ABSTRACT

This Letter reports on a first measurement of the inclusive $W + jets$ cross section in proton–proton collisions at a centre-of-mass energy of 7 TeV at the LHC, with the ATLAS detector. Cross sections, in both the electron and muon decay modes of the $W$-boson, are presented as a function of jet multiplicity and of the transverse momentum of the leading and next-to-leading jets in the event. Measurements are also presented of the ratio of cross sections $\sigma(W + n)/\sigma(W + n - 1)$ for inclusive jet multiplicities $n = 1–4$. The results, based on an integrated luminosity of 1.3 pb$^{-1}$, have been corrected for all known detector effects and are quoted in a limited and well-defined range of jet and lepton kinematics. The measured cross sections are compared to particle-level predictions based on perturbative QCD. Next-to-leading order calculations, studied here for $n \leq 2$, are found in good agreement with the data. Leading-order multiparton event generators, normalized to the NNLO total cross section, describe the data well for all measured jet multiplicities.

1. Introduction

The study of massive vector boson ($V$, where $V = W$ or $Z$) production in association with one or more jets ($V + jets$) is an important test of quantum chromodynamics (QCD). In addition, $V + jets$ processes are a significant background to studies of Standard Model processes such as $t\bar{t}$ or single-top production, as well as searches for the Higgs boson and for physics beyond the Standard Model. Measurements of the cross section and kinematic properties of $V + jets$ processes and comparisons to theoretical predictions are therefore of significant interest. This Letter reports on a first measurement at the Large Hadron Collider (LHC) of the $W + jets$ cross section in proton–proton ($pp$) collisions at a centre-of-mass energy ($\sqrt{s}$) of 7 TeV, in both electron and muon decay modes of the $W$-boson, with the ATLAS detector. The measurement is based on an integrated luminosity of approximately 1.3 pb$^{-1}$.

The cross section measurements are presented as a function of jet multiplicity and of the transverse momentum ($p_T$) of the leading and next-to-leading jets in each event. Measurements are also presented of the ratio of cross sections $\sigma(W + \geq n)/\sigma(W + \geq n - 1)$ for inclusive jet multiplicities $n = 1–4$. The results have been corrected for all known detector effects and are quoted in a limited and well-defined range of jet and lepton kinematics, fully covered by the detector acceptance, so as to avoid model-dependent extrapolations and to facilitate comparisons with theoretical predictions. Previous measurements of $W + jets$ production in proton–antiproton collisions at $\sqrt{s} = 1.96$ TeV were published by the CDF Collaboration [1]. Theoretical calculations at next-to-leading-order (NLO) in perturbative QCD (pQCD) have been computed for up to four jets for $W$ production [2,3]. Comparisons are made in this Letter with NLO pQCD calculations for $n \leq 2$; higher jet multiplicities are compared only to leading-order (LO) calculations.

2. The ATLAS detector

The ATLAS detector [4,5] consists of an inner tracking system (inner detector, or ID) surrounded by a thin superconducting solenoid providing a 2T magnetic field, electromagnetic and hadronic calorimeters and a muon spectrometer (MS). The ID consists of pixel and silicon microstrip (SCT) detectors, surrounded by the transition radiation tracker (TRT). The electromagnetic calorimeter is a lead liquid-argon (LAr) detector. Hadron calorimetry is based on two different detector technologies, with scintillator-tiles or LAr as active media, and with either steel, copper, or tungsten as the absorber material. The MS is based on three large superconducting toroids arranged with an eight-fold azimuthal coil symmetry around the calorimeters, and a system of three stations of chambers for the trigger and for precise measurements. The nominal pp interaction point at the centre of the detector is defined as the origin of a right-handed coordinate system. The positive $x$-axis is defined by the direction from the interaction point to the centre of the LHC ring, with the positive $y$-axis pointing upwards, while the beam direction defines the $z$-axis. The azimuthal angle $\phi$ is measured around the beam axis and...
the polar angle $\theta$ is the angle from the z-axis. The pseudorapidity is defined as $\eta = -\ln \tan(\theta/2)$.

3. Simulated event samples

Simulated event samples were used for most of the background estimates, for the correction of the signal yield for detector effects and for comparisons of the results to theoretical expectations. The detector simulation [6] was performed using GEANT4 [7]. The simulated event samples are summarised in Table 1. The ALPGEN samples were generated with the MLM matching scheme [8] and interfaced to HERWIG v6.510 [9] for parton shower and fragmentation processes and to JIMMY v4.31 [10] for underlying event simulation. Parton density functions (PDF) were: CTEQ6L1 [11] for the PDF set was CTEQ6.6M [15] for the NLO matrix element calculation of photons from charged leptons was treated in HERWIG and PYTHIA using PHOTOS v2.15.4 [16]. TAUOLA v1.0.2 [17] was used for tau decays. The underlying event tune was the ATLAS MC09 tune [18] for the ALPGEN samples, PYTHIA inclusive vector boson production, and PYTHIA QCD samples. The POWHEG sample used the ATLAS MC09 tune with one parameter adjusted. The AMBT1 [19] tune was used for the PYTHIA $W +$ jets samples.

4. Data and event selection

The data used in this analysis were collected from March to August 2010. Application of beam, detector, and data-quality requirements resulted in a total integrated luminosity of $1.3 \text{ pb}^{-1}$. The uncertainty on the luminosity determination is estimated to be $1\%$ [26]. Criteria for electron and muon identification, as well as for event selection, followed closely those for the W-boson inclusive cross section analysis [27].

In the electron channel, a hardware-based level-one trigger system selected events containing one or more electron candidates, based on the presence of a cluster in the electromagnetic calorimeter with a transverse energy ($E_T$) greater than 14 GeV; this is the only difference in the electron channel with respect to the W inclusive cross section analysis, and was motivated by the fact that, for this larger dataset, this trigger was the lowest-threshold, useful electromagnetic trigger without any additional higher-level trigger requirements. The impact of the trigger efficiency was negligible for electrons with $E_T > 20$ GeV. In the offline analysis, electrons were required to pass the standard "tight" electron selection criteria [27] with $E_T > 20$ GeV and $|\eta| < 2.47$; electrons in the transition region between the barrel and endcap calorimeter ($1.37 < |\eta| < 1.52$) were rejected. The "tight" selection was used in order to improve the rejection of the QCD background. No isolation requirement was applied to the electron selection. Events were also rejected if there was a second electron passing the "medium" electron selection criteria [27] and the same kinematic selections as above.

In the muon channel, the hardware-based trigger selected events containing one or more muon candidates, based on hit patterns in the MS, corresponding to $p_T > 10$ GeV. Offline, the muons were required to be identified in both ID and MS sub-systems and have $p_T > 20$ GeV and $|\eta| < 2.4$. The ID track was required to have $\geq 2$ hits in the pixel detector, $\geq 6$ hits in the SCT and, for tracks with $|\eta| < 2.0$, $\geq 1$ hit in the TRT. The muon impact parameter with respect to the primary vertex [20] was required to be $< 0.1 \text{ mm}$ and $< 10 \text{ mm}$ in the $r$–$\phi$ and $r$–$z$ planes, respectively. The first of these requirements was added to further reduce non-prompt muons from decays of hadrons, and muons from cosmic rays. The difference between the ID and MS $p_T$, corrected for the mean energy loss in upstream material, was required to satisfy $|p_T^{\text{ID}} - p_T^{\text{MS}}| < 0.5 \times p_T^{\text{ID}}$. Compared to the criteria used in Ref. [27], this scaled requirement reduced the background from decays-in-flight of hadrons and improved the signal efficiency at high $p_T$. As in Ref. [27], the muons were required to be isolated, following a track-based isolation, but the cone size was reduced from $\Delta R = 0.4 \rightarrow \Delta R = 0.2$ (where $\Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2}$ of the muon) and the isolation requirement was changed from $\Sigma p_T^{\text{ID}}/p_T < 0.2$ to $\Sigma p_T^{\text{ID}} < 1.8 \text{ GeV}$ to improve the QCD background rejection. With these optimised cuts, the QCD background was reduced by a factor of 1.7 for the inclusive 1-jet sample. In addition, a number of requirements were added on the tracks inside the isolation cone: the difference between the $z$ position of the track extrapolated to the beam line and the $z$ coordinate of the primary vertex was required to be $< 1 \text{ cm}$, and the total number of hits in the pixel and SCT detectors was required to be $\geq 4$. These additional requirements further improved the rejection of QCD background. Events were rejected if there was a second muon passing the same kinematic selections and isolation requirements as above.

The calculation of missing transverse energy ($E_T^{\text{miss}}$) and transverse mass ($M_T$) followed the prescription in Ref. [27]. $M_T$ was defined by the lepton and neutrino $p_T$ as $M_T = \sqrt{2p_T^l p_T^{\nu}(1 - \cos(\phi^l - \phi^{\nu}))}$, where the $(x,y)$ components of the neutrino momentum were inferred from the corresponding $E_T^{\text{miss}}$ components. $E_T^{\text{miss}}$ was calculated from the energy deposits of calorimeter cells inside three-dimensional clusters [28]. These clusters were then corrected to take into account the different response to hadrons compared to electrons or photons, as well as dead material and out-of-cluster energy losses [29]. In the muon channel, $E_T^{\text{miss}}$ was corrected for the muon momentum. Events were required to have $E_T^{\text{miss}} > 25 \text{ GeV}$ and $M_T > 40 \text{ GeV}$. After requiring $\geq 1$ primary vertex with $\geq 3$ associated tracks in the event, the primary vertex was required to be within $150 \text{ mm}$ along the beam direction relative to the centre of the detector. In events with multiple vertices along the beam axis, the vertex with the largest $\Sigma p_T^2$ of associated tracks was taken as the primary event vertex. Starting from approximately $9.6 \times 10^6$ triggered events in each of the electron and muon channels, these selection criteria reduced the sample to 4216 and 4911 events, respectively.

Jets were reconstructed using the anti-$k_t$ algorithm [30] with a radius parameter $R = 0.4$ [31]. The efficiency for reconstructing jets was found to be approximately $98\%$ in simulation for jet $p_T$ of 20 GeV, rising to close to $100\%$ efficiency for 30 GeV jets. Jets arising from detector noise or cosmic rays were rejected [32]. To take into account the differences in calorimeter response to electrons and hadrons, a $p_T$- and $\eta$-dependent factor, derived from simulated events, was applied to each jet to provide an average energy scale correction [31] back to particle-level. Jets were required to have $|\eta| < 2.8$ and $p_T > 20 \text{ GeV}$. All jets within $\Delta R < 0.5$ of an

---

*The cutoff for multiple parton interactions, PUPPI(82), was adjusted from 2.3 to 2.1 GeV, suitable for the CTEQ6L1 PDF.*
electron or muon (that passed the lepton identification requirements) were removed, regardless of the jet $p_T$ or $E_T$.

Jets from pile-up interactions were removed by a cut on the jet-$p_T$ (track, jet), requiring $\Delta R < 0.4$, the JVF was computed for each jet as the scalar sum $p_T$ of all matched tracks from the primary vertex divided by the total jet-matched track $p_T$ from all vertices. Jets which fell outside of the fiducial tracking region ($|\eta| < 2.5$) or which had no matching tracks were not considered for the JVF cut. Jets for which $JVF < 0.75$ were rejected; this requirement was chosen to optimise the Kölnergogor distance between the jet multiplicity (in data) with and without pile-up interactions. The application of the JVF cut reduced the sensitivity of the measured jet multiplicity distribution to additional jets from pile-up. The rejection rate of pile-up jets was found to be linear as a function of the number of pile-up interactions. The bias of the JVF cut on the jet multiplicity was found to be negligible for events with $< 4$ jets.

### 5. Signal and background yields

The major background processes in the electron channel are QCD and leptonic backgrounds. The latter consist of $W + Z$, $W + j$ and $Z + j$ samples. The dominant corrections in the electron channel come from trigger and reconstruction efficiency ($\approx 10%$ respectively). The corrections were computed using the ALPGEN $W + j$ event generator plus full detector simulation, restricting the events to the same phase space as the data analysis. The phase space requirements were applied to generated quantities. In this analysis, particle-level jets were constructed in simulated events by applying the jet finder to all final state particles (excluding muons and neutrinos) with a lifetime longer than 10 ps, whether produced directly in the $pp$ collision or from the decay of particles with shorter lifetimes. Correction factors were computed as one-dimensional functions of jet multiplicity and $p_T$.

ated photons within the energy of the lepton after radiation plus the energy of all radiated particle-level distributions. To treat the effect of final state radiation, data showed that these correction factors were sufficient to directly from the data as follows. In the electron channel, events were triggered either by an independent \( E_{T}^{miss} \) trigger or a loose electron trigger with an approximately 5 GeV threshold. The full \( W + \text{jets} \) selection was carried out in essentially the same way described above in order to isolate a pure electron sample. The trigger efficiency was found to be close to 100% in both data and simulation. In the muon channel, the trigger efficiency was computed with a sample of unbiased offline reconstructed muons from \( Z \rightarrow \mu\mu \) decays. Average trigger efficiencies of 82.0 \( \pm \) 1.4% and 86.9 \( \pm \) 0.1% were obtained in data and simulation, respectively; the difference between data and simulation comes from a mismodelling of both the efficiency of the forward muon chambers and of the programming of the muon trigger electronics. The trigger efficiency (and its uncertainty) from the data was used for the correction factor.

6. Systematic uncertainties

The primary sources of systematic uncertainty in the cross section for both electron and muon channels are uncertainties in the integrated luminosity and in the jet energy scale [31]. In the electron channel, the uncertainty due to the QCD background shape is also important. Both electron and muon channels are affected by uncertainties in the lepton reconstruction efficiency. The luminosity uncertainty enters primarily through the signal normalisation but also has an effect on the estimation of the leptonic backgrounds; the luminosity uncertainty is therefore larger in the muon channel.

Uncertainties in the jet energy scale (JES) and jet energy resolution (JER) were determined primarily from simulations [31]. The JES uncertainty varies as a function of jet \( p_T \) and \( \eta \), and ranges from around 10% at 20 GeV to about 8% at 100 GeV. The JER uncertainty is 14% of the jet energy resolution. To take into account the differences in calorimeter response to quark- and gluon-initiated jets, an additional uncertainty of 5% was added in quadrature to the JES uncertainty, based on the average difference in simulation of the calorimeter response between jets in the \( W + \text{jets} \) samples compared to those in the dijet samples (on which the JES

![Fig. 1. Results of fitting the signal and background templates to the \( E_{T}^{miss} \) distribution in the electron (left) and muon (right) channels for the 1-jet bin. In the electron channel, the fit was performed for \( E_{T}^{miss} > 10 \) GeV. All templates were from simulated events, except for the QCD background template in the electron channel which was obtained from the data.](image-url)
calibration is based). Uncertainties in the JES due to nearby jets in W + jets events were also studied but found to be small. To estimate the impact of the JES uncertainty, jet energies in the simulated events were shifted by the JES uncertainty, and the $E_T^{miss}$ vector was recomputed. In addition, calorimeter clusters not associated to a jet or electron, such as those coming from the underlying event, were scaled using a $p_T$-dependent uncertainty [27], ranging from ±20% for $p_T \approx 500$ MeV to ±5% at high $p_T$. Similarly the jet energies were smeared with a Gaussian representing the JER uncertainty and the $E_T^{miss}$ vector was recomputed. The full analysis was repeated with these variations, and the cross sections were recomputed; the change in the cross section was taken as the systematic uncertainty. The impact of the JES and $E_T^{miss}$ uncertainties on the cross section uncertainty was approximately 10%.

A significant source of uncertainty in the electron channel is the potential bias in the sample selection for building the template shape of the QCD background; with the current selection requirements, the contribution from semileptonic heavy flavour decays is underestimated. The size of the effect was determined with simulated events by comparing the background estimates from two templates: one based on the electron selection used for this cross section measurement and the other based on the selection used for the QCD background estimation in the electron channel. The resulting uncertainty on the QCD background estimate, including significant contributions from the limited statistics of the simulated event samples, was as high as 50%, but the effect on the cross section for the inclusive 1-jet bin was about 5%. The fit region for the QCD background was varied by ±5 GeV to account for shape differences in the low $E_T^{miss}$ region; the resulting uncertainty on the cross section was 1–2%.

The uncertainty in the electron identification efficiency was taken from the inclusive cross section measurement [27]. By examining the reconstruction efficiency in simulated events as a function of the $\Delta R$ separation between the jet and the electron, the reconstruction efficiency was found to be consistent with the value in Ref. [27]. Furthermore, in the region $\Delta R > 0.5$, the efficiency was found to be constant as a function of $\Delta R$ and as a function of jet multiplicity. The uncertainty in the muon reconstruction efficiency was estimated by comparing the efficiency measured with simulated events to that measured in the data with muons from $Z \rightarrow \mu \mu$ decays, following a method similar to that described in Ref. [27]. The resulting uncertainties in the cross section were approximately 5.5% in both electron and muon channels.

Other uncertainties which were considered include the trigger efficiency, jet reconstruction efficiency, lepton momentum scale and resolution, pile-up, and biases in the procedure for correcting for detector effects (for example, by comparing correction factors obtained with ALPGEN to those obtained with SHERPA). Their effect on the cross section was found to be smaller than the uncertainties described above. For example, the uncertainty on the electron energy resolution was based on extrapolations from test-beam measurements [27] and had a < 0.1% effect on the cross section. All of the above systematic uncertainties (except for the bias in the template shape for the QCD background in the electron channel) were also applied to the estimates of the QCD and leptonic backgrounds in both electron and muon channels. In addition, for the leptonic backgrounds the uncertainty in the NNLO cross section was taken to be 5% for W/Z production as in Ref. [27]. The Higgs cross section uncertainty was taken to be approximately 7%, amounting to the sum in quadrature of PDF uncertainties (3%) and uncertainties estimated by varying renormalisation and factorisation scales (6%) [34]. The resulting uncertainty on the W + jets cross section ranged from 0.1 to 2%, depending on the jet multiplicity, and was small compared to other systematic uncertainties.

The systematic uncertainties in the cross section measurement are summarised in Table 3 for $N_{jet} \geq 1$; most of the uncertainties are approximately independent of jet multiplicity, except for the uncertainty due to the jet energy scale and resolution, and the QCD background in the electron channel. The dominant systematic uncertainties are shown as a function of jet multiplicity and leading jet $p_T$ in Fig. 2. Both distributions are similar for electron and muon channels; the uncertainty is therefore shown as a function of jet multiplicity for the electron channel and as a function of leading jet $p_T$ for the muon channel. The main contribution to the other uncertainties in the electron channel comes from the QCD background (especially at high jet multiplicities), the electron identification efficiency and the electron energy scale. For the muon channel, the main contribution is from the muon reconstruction efficiency.

In the cross section ratio measurement, the uncertainty due to the jet energy scale uncertainty remains the dominant effect, amounting to approximately 10% on the ratio. The luminosity uncertainty does not completely cancel in the ratio because the background estimates are affected by the luminosity uncertainty and the background levels vary as a function of jet multiplicity.

7. Results and conclusions

The measured W + jets cross section (multiplied by the leptonic branching ratio) and the cross section ratios are shown as a function of corrected jet multiplicity in Tables 4 and 5 respectively, as well as in Figs. 3 and 4. The measurement was not performed in the inclusive 4-jet bin in the electron channel because of the poor signal-to-background ratio. The cross sections are quoted in the limited kinematic region: $E_T^{miss} > 20$ GeV, $|\eta^e| < 2.8$, $E_T^j > 20$ GeV, $|\eta^j| < 2.47$ (excluding 1.37 < $|\eta^j|$ < 1.52), $|\eta^\ell| < 2.4$, $p_T^\ell > 25$ GeV, $M_\ell > 40$ GeV, $\Delta R^{\ell j} > 0.5$, where $\ell$, $j$ and $\nu$ denote lepton, jet and neutrino, respectively. The quantities $p_T^\ell$, $|\eta^\ell|$, and $M_\ell$ include the energy of all radiated photons within $\Delta R = 0.1$ around the lepton. The W + jets cross section (times leptonic branching ratio) is shown as a function of the $p_T$ of the leading and next-to-leading jets in the event in Fig. 5; the leading jet is shown for $N_{jet} \geq 1$ and the next-to-leading jet is shown for $N_{jet} \geq 2$.

Also shown in Figs. 3, 4, and 5 are particle-level expectations from PYTHIA, ALPGEN and SHERPA simulations as well as a calculation using MCFM v5.8 [35]. PYTHIA is LO, while ALPGEN and SHERPA match higher-multiplicity matrix elements to a leading-logarithmic parton shower; these predictions have been normalised to the NNLO inclusive W production cross section. The version of MCFM used here provides NLO predictions at parton level for W-boson production with $N_{jet} \leq 2$; only leading-order predictions are available for W + three jets. No additional normalisation was applied to the MCFM predictions.

The MCFM results were obtained with the same jet algorithm and same kinematic selection requirements as applied to the data. Renormalisation and factorisation scales were set to $H_T/2$, where $H_T$ is the scalar sum of the $p_T$ of the unclustered partons and of the lepton and neutrino from the W decay. The PDFs were CTEQ6L1 [11] and CTEQ6.6M [15] for the LO and NLO calculations, respectively. Corrections for hadronisation and underlying event were computed with PYTHIA as a function of leading and next-to-leading jet $p_T$. Hadronisation and underlying event corrections ranged from −10% to −4% and +10% to +4%, respectively, for jet $p_T \approx 20$ GeV to jet $p_T > 80$ GeV. The partial cancellation of hadronisation and underlying event corrections [5] results in an overall correction of approximately 4%. The effect of final state QED radi-

**Fig. 2.** Summary of the systematic uncertainties on the cross section measurement shown as a function of jet multiplicity in the electron channel (left) and leading-jet \(p_{T}\) in the muon channel (right). The jet energy scale uncertainty includes the uncertainty on \(E_{T}^{miss}\). The main contribution to the "sum of other uncertainties" in the electron channel comes from the QCD background (especially at high jet multiplicities), the electron identification efficiency and the electron energy scale. For the muon channel, the main contribution is from the muon reconstruction efficiency.

The measured cross section times leptonic branching ratio for \(W + jets\) in the electron and muon channels as a function of corrected jet multiplicity with (in order) statistical, systematic, and luminosity uncertainties. The cross sections are quoted in a limited and well-defined kinematic region, described in the text. The measurement was not performed in the inclusive 4-jet bin in the electron channel because of the poor signal-to-background ratio. Theoretical predictions from MCFM are also shown, with all uncertainties combined. MCFM provides NLO predictions for \(N_{jet} \leq 2\) and LO prediction for \(N_{jet} = 3\).

The systematic uncertainty in the MCFM cross sections due to fragmentation was estimated by comparing PYTHIA with HERWIG. Underlying event uncertainties were estimated by comparing the AMBT1 [19] event generator tune with the tune from JIMMY [10] as well as by varying the AMBT1 tune to increase the underlying event activity by approximately 10%. Renormalisation and factori-

Fig. 3. $W + \text{jets}$ cross section results as a function of corrected jet multiplicity. Left: electron channel. Right: muon channel. The cross sections are quoted in a limited and well-defined kinematic region, described in the text. For the data, the statistical uncertainties are shown by the vertical bars, and the combined statistical and systematic uncertainties are shown by the hashed regions. Also shown are predictions from PYTHIA, ALPGEN, SHERPA, and MCFM, and the ratio of theoretical predictions to data (PYTHIA is not shown in the ratio). The theoretical uncertainties are shown only for MCFM, which provides NLO predictions for $N_{\text{jet}} \leq 2$ and a LO prediction for $N_{\text{jet}} = 3$.

Fig. 4. $W + \text{jets}$ cross section ratio results as a function of corrected jet multiplicity. Left: electron channel. Right: muon channel. The cross sections are quoted in a limited and well-defined kinematic region, described in the text. For the data, the statistical uncertainties are shown by the vertical bars, and the combined statistical and systematic uncertainties are shown by the hashed regions. Also shown are theoretical predictions from PYTHIA, ALPGEN, SHERPA, and MCFM. The theoretical uncertainties are shown only for MCFM, which provides NLO predictions for $N_{\text{jet}} \leq 2$ and a LO prediction for $N_{\text{jet}} = 3$.

sation scale uncertainties were estimated by varying the scales, in all combinations, up and down, by factors of two. PDF uncertainties were computed by summing in quadrature the dependence on each of the 22 eigenvectors characterising the CTEQ6.6 PDF set; the uncertainty in $\alpha_s$ was also taken into account. An alternative PDF set, MSTW2008 [13], with its set of 68% C.L. eigenvectors was also examined, and the envelope of the uncertainties from CTEQ6.6 and MSTW2008 was taken as the final PDF uncertainty. The total resulting uncertainties are given in Tables 4 and 5.

In conclusion, this Letter presents a measurement of the $W + \text{jets}$ cross section as a function of jet multiplicity in $pp$ collisions at $\sqrt{s} = 7$ TeV in both electron and muon decay modes of the
Fig. 5. \(W+\) jets cross section as a function of the \(p_T\) of the two leading jets in the event. The \(p_T\) of the leading jet is shown for events with \(\geq 1\) jet while the \(p_T\) of the next-to-leading jet is shown for events with \(\geq 2\) jets. Left: electron channel. Right: muon channel. The cross sections are quoted in a limited and well-defined kinematic region, described in the text. For the data, the statistical uncertainties are shown by the vertical bars, and the combined statistical and systematic uncertainties are shown by the hashed regions. Also shown are theoretical predictions from PYTHIA, ALPGEN, SHERPA and MCFM, and the ratio of theoretical predictions to data (PYTHIA is not shown in the ratio). The theoretical uncertainties are shown only for MCFM, which provides NLO predictions for \(N_{\text{jet}} \leq 2\) and a LO prediction for \(N_{\text{jet}} = 3\).

\(W\)-boson, based on an integrated luminosity of 1.3 pb\(^{-1}\) recorded with the ATLAS detector. Measurements are also presented of the ratio of cross sections \(\sigma(W+\geq n)/\sigma(W+\geq n-1)\) for inclusive jet multiplicities \(n=1-4\), and of the \(p_T\) distribution of the leading and next-to-leading jets in the event. The results have been corrected for all known detector effects and are quoted in a limited and well-defined range of jet and lepton kinematics. This range is fully covered by the detector acceptance, so as to avoid model-dependent extrapolations and to facilitate comparisons with theoretical predictions. As expected, the PYTHIA samples considered, which contain a \(2\rightarrow 1\) matrix element merged with a \(2\rightarrow 2\) matrix element and a leading-logarithmic parton shower, does not provide a good description of the data for jet multiplicities greater than one. Good agreement is observed with the predictions of the multi-parton matrix element generators ALPGEN and SHERPA. Calculations based on \(O(\alpha_s^3)\) matrix elements in MCFM (available for jet multiplicities \(n \leq 2\)) are also in good agreement with the data.

Acknowledgements

We thank Zbigniew Was and Frank Krauss for useful discussions. We wish to thank CERN for the efficient commissioning and operation of the LHC during this initial high-energy data-taking period as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DSRF, DNSRC and Lundbeck Foundation, Denmark; ARTEMIS, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; CNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNISW, Poland; GRCES and FCT, Portugal; MERSY (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantonsw Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.
