are both alive, whose father is aged between 40 and 75 and whose mother is aged 37 to 72.¹¹ We define as cohabiting children those children who live with their parents. Overall there are 29,024 observations in the sample.¹² Roughly four out of five men aged 18 to 33 live with their parents. About half of these young adults work, suggesting that rationing in the labor market alone cannot explain living arrangements.¹³ Average annual income is expressed in million lira at 1995 prices and is defined net of taxes and social security contributions. Virtually all the children’s income in our sample comes from labor earnings. Children’s housing costs, defined as annual rental costs, increase by more than 20% over the sample period (1989-1998)¹⁴. The average age of the sample increases by over a year over this period, reflecting the gradual aging of the baby boom cohort of the 1960.¹⁵ Similarly, the proportion of those living at the North decreases, reflecting the pronounced fall in fertility in the northern industrialized regions.¹⁶ No clear trend is detectable in the number of those enrolled in school. At the bottom of the table we report the average age of the mothers and fathers of the children in the sample.

Table 5 reports descriptive statistics for the parents. We define as “parents” all individuals in couples where the man is aged 40 to 75 and the woman is aged 37 to 72.¹⁷ Overall we have information on 18,533 parental households. Total father’s income is more than twice children’s income. An increasing share of father’s income comes from Social Security payments over this

¹¹ These correspond to the bottom and top percentiles of the distribution of parents’ age for the children in the sample.

¹² Since there is no way to identify grandchildren, parents or grandparents of the head in our data, we ignore children living in three-generation households headed by one of the children’s grandparents. Similarly, we treat those children living with their parents or grandparents (or both) who are classified as heads as living on their own. Finally we assume that if a child lives only with one parent, the other parent is not alive.

¹³ Work is defined as at least one employment spell in the year.

¹⁴ Housing costs refer only to those faced by households headed by men aged 18-33. We have computed these costs by taking (actual and imputed) rents for all households headed by men aged 18-33 in the SHIW sample.

¹⁵ In Italy the baby boom took place about 20 years after the US baby boom.

¹⁶ For an analysis of fertility (and women’s labor supply) in Italy, see Del Boca (2002).

¹⁷ These couples may or may not have children. While we know whether they have cohabiting children, we have no information on whether they have non-cohabiting children.

period, which includes both contributed and non-contributed pensions. This reflects a rise in the proportion of fathers who are retired from 34% to 38% over the 10 years.

Approximately 20% of mothers receive some pensions while around 30% work. The remaining 50% is either unemployed or not participating, while receiving no pension income. Maternal earnings (calculated over the whole population of mothers) are on average a third of those of their husbands, although this in part reflects the lower labor force participation of women. Fathers are on average better educated than mothers (although one observes a fall in the proportion with at most primary education for both). Average age as self-reported by parents is approximately one year lower than parents' age as reported by children. This is attributable to the fact that fertility among new cohorts of parents has fallen so that there are more children of older parents in the sample. To account for this, we present both unweighted and weighted regressions, with the weights based on the age distribution of the parents of the children in the sample. In this way we give more weight to older parents, reflecting the fact that their children are more numerous in the sample.

3.2 Econometric model

To test our hypothesis that increases in parental income raise the probability that children live with their parents, we assume that k in equation 2 is uniformly distributed and estimate the following linear probability model:

$$(6) \quad H_{it} = \beta_0 + \beta_1 YP_{it} + X_{it}'\beta_2 + u_{it}$$

where i denotes a generic child and t is time; H is a dummy equal one if child i lives with his parents at time t ; YP is parental income; X is a set of controls; u is a random term that reflects measurement and labor market errors, as well as any systematic factor affecting children's living arrangements on top of parental income. As discussed below, we cannot rule out that the error term is correlated with the regressors in the model. Notice that, based on the theoretical model in section 2, the model also includes children's income YK and housing costs R on the right hand side of the regression model.

The coefficient of interest is β_1 . As argued in the theoretical section, an increase in parents' income should increase the probability that children live at home if the parents are not altruistic: $\beta_1 > 0$. If parents are altruistic this coefficient is negative: $\beta_1 < 0$.

In estimating equation 6 we face two problems. First, data on both parental income and children's living arrangements (as well as their income and housing costs) are needed. Typically, however, household data do not contain information on parental income for those children who live on their own and our data are no exception. While parental income for cohabiting children is observed in the SHIW, parental income of non-cohabiting children is not available.

But even if parental income for non-cohabiting children was available, parental income would arguably be endogenous to housing arrangements, and OLS estimates of β_1 would be inconsistent. One reason why parents' income may be endogenous to children's living arrangements is that parents may adjust their labor supply depending on their children's living arrangements. Given the high youth unemployment rate in Italy, it is not uncommon for parents to work more in order to support their unemployed children.

Another reason for parents' income may be endogenous is that some children may decide to live with their parents if their parents suffer negative income shocks. In general, any omitted factor affecting the probability that children live with their parents that is correlated with parental income is likely to lead to biased estimates of the effect of parental income on children's living arrangements.

We use a Two-Sample instrumental variable strategy to address both the problem of missing parental income for non-cohabiting children and the problem of endogeneity of parental income. The ideal instrument is correlated with parental income but uncorrelated with all other factors that determine living arrangements (including children's income, housing costs and children's age). Moreover, to address the fact that parental income is unobserved for non-cohabiting children, the instrument must be available for both cohabiting and non-cohabiting children. With such an

instrument, one can estimate β_1 in two steps. First, estimate the first stage regression on the sample of parents:

$$(7) \quad YP_{it} = \gamma_0 + \gamma_1 Z_{it} + X_{it}' \gamma_2 + e_{it}$$

where Z denotes the instrument. Then, estimate the reduced form equation on the sample of children:

$$(8) \quad H_{it} = \theta_0 + \theta_1 Z_{it} + X_{it}' \theta_2 + v_{it}$$

A consistent estimate of β_1 is given by the two-sample IV estimator (Angrist and Krueger, 1995):

$$(9) \quad \text{est}(\beta_1^{IV}) = \text{est}(\theta_1^{OLS}) / \text{est}(\gamma_1^{OLS})$$

One limitation of our data is that the children's variables (such as children's income YK , housing costs R , and children's age) are available in the children sample, but not in the parents sample, and therefore we cannot include them in our empirical analysis. Similarly, parental variables are available in the parents sample, but not in the children sample (with the exception of parents' age), and therefore cannot be included in our models either. This is a concern because children's income, housing costs, children's age and parental characteristics are likely to be important determinant of living arrangement decisions. However, *if the instrument is orthogonal to children's income, housing costs, children's age and parental characteristics other than age*, our estimator in (9) is still consistent. The assumption that the instrument is orthogonal to children's income, housing costs, children's age and parental characteristics can be tested, since we observe children characteristics in the children sample, parental characteristics in the parental sample, and the instrument in both samples. Below we show that such assumption holds true in the data. This suggests that the instrumental variable estimates are not affected by the failure to control for child and parental characteristics.

3.3 Using Changes in Social Security Eligibility to Instrument for Parental Income

We propose to use changes in social security eligibility and retirement age introduced in Italy in 1992 as an instrument for parental income. Retirement typically reduces disposable income, since replacement ratios are generally below one. We show that changes in the normal retirement age introduced by the 1992 reform of Social Security had a significant effect on the disposable income of the fathers, and we use these changes as an instrument for parental income. We argue that conditional on parental age, the reform is uncorrelated with other determinants of living arrangements. An advantage of this instrument is that it is based on parental age, which is available for both cohabiting and non-cohabiting children.

Italian workers can retire if they have accumulated enough years of social security contributions or when they reach a certain age, called “normal retirement age”. Normal retirement age and the minimum number of years of social security contributions are set by law. Before 1992, normal retirement age was 60 for most men.¹⁸ In 1992 a major reform of the Social Security system gradually increased the normal retirement age from 60 in 1992 to 65 in 2000.¹⁹

The rise in normal retirement age effectively forced some individuals in the affected cohorts to remain in the labor force longer than they would have otherwise. We use the change in retirement eligibility mandated by the reform as a source of variation in fathers’ income that is arguably exogenous to children’s living arrangements. Specifically, the instrument is a dummy equal to one if the father is older than normal retirement age for each year. In particular, the instrument equal 1 for fathers older than 60 in 1989 and 1991, 62 in 1993, 63 in 1995 and 64 in 1998. (Data for 2000 are not available). Because replacement ratios are less than one and retirement is associated with an

¹⁸ Normal retirement age and the minimum number of years of social security contributions are different for private and public workers. Here we only consider the rules for private sector workers despite the fact that the 1992 reform also affected normal retirement age of workers in the public sector. The reason for this choice is that private sector workers are by far the largest group and we have no information on the sector of activity of the fathers for non-cohabiting children or retired fathers. For a detailed account of the changes introduced by the 1992 social security reform see Brugiavini (1999); and Attanasio and Brugiavini, (2001). We are grateful to Agar Brugiavini for having clarified some details of the Social security system in Italy.

¹⁹ The reform also reduced the generosity of the pension system by changing the base for benefit calculations and increased the number of years of compulsory contributions.

income loss, we expect the first-stage coefficient on the instrument to be negative.²⁰ For example, the effect of the reform can be estimated by comparing the average income of fathers who are older than 61 in 1993 (all of whom can retire) with the average income of fathers who are older than 61 in 1993 (some of whom cannot retire). Consistent with our expectations, we find the average income of the former group to be lower than the average income of the latter group, suggesting that changes in retirement age mandated by the reform have a significant impact on parental income.

Since our source of identification depends on changes in social security eligibility, not actual retirement decisions, it is arguably exogenous to children's living arrangement decisions and it should be robust to the sources of potential endogeneity outlined in Section 3.2 above.

The fact that the law mandated increases in the retirement age over time allows us to control for father's age. Since the age of the father is potentially an important determinant of children's living arrangements, our model includes an unrestricted set of dummies for father's age in the vector X , together with year dummies. Identification of the instrumental variable estimates comes then from the interaction of father's age and time, i.e. the changes over time in the retirement age mandated by the law. Below, we show that the instrument is orthogonal to observed children and parents' characteristics, lending credibility to our identification assumption.

In a series of papers that use an identification strategy that is similar to ours Bertrand, Mullainathan and Miller (2001), Duflo (2000) and Edmonds, Mammen and Miller (2001) exploit a special feature of the South African Pension system as a source of exogenous variation in household income. Their instrument is based on differences in pension entitlement across age (and gender) groups. Since their data consist of a single cross section, their identification comes from a comparison of individuals of different ages. In contrast, our approach which depends on changes

²⁰ To the extent that working lowers utility, and that without the reform some individuals in the effect cohorts would have retired earlier, the reform presumably reduced the utility of the cohorts affected.

over time in the age for pension eligibility, allows us to control for age differences.²¹ This is important, because father age is arguably an important determinant of children living arrangements decisions.

One concern is that it is in theory possible that father retirement decisions may have a direct effect on the children propensity to live with their parents. This would be the case, for example, if the presence of a retired father who spends most of his day at home makes living at home less appealing to his children. Father retiree status would affect children residency decision not through father income, but through the presence of the father at home during the day. In this case, our instrument would lead us to overestimate the true effect of income on residency decisions. To test whether this is in fact a problem in our sample, we re-estimate all the models including only working children. Children with jobs presumably spend most of the day outside the house. Therefore, the presence of their retired father at home during the day should make little difference for children with jobs. We find that estimates obtained using the full sample are similar to estimates obtained using the restricted sample of working children. This lends some credibility to our assumption that this issue is unlikely to be a major source of bias for our estimates.

3.4 Empirical Results

We first examine whether observable characteristics of parents and children are correlated with the instrument as an informal test of instrument exogeneity. Finding that the instrument is correlated with predetermined characteristics, would cast doubt on the validity of the instrument. Having shown that the instrument is orthogonal to predetermined characteristics of parents and children, we turn to the main results of the paper. We show how parental income changes as a result of changes in retirement age mandated by the 1992 reform (equation 7) and how living arrangements change as a

²¹ A second difference with these papers is that while in the South Africa case old-age pension recipients experienced

result of changes in retirement age (equation 8). We conclude by using these first stage and reduced form coefficients to obtain estimates of β_1 (equation 9).

In Table 6 we report coefficients from bivariate regressions of different children's characteristics on the instrument. Recall that the instrument is a dummy equal to one if the father is older than normal retirement age mandated by law for each year. The estimates in table 6 are based on the child sample. Estimates presented in the first column come from a regression that controls for unrestricted additive year effects and father age effects (the vector X) only, while in column 2 we also include unrestricted mother age effects.

The first row of Table 6 indicates that the instrument is negatively correlated with coresidence. This is a first indication that parental income may be a determinant of living arrangements, since the children of those who retire (and therefore experience an income loss) display a higher probability of leaving the parental home. There is no statistically significant effect of the instrument on children's school enrollment while there is a clear effect on employment, earnings and housing costs. This should not come as a surprise since all these variables are likely to be endogenous to living arrangements. For example, housing arrangements are likely to affect employment via their effect on the set of available job opportunities.

In order to account for this potential endogeneity, we report the correlation between the instrument and the average employment, earnings, school enrollment and housing costs calculated for each age and area. These averages are calculated excluding the individual under analysis and therefore should be uncorrelated with the instrument for the instrument to be valid.²² The estimates in the last four columns confirm that the instrument is orthogonal to the area average of employment,

large income *increases*, in Italy retirees experience income *losses*.

²² Separate regressions of individual outcome variables on area averages (excluding the individual under analysis) lead to the following estimates (s.e. errors in brackets): 0.955 (0.009), 0.938 (0.009), 0.906 (0.012), 0.710 (0.014) respectively for employment, earnings, school enrollment and housing costs. All regressions control for unrestricted father age and year dummies.

earnings and housing costs. The instrument is correlated with children's age, but the coefficient becomes insignificant once we also control for mother's age in column 2. All other coefficients remain essentially unchanged when we condition on mother's age. In Table 7 we report the correlation between the instrument and parents' characteristics. As in Table 6, the first column allows for unrestricted father age and year effects while the second column also controls for mother's age. The regressions are based on the parents sample. Estimates in rows 1 to 3 indicate that the reform affects the proportion of fathers retiring as well as their pensions. In particular, the reform forces about 7% of the fathers in the sample continue to work (row 1 and 2). The average increase in pension income associated with the reform is more than 2 million lira per year (row 3). Since earnings decline on average by almost 4 million lira (row 4), the effect of the instrument on total income is a loss of about 2 million lira per year (row 5).

The next set of results suggests that the reform had no effect on maternal labor supply decisions (rows 6 and 7). When looking at the effect of the instrument on household income (calculated excluding children), we find a negative coefficient (rows 13). The last set of results (rows 14-16) tests whether the instrument is correlated with observable parental characteristics. We find that the instrument is orthogonal to father's education and mother's education, while geographic location is marginally significant. When we include mother age effects in column 2, the estimates do not change.

Table 8 reports estimates of models similar to those in table 7, only weighted according to the age distribution of the parents of the children in the sample. Weighting has very little impact on the results, only the coefficients on household income become marginally more precisely estimated with the weights.

From Tables 6, 7 and 8 we draw three main conclusions. First, the instrument is not correlated with exogenous children's and parent's characteristics, lending some credibility to our

exclusion restriction. This allows to use the reform to estimate consistently the effect of parental income on coresidence. Second, the coefficient on the pension reform variable is negative and significant in the first stage regression of father and household income. Retirement is associated with 2.1-2.3 million liras income loss (row 5 and 13 in tables 7 and 8). Third, the reduced form coefficient is significant, as the instrument has a significant negative effect on the probability of cohabitation. Retirement of fathers induced by the reform is associated with a 7% decline in the propensity to cohabit (row 1 in Table 6). Taken together, the last two conclusions suggest that parental income has a positive effect on the propensity of children to cohabit. But before we turn to the 2-samples IV estimates of the coefficient of interest, we further explore the robustness of our first stage and reduced form coefficients.

Table 9 reports estimates from regressions of parental income on the instrument (equation 7) including different sets of controls in order to assess the stability of the first stage coefficient. These regressions are based on the parent sample. In columns 1 and 2 the dependent variable is father's income, while in column 3 and 4 the dependent variable is household income. We report both unweighted and weighted regression results. The coefficients in the first two rows are from regressions in which we control only for father's age, year dummies and mother age, and are the same as those found in Tables 7 and 8 (rows 5 and 13). Rows 3-7 present estimates of the coefficient on the instrument in regressions that include additional controls. As we add more controls, the results are remarkably robust and show that retirement is associated to a fall in income of between approximately 2 to 3 million lira. The introduction of additional controls does not significantly affect the point estimates, which is consistent with the results in Table 7 indicating that the instrument is uncorrelated with parental characteristics. The addition of extra controls improves the precision of our estimates.

In Table 10 we report additional estimates of a regression of a dummy for cohabitation on the instrumental variable (equation 8). Estimates are based on the children sample as in Table 6. The coefficient in the first row is taken from Table 6, row 1. It suggests that the households affected by the reform experience a decline in the probability that children live with their parents of about 7 percentage points. As before, the remaining models are intended to probe the robustness of the base case estimates to the inclusion of different controls. The inclusion of different controls does not appreciably affect the point estimates, though it makes them slightly more precise.

From Tables 9 and 10 we confirm that retirement, as induced by the reform, tends to lower parents' income and reduces the propensity of children to live at home, and that this effect is fairly stable across specifications. We now combine the estimates in rows 1 and 2 of Table 9 and 10 to obtain instrumental variable estimates of the effect of father's income on the children's propensity to cohabit.

Table 11 reports the results of the Two-Sample IV regressions.²³ All specifications control for additive year and father age effects. Recall that because the controls in Table 9 and 10 are available only in one of the two samples (children or parents), we cannot estimate models with additional controls. However, since the instrument is uncorrelated with observable characteristics of parents and children (as evident in Tables 7 and 8), the TSIV estimates should still be consistent.

We report results with and without controls for mother age, for the two definitions of parental income used in Table 10 and using weighted and unweighted data. The IV estimates in Table 11 are obtained by dividing the reduced forms coefficients in Table 9 (rows 1 and 2) by the first stage coefficients in Table 10 (row 1). For example, the coefficient in row 1 column 1 of Table 11 (.033) is the ratio of the coefficient in the first row and first column of Table 9 (-.072) and the coefficient in the first row of Table 10 (-2.169). The other coefficients are calculated similarly. The point estimates

²³ For details on how to compute the standard errors, see Angrist and Kruger (1995).

of β_1 are stable across models and generally significant. A rise of one million lira in parents' income is associated with a 3-3.5 percentage point rise in the probability that children live at home.²⁴ The results are marginally more significant when data are weighted and when parents' income is defined as father's income. This implies an elasticity of about one.²⁵

This evidence suggests that a rise in parents' income tends to raise the probability that children live at home. We cannot reject the hypothesis that Italian parents "bribe" their children to induce them to live with them longer.

4. Conclusions

Among industrialized countries, Italy is an outlier in terms of the living arrangements of its young men. Although labor and housing market conditions are clearly part of the explanation for the high rates of cohabitation, in this paper we argue that intra-household transfers play an important role in determining living arrangements of young Italian men.

We hypothesize that parents and children bargain over the latter's living arrangements. Children are willing to give up some of their independence (a good for children) in exchange for financial transfers on the part of their parents. Parents are willing to give up some consumption in exchange for their children's presence at home (a good for parents). Evidence from the World Value Survey indicates that this assumption is not unrealistic for Italy. In this framework, the effect of parental income on children living arrangements decisions depends on whether parents are altruistic, i.e. whether they care about child well-being. While in the non-altruistic case, children of richer parents are more likely to live with their parents, the opposite occurs when parents are altruistic.

²⁴ An OLS regression of children's living arrangements H on children's income delivers a coefficient of $-.010$ (s.e. $.0001$). If children's income is instrumented by the area average (excluding the individual under analysis) this delivers an IV coefficient of $-.019$ (s.e. $.0003$). Both regressions control for unrestricted father age and year dummies.

²⁵ From Tables 4 and 5, the average probability of living at home is approximately 85% and the average father income is approximately 25 (million), so the elasticity is $3.5 * 25 / 85$.

We use Bank of Italy micro data to empirically estimate the effect of parental income on children living arrangements decisions. The key econometric issue is the endogeneity of parental income. To obtain consistent estimates, we use a two-sample instrumental variable estimator based on the reform of Social Security that took place in Italy during the 1990s. This reform raised normal retirement age for men, forcing some cohort of fathers to stay in the labor force longer than the cohorts just preceding them.

We use this discontinuous change in retirement rules to show that retirement is associated with a significant fall in father's income, and with an increase in the probability that children move out of the parental household. We interpret this finding as evidence that parental income affects children living arrangements. We cannot completely rule out the possibility that unobserved heterogeneity may play a role in explaining the relationship between parental income and living arrangements. However, we show that our instrument is orthogonal to children and parents predetermined observable characteristics. This finding lends some credibility to the assumption that our estimates are not completely spurious.

We find that a one million lira rise in parents' annual income (approximately 500 US\$) increases the probability that children live with their parents by between 3 and 3.5 percentage points. This finding lends support to the hypothesis that Italian parents are non-altruistic.

Appendix

Proof of (1):

$$H=1 \quad \text{if}$$

$$\log(YK+b_0+b_1)-\log(a_1) \geq \log(YK+b_0-R)$$

$$YK+b_0+b_1 \geq a_1(YK+b_0-R)$$

Proof of (2):

Parents will chose H=1 if:

$$\log(YP-b_1+k)+\log(c_1) \geq \log(YP)$$

$$c_1 YP - c_1 b_1 + c_1 k \geq YP$$

Suppose:

$$b_1 = (a_1 - 1)YK - a_1 R$$

so that children are indifferent between living at home and not living at home. Then:

$$c_1 YP - c_1 (a_1 - 1)YK + c_1 a_1 R + c_1 k \geq YP$$

$$c_1 k \geq -(c_1 - 1)YP + c_1 (a_1 - 1)YK - c_1 a_1 R$$

$$k \geq -(c_1 - 1) / c_1 YP + (a_1 - 1)YK - a_1 R$$

Proof of (3):

Same as (1) where YK replaced by YK+b₀.

Proof of (4)

In order to derive b₀, observe that parents will set it so to maximize their own utility when H=0, so, from the f.o.c.:

$$1/(YP-b_0) - \rho/(YK+b_0-R) = 0$$

$$(YK+b_0-R) - \rho (YP-b_0) = 0$$

$$b_0 = (\rho YP + R - YK) / (1 + \rho)$$

Proof of (5):

Parents will chose H=1 if:

$$\log(YP-b_0-b_1+k)+\log(c_1)+\rho[\log(YK+b_0+b_1)-\log(a_1)]\geq\log(YP-b_0)+\rho\log(YK+b_0-R)$$

and in equilibrium:

$$b_1=(a_1-1)(YK+b_0)-a_1R=(a_1-1)\frac{\rho}{(1+\rho)}(YP+YK)+\frac{(a_1-1)}{(1+\rho)}R-a_1R$$

$$=(a_1-1)\frac{\rho}{(1+\rho)}(YP+YK)-\frac{(1+\rho a_1)}{(1+\rho)}R$$

so that children are indifferent between living at home and not living at home. So, the parents' problem can be rewritten as:

$$\log(YP-b_1-b_0+k)+\log(c_1)\geq\log(YP-b_0)$$

$$c_1(YP-b_0-b_1+k)\geq(YP-b_0)$$

$$c_1k\geq-(c_1-1)(YP-b_0)+c_1b_1$$

$$c_1k\geq-(c_1-1)(YP+YK-R)/(1+\rho)+c_1(a_1-1)\frac{\rho}{(1+\rho)}(YP+YK)-c_1\frac{(1+\rho a_1)}{(1+\rho)}R$$

$$c_1(k)\geq[-(c_1-1)+c_1(a_1-1)\rho]/(1+\rho)(YP+YK)-(c_1\rho a_1+1)/(1+\rho)R$$

$$k\geq[-(c_1-1)/c_1+(a_1-1)\rho]/(1+\rho)(YP+YK)-(\rho a_1+1/c_1)/(1+\rho)R$$

Sample size	3,983	4,031	3,561	3,650	3,308

Notes. Sample: men aged 40-75 and women 37-72 in couples. Source: SHIW individual records. All money variables in 1995 million lira. Total income: sum of pension and labor earnings. Household income excludes children income. Source: SHIW individual records.

Table 6

The effect of the instrumental variable on children living arrangement and children characteristics

Dependent Variable	Coeff.	p. value	coeff.	p. value
1) Living with parents	-0.072	0.00	-0.080	0.00
2) Student	-0.022	0.13	-0.022	0.12
3) Working	0.056	0.00	0.054	0.00
4) Earnings	1.720	0.03	1.818	0.02
5) Rent	0.087	0.00	0.081	0.00
6) Age	-0.257	0.03	-0.129	0.25
7) North	-0.014	0.40	-0.014	0.42
8) Mother age	-0.627	0.00	-	-
9) Area employment	-0.001	0.91	0.004	0.65
10) Area earnings	0.122	0.62	0.248	0.30
11) Area students	-0.001	0.91	0.004	0.65
12) Area rent	0.007	0.29	0.005	0.45
Father age dummies	yes		yes	
Mother age dummies	no		yes	

Notes. The table reports the estimated coefficient of a regression of each variable on the instrument and the associated p-value. All regressions control for year dummies. Area variables are calculated as regional means excluding the individual under observation. Number of observations 29,024.

Table 7
The effect of the instrumental variable on parental income and parental characteristics

Dependent Variable	coeff.	p. value	coeff.	p. value
1) Father retired	0.066	0.00	0.070	0.00
2) Father working	-0.068	0.00	-0.072	0.00
3) Father pensions	2.241	0.01	2.262	0.00
4) Father earnings	-3.894	0.01	-4.422	0.00
5) Father total income	-2.169	0.02	-2.310	0.01
6) Mother retired	0.005	0.77	0.021	0.19
7) Mother working	0.005	0.81	-0.003	0.90
8) Mother pensions	-0.311	0.72	0.499	0.56
9) Mother earnings	1.215	0.52	0.288	0.88
10) Mother total income	0.464	0.65	0.621	0.55
11) Household pensions	1.299	0.14	1.605	0.06
12) Household earnings	-3.576	0.03	-4.404	0.01
13) Household total income	-2.218	0.05	-2.301	0.04
14) Father education > compulsory	0.087	0.07	0.079	0.10
15) Mother education > compulsory	0.023	0.24	0.020	0.30
16) North	0.043	0.08	0.047	0.05
Father age dummies	yes		yes	
Mother age dummies	no		yes	

Notes. The table reports the estimated coefficient of a regression of each variable on the instrument and the associated p-value. All regressions control for year dummies. Household income is defined excludes any income of cohabiting children. Number of observation 18,533.

Table 8
The effect of the instrumental variable on parental income and parental characteristics
Reweighted data

Dependent Variable	coeff.	p. value	coeff.	p. value
1) Father retired	0.080	0.00	0.085	0.00
2) Father working	-0.089	0.00	-0.094	0.00
3) Father pensions	2.594	0.00	2.637	0.00
4) Father earnings	-4.340	0.00	-4.915	0.00
5) Father total income	-2.336	0.01	-2.473	0.00
6) Mother retired	0.005	0.72	0.026	0.07
7) Mother working	0.008	0.68	-0.002	0.94
8) Mother pensions	-0.250	0.76	0.745	0.34
9) Mother earnings	1.282	0.46	0.277	0.87
10) Mother total income	0.456	0.63	0.658	0.49
11) Household pensions	1.657	0.05	1.657	0.05
12) Household earnings	-3.943	0.01	-3.943	0.01
13) Household total income	-2.390	0.02	-2.448	0.02
14) Father education	0.094	0.03	0.086	0.05
15) Mother education	0.024	0.18	0.022	0.22
16) North	0.034	0.13	0.036	0.10
Father age dummies	yes		yes	
Mother age dummies	no		yes	

Notes. The table reports the estimated coefficient of a regression of each variable on the instrument and the associated p-value. All regressions control for year dummies. Household income is defined excludes any income of cohabiting children. Number of observation 18,533. Observations are reweighted by the age distribution of the children' s parents.

Table 9
The Effect of Pension Eligibility on Income
Dependent Variable: Father or Household Income
Independent variable: IV

	Controls	Dependent variable			
		Father income		Household income	
1.	Base case	-2.169 (.909)	-2.336 (.863)	-2.218 (1.114)	-2.390 (1.057)
2.	Mother age	-2.310 (.908)	-2.473 (.863)	-2.301 (1.113)	-2.448 (1.056)
3.	Parents' education	-3.033 (.827)	-3.304 (.785)	-3.874 (.961)	-4.203 (.912)
4.	Area	-2.123 (.901)	-2.258 (.857)	-2.160 (1.098)	-2.273 (1.044)
5.	Mother income	-2.168 (.901)	-2.339 (.855)	-2.212 (.904)	-2.407 (.857)
7.	All controls	-3.086 (.827)	-3.343 (.785)	-3.140 (.831)	-3.417 (.787)
	Reweighted		no yes	no yes	

Notes. All specifications control for year dummies and unrestricted father age dummies. Standard errors in parentheses.

Table 10
The Effect of Pension Eligibility on Living Arrangements
Dependent variable: Living with parents
Independent variable: IV

Controls		
1.	Base Case	-.072 (.012)
2.	Mother age	-.080 (.012)
3.	Age	-.092 (.010)
4.	Area Employment	-.073 (.011)
5.	Area earnings	-.064 (.011)
6.	Area rent	-.071 (.012)
7.	Area students	-.083 (.011)
8.	Area dummies	-.072 (.012)
9.	All controls	-.093 (.010)

Notes. All specifications control for year dummies and unrestricted father age dummies. Standard errors in parentheses.

Table 11
 Two-Sample IV estimates
 Dependent variable: Living with Parents
 Independent variable: Parents Income

	Controls	Definition of income			
		Father income		Household income	
1.	Father age	.033 (.014)	.031 (.012)	.033 (.017)	.030 (.014)
2.	Father age and Mother age	.035 (.013)	.032 (.012)	.035 (.017)	.033 (.015)
	Rewighted	no	yes	no	yes

Notes. All specifications control for year dummies. Standard errors in parentheses.
