Introduction: Pulmonary embolism (PE) is a life-threatening illness with high morbidity and mortality. Echocardiography (ECG) plays an important role in the early identification of right ventricular (RV) dysfunction, making it a helpful tool in identifying hemodynamically stable patients affected by PE with a higher mortality risk. The purpose of this study was to evaluate if one or more ECG indexes could predict a short-term evolution towards RV dysfunction.

Methods: We selected all patients consecutively admitted to the Careggi Hospital Emergency Department with the clinical suspicion of PE, confirmed by computed tomography angiography prior to enrollment. Subsequently, properly trained emergency physicians acquired a complete ECG to measure RV morphological and functional indices. For each patient, we recorded if he or she received a fibrinolytic treatment, a surgical embolectomy or heparin therapy during the emergency department (ED) stay. Then, every patient was re-evaluated with ECG, by the same physician, after 1 week in our intensive observation unit and 1 month as outpatient in our ED regional referral center for PE.

Results: From 2002 to 2007, 120 consecutive patients affected by PE were evaluated by echocardiography at the Careggi Hospital ED. Nine patients (8%) were treated with thrombolytic therapy. Six died within 1 week and 4 abandoned the study, while the remaining 110 survived and were re-evaluated by ECG after 1 week and 1 month. The majority of the echocardiographic RV indexes improve mostly in the first 7 days: Acceleration Time (AT) from 78±14 ms to 117±14 ms (p<0.001), Diameter of Inferior Vena Cava (DIVC) from 25±6 mm to 19±5 mm (p<0.001), Tricuspid Annular Plane Systolic Excursion (TAPSE) from 16±6 mm to 20±6 mm (p<0.001). Pulmonary Artery Systolic Pressure (PASP) showed a remarkable decrease from 59±26 mmHg to 37±9 mmHg, (p<0.001). The measurements of the transverse diameters of both ventricles and the respective ratio showed a progressive normalization with a reduction of RV diameter, an increase of Left Ventricular (LV) diameter and a decrease of RV/LV ratio over time. To evaluate the RV function, the study population was divided into 3 groups based on the TAPSE and PASP mean values at the admission: Group 1 (68 patients) (TAPSE+/PASP-), Group 2 (12 patients) (TAPSE-/PASP-), and Group 3 (30 patients) (TAPSE-/PASP+). Greater values of AT, minor RV diameter, greater LV diameter and a lesser RV/LV ratio were associated with a short-term improvement of TAPSE in the Group 2. Instead, in Group 3 the only parameter associated with short-term improvement of TAPSE and PASP was the treatment with thrombolytic therapy (p<0.0001).

Conclusion: Greater values of AT, minor RV diameter, greater LV diameter and a lesser RV/LV ratio were associated with a short-term improvement of TAPSE-/PASP- values. Patients with evidence of RV dysfunction (TAPSE-/PASP+), may benefit from thrombolytic therapy to improve a short-term RV function. After 1 month, also a decreased DIVC predicted improved RV function. [West J Emerg Med. 2013;14(5):509–517.]
INTRODUCTION

Acute pulmonary embolism (PE) is defined as a partial or complete occlusion of the pulmonary artery branches; together with deep vein thrombosis it is a possible manifestation of the same disease: venous thromboembolism. Clinical features of PE can range from a totally silent presentation to sudden dyspnea and tachypnea, associated with tachycardia, chest pain, hemoptysis or syncope. Those signs are neither specific nor sensitive, because of a wide spectrum of possible differential diagnoses, including coronary artery disease, pneumonia, congestive heart failure, pericarditis, pleurisy and primary pulmonary hypertension.

PE is associated with high morbidity and mortality, especially when associated with signs of right ventricular (RV) dysfunction. Patients can be prognostically stratified into 3 risk classes: high-risk PE with a short-term mortality >15% including hemodynamically unstable patients, intermediate-risk PE according to the identification of either RV dysfunction or blood markers of myocardial injury, and low-risk PE. Echocardiography (Echocardiography (ECG)) represents a very important source of prognostic information in PE, as it can recognize many signs of RV dysfunction and is therefore helpful to assign the patient to low- or intermediate-risk classes.

Many studies have analyzed 1 or more ECG indices of RV dysfunction in relation to short-or long-term patient survival, but none assess whether 1 or more of these ECG indices could predict short-term changes of RV dysfunction or pulmonary hypertension in patients with PE. Thus, the aim of our study was to identify 1 or more ECG indices of RV anatomy and function predictors of short-term RV dysfunction in patients with PE.

METHODS

The study, which is consistent with the principles of the Declaration of Helsinki on clinical research involving human subjects, was approved by an Institutional Review Board.

We enrolled all patients consecutively admitted to the Careggi Hospital Emergency Department (ED) with current and past history, clinical symptoms, and pretest probability suggestive of PE confirmed by computed tomography angiography in this study.

Subsequently, each patient underwent an ECG to measure several morphological and functional RV indices.

- Age, heart rate (HR), respiratory rate (RR), systolic blood pressure (SBP) and diastolic blood pressure (DBP) of all patients were obtained on admission to the ED; if a patient had a shock index (defined as heart rate divided by systolic blood pressure), >1 he or she was considered affected by high-risk PE.

- All patients had a transthoracic ECG performed using standard views (parasternal long-axis view, parasternal short-axis view, apical four-chamber view and subcostal long-axis view) with M-Mode, B-Mode, Continuous-Wave Doppler, Pulsed-Wave Doppler and Color-Doppler techniques.

We acquired the images with an Acuson Sequoia 512 system (Siemens AG, Erlangen, Germany) equipped with a sectorial transducer with frequencies between 2.5 and 3.5 MHz. Each ECG was executed and interpreted by emergency physicians (EP). All EPs attended an initial training during an introductory course of 24 hours covering the core applications with practical hands-on sessions, and subsequent detailed courses covering single applications (vascular, cardiac and chest ultrasonography lasting 8 hours for each area). Then they performed, under a tutor’s supervision, 250 ultrasonographic exams of each kind before being certified to perform ultrasonography.

We measured right and left ventricular dimensions following the American Society of Echocardiography guidelines. M-mode ECG was used to evaluate the RV systolic function from long and short axis views. We detected RV long axis function by measuring the tricuspid annular plane systolic excursion (TAPSE), placing the M-mode cursor in the apical four-chamber view at the junction of the RV free wall and tricuspid annular plane and recording the longitudinal displacement of the annulus towards the apex from end-diastole to end-systole. The larger the excursion, the better was the RV systolic function, and values less than 16 mm were considered indicative of RV dysfunction.

We evaluated RV short axis function from the parasternal short-axis view at the level of the aortic root. With the M-mode technique, we recorded the right ventricular outflow tract fractional shortening (RVOTFS). The dimensions were measured at end-diastole and end-systole using endocardial leading edge methodology. We calculated RV fractional shortening as the percentage fall in right ventricular outflow tract diameter in systole with respect to that in diastole.

We recorded the diameter of the inferior vena cava (IVC) and its variation with inspiration expressed in percentage (%DIVC) from the subcostal long-axis view. The mid-cavity diameters of the right and left ventricles in end-diastole were measured from the standard parasternal long-axis, subcostal long-axis and apical four-chamber views. From these measurements, for each view we calculated the right ventricle to left ventricle ratio (RV/LV). This measure is considered an important ECG index, because a RV enlargement resulting in a RV/LV >1, can be indicative of a hemodynamically significant PE. Using the Continuous-wave Doppler technique from the parasternal short-axis view, we estimated the RV to right atrial pressure gradient, and calculated the pulmonary artery systolic pressure (PASP) with the information about the diameter and the respiratory collapse of the inferior vena cava (IVC).

Using the Pulsed-wave Doppler technique with the sample volume positioned at the tricuspid valve in apical four-chamber view, we recorded the diastolic flow, visualizing the E and A waves of the tricuspid flow and calculating the E to A ratio (E/A) and the deceleration time of the E wave (DTE). Using the same technique the acceleration time of the RV (AT) was measured in the parasternal short-axis view, positioning the sample volume at the tricuspid valve in apical four-chamber view.
the sample volume at the pulmonary valve.\textsuperscript{5,19}

Furthermore, we evaluated the presence of 2 ECG signs of RV dyskinesia: the McConnell’s sign (a distinct regional pattern of right ventricular dysfunction, with akinesia of the mid free wall but normal motion at the apex) and the D-shaped LV (systolic movement of the interventricular septum toward the LV).\textsuperscript{6}

For each patient, a record was made if he or she received a fibrinolytic treatment, a surgical embolectomy or heparin therapy during the ED stay. Then every patient was re-evaluated with ECG, by the same EP, after 1 week in our Intensive Observation Unit and 1 month as outpatient in our ED regional referral center for pulmonary embolism.

\section*{Statistical analysis}

Data are presented as mean ± standard deviation for continuous variables, and numbers or percentage for categorical variables. We tested differences by Student’s t test or χ square test or Fisher’s exact test, as appropriate. Analysis of variances and Sheffe’s post-hoc test assessed differences for multiple comparisons of continuous variables. Univariate logistic regression analysis assessed the association between every ECG parameter and the 7-day survival, eventually followed by a multivariate logistic regression analysis.

\section*{RESULTS}

We enrolled 120 patients (44\% male) who had been diagnosed with pulmonary embolism in the ED by computed tomography (CT) angiography from January 2002 to December 2007. Mean age was 73±14 years, and at the time of presentation 12 patients (10\%) were in shock. The remaining 108 patients (90\%) had a mean HR of 101±25 beats per minute, a RR of 23±9 breaths per minute, a SBP of 130±25 mmHg and a DBP of 77±13 mmHg.

One-hundred eleven of the 120 patients (92\%) never

\textsuperscript{ç}Normal values from 26.
had a history of PE, while 9 (8%) had a recurrence of venous thromboembolism. Nine of the 120 patients (8%) were treated with thrombolytic therapy.

In 9 patients (8%) the ECG exam was incomplete due to inadequate visualization of the heart. Therefore, it was not possible to record the dimensions of the RV in 1 patient in parasternal long-axis view (1%) and in 9 patients (8%) in subcostal long-axis view, and the LV was impossible to evaluate in 8 patients (7%) in subcostal long-axis view.

Six patients (5%) died within a week, and all belonged to group 3 (TAPSE-/PASP+). One of these was treated with thrombolytic therapy.

Two patients (2%) received a surgical embolectomy because of absolute contraindications to fibrinolysis, 1 (1%) was transferred to another hospital and 1 (1%) refused admission to the hospital; the remaining 110 patients (92%) were hospitalized and followed up with ECG after 1 week and 1 month.

The mean values of the ECG indices we evaluated were altered at ED presentation, compared to normal values presented in other studies, except for TAPSE and the mid-cavity diameter of the RV in the apical four-chamber view (Table 1).

Analyzing the development of the various ECG indices obtained from the 110 patients that were re-evaluated after

RV, right ventricle; LV, left ventricle; RV/LV, right ventricle to left ventricle ratio

* p<0.001 compared with the values at the admission with the Sheffé’s post-hoc test.
§ p<0.001 compared with the Sheffé’s post-hoc test.
c p=0.025 compared with the Sheffé’s post-hoc test.
1 week and 1 month, we found that the majority improved primarily in the first 7 days, with further, but not statistically significant, improvements within 1 month (Table 2).

In detail, the AT improved from a mean value of 78 ± 14 ms, recorded at the first ECG done in the ED, to 117 ± 14 ms after 1 week (p<0.001); after a month the improvement was minimally better (119±21 ms) but not statistically significant (versus 1 week).

The dimension of the inferior vena cava associated with its collapsibility during inspiration is a very reliable parameter to estimate right atrial pressure (RAP), and accordingly central venous pressure. DIVC showed a progressive and significant decrease, starting from mean values of 25 ± 6 mm at presentation to 19 ± 5 mm after one week (p<0.001), decreasing further to a mean value of 17 ± 3 mm after 1 month (p=NS versus 1 week).

The RVOTFS was described by Lindqvist et al at least as reliable as TAPSE for the evaluation of RV function: according to our analysis, RVOTFS was correlated with TAPSE showing a progressive increase of the average value (38 ± 16% at presentation, 49 ± 14% after 1 week, p<0.001, and 53±13% after 1 month, p=NS versus 1 week), comparable to that of TAPSE (16 ± 6 mm at presentation, 20 ± 6 mm after 1 week, p<0.001, and 22±6 mm after 1 month, p=NS versus 1 week).

The 2 parameters showed a highly significant linear correlation (r=0.980; p<0.001) and the standard error in the estimate of TAPSE using the RVOTFS values was ±1.34 mm. The range of TAPSE observed in our study is 5-24 mm, and using the RVOTFS to assess TAPSE, there would be a mean error of approximately ±9% (Figure 1).

The DTE and the E/A of the trans-tricuspid flow measured with Doppler technique are ECG indices of diastolic function of the right heart; these parameters significantly improved in our patients, showing an increase of the mean value of DTE from 125 ± 16 ms at presentation to 145 ± 19 ms after 1 week (p<0.001), to 158 ± 16 ms after 1 month (p=NS versus one week), while E/A mean value started from 0.67 ± 0.27 at the admission and increased after 7 days to 0.93 ± 0.28 (p<0.001) and then to 1.13 ± 0.28 after 1 month (p=NS versus 1 week).

The estimate of PASP showed a remarkable and
progressive decrease in our series: starting from a mean value of \(59 \pm 26\) mmHg upon admission. After 7 days we saw a marked and statistically significant decrease in pressure (\(37 \pm 9\) mmHg, \(p<0.001\)) that continued even after 1 month (\(30 \pm 8\) mmHg, \(p=NS\) versus 1 week).

The measurements of the transverse diameters of both ventricles and the respective ratio in the apical 4-chamber, parasternal long-axis and subcostal long axis views all showed a progressive normalization of the mean values, which is a reduction of RV dimension, an increase of LV dimension and a RV/LV ratio that decreased over time (Table 2).

Comparing survivors with non-survivors at 1 month, we saw that all the ECG indices we studied showed differences between the 2 groups (\(p<0.001\)), but age and vital signs registered on admission to the ED did not show statistically significant differences (Table 3).

In the univariate logistic regression analysis the parameters that showed an association with increased mortality within 7 days were as follows: an increased DIVC, an augmented DTE, a decreased E/A, an increased RV diameter in parasternal long-axis view and a diminished LV diameter in all 3 ECG views we performed (Table 4); but when those parameters were included in a multivariate logistic regression model, none of them proved to be an independent

\(RV\), right ventricle; \(LV\), left ventricle; \(RV/LV\), right ventricle to left ventricle ratio; \(NS\), not statistically significant
McConnell’s sign was found in 45 patients (39%) upon admission. Six of them died within 1 week. The 75 patients without McConnell’s sign survived 1 month (p=0.003).

All survivors with positive McConnell’s sign (39) were still positive for this sign after 1 week (p=NS), but after 1 month McConnell’s sign was detected in 21 patients (p=0.047).

The presence of a D-shaped LV was detectable in 55 patients (47%) upon admission and was present in 6 of the patients who died within 7 days, unlike the group of the 55 patients that did not have a D-shaped LV, who all survived one month (p=0.01).

Of the 49 patients with D-shaped LV that survived, 26 had this finding after 1 week (p=0.0051), with only 1 patient still positive after 1 month (p<0.001).

Of the 42 patients (36%) whose IVC was not collapsible, 6 died within 7 days, while all those whose IVC was collapsible with inspiration survived (p=0.002).

Of the 36 survivors with non-collapsible IVC, only 1 patient had this sign (p<0.001) after 1 week and 1 month, while the others reverted to normal (p=NS).

Therefore, the presence of McConnell’s sign, a D-shaped LV, or evidence of a non-collapsible IVC with inspiration showed a correlation with a higher mortality. However, performing further regression curve analysis, this relationship was not statistically significant (p=NS).

To evaluate right heart function, we divided the population of our study into 3 groups based on the TAPSE and PASP values: at the admission in the ED, 68 patients formed Group 1 (TAPSE+/PASP-), 12 patients formed Group 2 (TAPSE-/PASP-) and the remaining 30 patients formed Group 3 (TAPSE-/PASP+) (Figure 2). All patients in Group 1 remained in this group after 1 week and 1 month, not showing a deterioration in right heart function. After 1 week, 10 of 12 patients (83%) in Group 2 showed an improvement of right ventricular contractility (TAPSE+) moving to Group 1. The remaining 2 patients (17%) showed no improvement even after 1 month, remaining in the initial group. In Group 3, the majority (22 out of 30, 73%) moved to Group 2 due to a reduction of pulmonary hypertension (PASP-) not associated with a significant improvement of the systolic function of the RV, while the remaining 8 patients (27%) moved directly to Group 1 due to both an improvement of RV systolic function and reduction of pulmonary hypertension (TAPSE+/PASP-).

After 1 month, 5 out of 22 patients that moved from Group 3 to Group 2 showed a further improvement, shifting to Group 1. The following findings were all associated with a short-term improvement of TAPSE and PASP in this subgroup of patients: greater values of AT, a smaller RV diameter, a greater LV diameter in parasternal and subcostal-long axis views and a lower RV/LV ratio in apical four-chamber and subcostal long-axis views.

In Group 3 the only parameter related to 7-days improvement of RV function was the receipt of thrombolytic therapy. Indeed among this group of 30 patients, 22 (73%) did not receive thrombolytics, and improved to Group 2 status due to reduction of pulmonary hypertension (PASP-) but not a significant improvement in systolic function of the RV. The remaining 8 (27%) patients who were treated with thrombolysis, improved to a greater degree and moved directly to Group 1 due to both improvement of RV systolic function (TAPSE+) and reduction of pulmonary hypertension (PASP-). This difference in degree of improvement between the 22 patients without thrombolytics and the 6 with, was statistically significant (p<0.0001) (Fisher’s Exact Test). Furthermore, we note that 6 of the 8 patients thrombolysed, had intermediate-risk PE, while 2 were in shock, indicating that thrombolytic therapy may be of benefit not only for patients in extremis. Finally in Group 3 a decreased DIVC after 1 month was predictive of an improvement in RV function.

**DISCUSSION**

Our study investigated whether 1 or more ECG indexes could predict a short-term evolution towards RV dysfunction in patients affected by PE. Accordingly, the study was not aimed at evaluating the diagnostic ECG indices suggestive of pulmonary thromboembolism that were already extensively evidenced in the medical literature. Being able to predict short-term evolution towards RV dysfunction is important for the EP, to tailor therapy in the first hours after diagnosis according to the hemodynamic profile. We examined a consecutive group of 120 patients with PE on CT angiography, without regard to severity determined purely on clinical presentation.

Mortality rate in our population (5%) was similar to that of other studies.3,4,24 In those who survived (and excluding those not re-evaluable by ECG) the evolution after 1 week and 1 month of every ECG index was recorded. Every index showed a more or less rapid back-to-normal trend, but in some patients this trend was much slower than in others.

We used 2 ECG parameters studied extensively TAPSE and PASP to identify patients with a worse right heart dysfunction among those with the same clinical severity.

This way, we managed to verify an improvement or not of the right heart dysfunction after 1 week and 1 month, and so a favorable outcome or not, as reported in literature.16

As a matter of fact, in the group in which TAPSE and PASP were under the mean values, a higher AT, lower diameters of the RV, greater diameters of the LV, and a lower RV/LV ratio were all related to the improvement of the RV dysfunction after only 1 week from the episode of PE.

In the group 3, TAPSE-/PASP+, we were able to predict considerable improvement of RV dysfunction after 7 days, only if the patients had been treated with thrombolysis compared to those treated only with heparin. Furthermore, since the majority of patients who received
thrombolytic therapy (6 out of 8) belonged to the category 
at intermediate prognostic risk of pulmonary embolism, we 
can reasonably state that not only patients with high-risk PE 
(hemodynamically unstable patients) (2 out of 8) but also 
patients with an intermediate-risk PE showing an impairment 
of the RV function (reduced TAPSE and elevated PAPs) 
may benefit from thrombolytic therapy, after the exclusion 
of bleeding risk factors. This is very important for the ED 
physician approach to PE. These results therefore allow for 
the chance to improve the clinical status of a patient with 
PE based solely on ECG parameters recorded at the time of 
presentation in the ED.

Regarding DIVC, our study showed that this index 
remained higher than normal after 1 month, documenting the 
persistence of right heart dysfunction.

Moreover, we investigated the association between 
TAPSE and RVOTS, as described by Lindqvist et al. In those 
authors’ opinion, RVOTS is strictly related to TAPSE and in 
patients with PE it is highly indicative of RV dysfunction.

In our study, we confirmed the existence of a direct 
correlation between those 2 parameters, but TAPSE has a 
standard error of estimates of about ±1.34 mm for constant 
values of RVOTS. This means that for every value of RVOTS, 
TAPSE would have a CI of ±2.6 mm in a population in which 
TAPSE ranges from 5 to 24. This information, along with 
the absence in the literature of a reference value for normal 
population, suggests that further study is needed for a better 
definition of the relationship between TAPSE and RVOTS.

This study is the first analysis on the prognostic indices 
for PE detected by ECG in the emergency medicine literature.

LIMITATIONS

The most important limitation of our study is that we 
analyzed a highly select population in which the diagnosis of 
PE was already done, although the first ECG was performed in 
the ED soon after the CT angiogram.

CONCLUSION

ECG represents an invaluable instrument for the definition 
of prognosis of patients with PE. Even though an index or 
ECG sign that is more specific than another does not exist, 
each one supports the classification as an “intermediate-risk 
patient,” and only the absence of any sign of RV dysfunction 
predicts a good short-term prognosis.

In intermediate-risk patients AT, RV diameter in all 
views, LV diameter in parasternal long-axis and subcostal 
long-axis views, and the RV/LV ratio in apical 4-chamber and 
subcostal long-axis views could also be investigated to obtain 
information about diagnosis and rate of improvement in right 
heart dysfunction.

Moreover, although it is also recognized that massive 
acute pulmonary embolism causing a hemodynamic instability 
the clearest indication for thrombolytic agents, thrombolysis 
is probably useful in some patients with hemodynamic 
stability. This study attempts to identify how many and 
which patients are the best candidates. We found that those 
patients with low bleeding risk affected by intermediate-risk 
PE in which TAPSE is depressed and PASP is elevated could 
come from a thrombolytic therapy. This would result in a 
short-term improvement in RV function compared to those 
patients treated with heparin alone. Finally, patients in whom 
DIVC remains elevated after 1 month will maintain the RV 
dysfunction, with the long-term risks related to this condition. 
Further investigations, with a larger sample size will be 
needed to confirm these data.
