(22 Novenber 2007)

Cross sections for heavy element formation by compound-nucleus reactions have been measured for reactions with ${ }^{22} \mathrm{Ne},{ }^{23} \mathrm{Na},{ }^{26} \mathrm{Mg},{ }^{27} \mathrm{Al},{ }^{30} \mathrm{Si},{ }^{31} \mathrm{P}$, and ${ }^{37} \mathrm{Cl}$ projectiles and ${ }^{238} \mathrm{U}$ targets. Together with previously published results for reactions of ${ }^{18} \mathrm{O},{ }^{19} \mathrm{~F},{ }^{34} \mathrm{~S},{ }^{40} \mathrm{Ar}$, and ${ }^{48} \mathrm{Ca}$ projectiles with ${ }^{238} \mathrm{U}$ targets, the systematics of heavy element formation cross sections are analyzed. Conclusions about critical angular momentum for fusion and neutron evaporation in competition with fission during de-excitation are drawn.

PACS Number(s): 25.70.Gh, 27.90.+b
Isotopes of the heaviest elements $(Z \geq 100)$ can be produced in compound nucleus evaporation reactions. Several authors have noted an exponential decrease [1-3] in heavy element formation cross sections with increasing compound nucleus Z. Recent reports [2] of constant picobarn-level cross sections for formation of superheavy elements (SHE) in ${ }^{48} \mathrm{Ca}$ irradiations of actinide targets constitute a break in this well-established trend. There are now reports of two independent confirmations [4,5] of SHE production in such reactions. Understanding the heavy element formation cross section mechanism has taken on a new importance.

Oganessian has indicated that the large cross sections for SHE production in ${ }^{48} \mathrm{Ca}$ reactions with actinide targets result from enhanced survivability of the compound nucleus during de-excitation by neutron evaporation in competition with fission [2]. Spherical shell effects expected in the region approaching $\mathrm{Z}=114$ and $\mathrm{N}=184$ should lead to larger fission barriers, which could be expected to result in enhanced survival of the heavy element products. However, compared to the trend of exponentially decreasing cross sections with increasing Z (see fig. 11 of [2]), up to six orders of magnitude of cross section enhancement during evaporation of four neutrons is required to explain the picobarn-level SHE cross sections. It should be noted that a similar enhancement of the compound nucleus evaporation residue (EVR) cross sections was not observed [6] in the vicinity of the strong spherical $\mathrm{N}=126$ shell.

We have undertaken a systematic study of heavy element formation by compound nucleus - evaporation reactions using ${ }^{238} \mathrm{U}$ targets with neutron-rich projectiles from ${ }^{22} \mathrm{Ne}$ through ${ }^{37} \mathrm{Cl}$ to provide data for understanding and modeling these reactions. Together with data from similar reactions with ${ }^{18} \mathrm{O}[7],{ }^{19} \mathrm{~F}[7],{ }^{34} \mathrm{~S}[8],{ }^{40} \mathrm{Ar}[9]$, and ${ }^{48} \mathrm{Ca}[5,10-14]$, cross section
trends are analyzed to arrive at conclusions about critical angular momentum for fusion $\left(l_{c r i t}\right)$, survival during deexcitation by neutron evaporation in competition with fission and other deexcitation modes $\left(\Gamma_{n} / \Gamma_{\text {tot }}\right)$, comparisons with the standard fusion-evaporation model HIVAP [15], and extrapolation to SHE cross sections.

The LBNL 88-Inch Cyclotron accelerated beams of ${ }^{22} \mathrm{Ne},{ }^{23} \mathrm{Na},{ }^{26} \mathrm{Mg},{ }^{27} \mathrm{Al},{ }^{30} \mathrm{Si},{ }^{31} \mathrm{P}$, and ${ }^{37} \mathrm{Cl}$ to selected energies (Table I). Products of compound nucleus reactions were separated from beam and other reaction products with the Berkeley Gas-filled Separator (BGS) [12,13,16]. Targets were prepared by evaporation of $\mathrm{UF}_{4}$ onto arc-shaped Al or C backing foils. $\mathrm{UF}_{4}$ target segments were arranged on the periphery of a $35-\mathrm{cm}$ diameter target wheel located 1 cm downstream of a carbon entrance window. To prevent local overheating of the targets, the wheel was rotated at $\sim 10 \mathrm{~Hz}$. The product of beam intensity and target thickness was monitored by detecting Rutherford-scattered projectiles with two Si $p-i-n$ diode "monitor detectors" mounted at $\pm 27^{\circ}$ from the beam axis. Beam energies in the $\mathrm{UF}_{4}$ target layer were calculated by the residual range technique with range values taken from SRIM2003 [17]. Compound nucleus excitation energies, $E^{*}$, were calculated using experimental mass defects for the projectile and target, together with Thomas-Fermi mass defects $[18,19]$ for compound nuclei.

Compound nucleus EVRs are formed with the momentum of the projectile and recoil from the target. The BGS separates EVRs from beam and other reaction products by their differing magnetic rigidities in $66-\mathrm{Pa} \mathrm{He}$ gas. Magnetic rigidities for EVRs were estimated as in previous work [13], with an additional correction for higher average EVR charge states observed for low-velocity EVRs in He. The efficiency, $\varepsilon_{B G S}$, for collecting EVRs at the BGS focal plane detector was estimated using a Monte Carlo simulation of EVR trajectories in the BGS, as described earlier [12,16] (Table I).

Details of the Si-strip detector array and data acquisition system are as reported earlier [13,20]. However, because of the short range expected for EVRs from these asymmetric reactions, no multiwire proportional counter was used with beams lighter than ${ }^{37} \mathrm{Cl}$.

$$
\text { For }{ }^{238} \mathrm{U}\left({ }^{22} \mathrm{Ne}, x n\right){ }^{260-x} \mathrm{No},{ }^{238} \mathrm{U}\left({ }^{23} \mathrm{Na}, x n\right)^{261-x} \mathrm{Lr} \text {, and portions of the }{ }^{238} \mathrm{U}\left({ }^{26} \mathrm{Mg}, x n\right)^{264-x} \mathrm{Rf}
$$ irradiations, the beam was chopped at a $50 \%$ duty factor with a period of $600 \mathrm{~ms} .{ }^{254-256}$ No were identified in $\alpha$-decay singles spectra recorded between beam pulses. ${ }^{255-257} \mathrm{Lr}$ and ${ }^{259} \mathrm{Rf}$ were identified using EVR- $\alpha$ correlations (EVR during beam pulse, $\alpha$ between beam pulses). All other irradiations were carried out with a DC beam. ${ }^{258,260} \mathrm{Rf}$ and ${ }^{262,264} \mathrm{Sg}$ were identified by EVR-SF correlations. To measure $\alpha$ decay of ${ }^{261} \mathrm{Rf},{ }^{259-261} \mathrm{Db},{ }^{263} \mathrm{Sg}$, and to search for $\alpha$-decay of ${ }^{264} \mathrm{Bh}$ and ${ }^{270,271} \mathrm{Mt}$, a fast beam shutoff mode was used. Upon detection of a potential EVR followed by a time- and position- correlated parent $\alpha$-decay candidate, the beam was switched off for a preset time to allow a search for $\alpha$ - and SF-decays of the daughters under greatly reduced background conditions. Cross sections are presented in Table I. Error limits represent $68 \%$ statistical confidence limits calculated by a Poisson technique [21]. Results for the ${ }^{238} \mathrm{U}\left({ }^{30} \mathrm{Si}, x n\right){ }^{268-x} \mathrm{Sg}$ reaction have been reported earlier [22].

Excitation functions for EVR cross sections measured in this work are presented in Fig. 1. The curves in Fig. 1 are fits using a Gaussian smoothly joined to an exponential on the high-energy side,

$$
\begin{align*}
& \sigma=\sigma_{\max } e^{-\left(E^{*}-c\right)^{2} / 2 w^{2}}, E^{*} \leq \lambda w^{2}+c  \tag{1}\\
& \sigma=\sigma_{\max } e^{\lambda^{2} w^{2} / 2} e^{-\lambda\left(E^{*}-c\right)}, E^{*}>\lambda w^{2}+c
\end{align*}
$$

where $\sigma_{\max }$ is the amplitude of a Gaussian with centroid, $c$, and width, $w,-\lambda$ is the exponential slope, and $E^{*}$ is the excitation energy. For all target-projectile pairs, $w$ was fixed at $2.8,3.3$, and 3.8 MeV , and $\lambda$ was fixed at $0.48,0.38$, and $0.28 \mathrm{MeV}^{-1}$ for the $4 \mathrm{n}, 5 \mathrm{n}$, and 6 n exit channels,
respectively, to empirically match the excitation function shapes. The centroids and amplitudes of the fits for reactions with even-Z projectiles are listed in Table II. The ${ }^{238} \mathrm{U}\left({ }^{22} \mathrm{Ne}, x n\right)^{260-x} \mathrm{No}$ excitation functions from this work agree with published results [7], once the laboratory-frame beam energies from the earlier work are adjusted by -4 MeV . This gives us confidence to include data from their ${ }^{238} \mathrm{U}\left({ }^{18} \mathrm{O}, x n\right){ }^{256-x} \mathrm{Fm}$ and ${ }^{238} \mathrm{U}\left({ }^{19} \mathrm{~F}, x n\right){ }^{257-x} \mathrm{Md}$ experiments in our analysis of cross section systematics. Peak cross sections ( $\sigma_{\max }$ ) for $4 n, 5 n$, and $6 n$ exit channels, together with some tentative $3 n$ cross sections, for various projectiles with ${ }^{238} \mathrm{U}$ targets are plotted in Fig. 2 as a function of the fusing system effective fissility [25]. Also included in Fig. 2 are data from experiments with heavier projectiles [8,9], including a point for the ${ }^{238} \mathrm{U}\left({ }^{48} \mathrm{Ca}, 3 n\right)^{283} 112$ cross section resulting from a meta-analysis of results from several experiments [5,10-14]. The heavy straight lines are exponential fits to peak cross sections for even- $Z$ projectiles. Examination of Table II and Fig. 2 shows that the exponential fits to the $4 n, 5 n$, and $6 n$ excitation function peaks are nearly parallel. The $5 n$ exit channels have the largest $\sigma_{\max }$, peaking near $E^{*}=49.5 \mathrm{MeV}$. The $6 n$ exit channels peak near $E^{*}=56.1 \mathrm{MeV}$, with $\sigma_{\max } \sim 0.4$ of the maxima of the respective $5 n$ exit channels. The $4 n$ exit channels peak near $E^{*}=41.9 \mathrm{MeV}$ with $\sigma_{\max } \sim 0.2$ of the maxima of the respective $5 n$ exit channels. The $\sigma_{\max }$ for reactions with odd- $Z$ projectiles are lower than the trends indicated by the heavy lines through the $\sigma_{\max }$ of the even- $Z$ cross sections because the odd- $Z$ reactions occur at energies approximately 5 MeV further below the barrier than those with even- $Z$ projectiles. This is illustrated by the relative positions of reaction thresholds and barriers in Fig. 1. Also included in Fig. 2 are the excitation function peaks as calculated with the standard fusion-evaporation code, HIVAP [15]. HIVAP correctly predicts a) approximate excitation function peak cross sections, b) cross section trends with increasing compound-nucleus Z , and c ) the magnitude of odd-even effects.

Formation cross sections for EVRs, $\sigma_{E V R}$, in heavy element compound nucleus reactions can be described as
$\sigma_{E V R}=\sigma_{c a p} \cdot P_{C N} \cdot P_{x} \cdot \prod_{i=1}^{x}\left(\Gamma_{n} / \Gamma_{\text {tot }}\right)_{i}$,
where $\sigma_{c a p}$ is the capture cross section, $P_{C N}$ is the compound nucleus formation probability after capture occurs, and $P_{x}$ is the probability for emitting exactly $x$ neutrons. All terms are functions of $Z, A$, and $E^{*}$. Using relation (2) to calculate a cross section ratio for reactions differing by a single neutron in the exit channel, and solving for first-stage $\Gamma_{n} / \Gamma_{\text {tot }}$ in the reaction resulting from emission of the larger number of neutrons gives

$$
\begin{equation*}
\Gamma_{n} / \Gamma_{\text {tot }}\left(A, E_{1}\right)=\frac{\sigma_{E V R}\left(A-x, E_{1}\right)}{\sigma_{E V R}\left(A-x+1, E_{2}\right)} \cdot \frac{\sigma_{c a p}\left(A, E_{2}\right)}{\sigma_{c a p}\left(A, E_{1}\right)} \cdot \frac{P_{C N}\left(A, E_{2}\right)}{P_{C N}\left(A, E_{1}\right)} \cdot \frac{P_{x-1}\left(A, E_{2}\right)}{P_{x}\left(A, E_{1}\right)} \cdot \prod_{i=2}^{x}\left(\frac{\Gamma_{n} / \Gamma_{\text {tot }}\left(A-i+2, E_{i}\right)}{\Gamma_{n} / \Gamma_{\text {tot }}\left(A-i+1, E_{i}\right)}\right) \tag{3}
\end{equation*}
$$

Here A is the compound nucleus mass number. $E_{l}$ is the excitation energy of the compound nucleus for the $\sigma_{E V R}\left(A-x, E_{1}\right)$ reaction. $E_{2}$ is the resulting excitation energy in the $A-1$ product after neutron emission. The $\sigma_{E V R}\left(A-x+1, E_{2}\right)$ is chosen at $E_{2}$ to closely match the excitation energies in the subsequent neutron evaporation cascades. $E_{2}$ through $E_{x}$ in the product term are identical for both members of the reaction pair. $\sigma_{E V R}\left(A-x, E_{1}\right) / \sigma_{E V R}\left(A-x-1, E_{2}\right)$ are determined from the fits to the excitation functions (Fig. 1, Table II). $\sigma_{c a p}\left(A, E_{2}\right) / \sigma_{c a p}\left(A, E_{1}\right)$ have been calculated using the approximate "barrier distribution" scheme of Świątecki, Siwek-Wilczyńska and Wilczyński [26] with updated parameters [27]. $P_{C N}\left(A, E_{2}\right) / P_{C N}\left(A, E_{I}\right)$ have been assumed to be 1. $P_{x}$ have been calculated according to the formalism summarized by Vandenbosch and Huizenga [28]. $E_{i}$ were chosen so that successive values differ by the sum of the appropriate neutron separation energy and an average neutron kinetic energy. In addition, $E_{5}$ were chosen to match the peaks of the $5 n$ excitation functions, ensuring that $P_{4-6}$ are large, and $P_{x-1}\left(A, E_{2}\right) / P_{x}\left(A, E_{1}\right)$ are near 1. Sikkeland, Ghiorso, and Nurmia [29] have made an
$E^{*}$-independent empirical fit to the geometric mean of the $\Gamma_{n} / \Gamma_{f}$ for several stages of neutron evaporation as a function of $Z$ and average $N$ of the neutron cascade for $Z=98-104$. For all deexcitation cascades considered in this work, this results in
$\Gamma_{n} / \Gamma_{\text {tot }}(A+1) / \Gamma_{n} / \Gamma_{\text {tot }}(A)=1.12$
which has been applied inside the product term at the end of equation (3). The resulting $E_{l}$ and $\Gamma_{n} / \Gamma_{\text {tot }}\left(A, E_{l}\right)$ appear in the last two columns of Table II. The first-stage $\Gamma_{n} / \Gamma_{\text {tot }}$ values for the $5 n$ excitation energies show a weak dependence on compound nucleus $Z$ and have large values, similar to those reported by Andreyev [30]. However, use of an energy-dependent $P_{C N}$ could result in $P_{C N}\left(A-1, E_{2}\right) / P_{C N}\left(A, E_{1}\right)<1$, and correspondingly smaller first-stage $\Gamma_{n} / \Gamma_{\text {tot }}$ values for the $5 n$ excitation energies. For each entry in Table II, the capture cross section, $\sigma_{c a p}$, has been calculated $[26,27]$. The maximum angular momenta, $l_{\max }$, associated with these capture cross sections are listed. The fact that the amplitudes of the $5 n$ excitation functions are larger than those for the $4 n$ exit channels shows that $l_{\text {crit }}$ does not limit fusion at energies up to the centroids of the $5 n$ channels, with $l_{\max }=26-33 \hbar$. The smaller first-stage $\Gamma_{n} / \Gamma_{\text {tot }}$ at the $6 n$ excitation energies for ${ }^{26} \mathrm{Mg}+{ }^{238} \mathrm{U}$ and ${ }^{30} \mathrm{Si}+{ }^{238} \mathrm{U}$ are unexpected. Assuming $l_{\text {crit }}$ values slightly larger than $l_{\max }=26-33 \hbar$ would result in larger values for first-stage $\Gamma_{n} / \Gamma_{\text {tot }}$ than listed at the $6 n$ excitation energies in Table II. $l_{\text {crit }}$ values of $>33 \hbar$ [31] and 40-49 $\hbar$ [32] have been reported for production of $\mathrm{Z}=102-107$ isotopes in more symmetric reactions with $\mathrm{Tl}-\mathrm{Bi}$ targets.

Cross sections for heavy element formation in reactions with heavy ions and ${ }^{238} \mathrm{U}$ targets decrease exponentially with increasing $Z$ or effective fissility. The point for the ${ }^{238} \mathrm{U}\left({ }^{48} \mathrm{Ca}, 3 \mathrm{n}\right){ }^{283} 112$ reaction in Fig. 2 lies two orders of magnitude above the exponential trend. Reported picobarn-level SHE cross sections for all other reactions [2] between ${ }^{48} \mathrm{Ca}$ projectiles and actinide targets (with effective fissilities as large as 0.899 ) are as much as 5 orders of
magnitude above the respective Fig. 2 trend lines. An enhanced understanding of $\Gamma_{n} / \Gamma_{\text {tot }}$ and/or $P_{C N}$ is needed to explain SHE cross sections. Future experiments with more neutron-deficient projectiles can obtain more accurate values for $\Gamma_{n} / \Gamma_{\text {tot }}$ by forcing the product term in equation (3) to 1 , and eliminating the need for use of the equation (4) approximation.

We gratefully acknowledge the operations staff of the 88 -Inch Cyclotron for providing stable, high-intensity beams. Some ${ }^{238} U$ targets and carbon foil entrance windows were produced by the target lab at the Gesellschaft für Schwerionenforschung. Financial support was provided by the Office of High Energy and Nuclear Physics, Nuclear Physics Division of the U.S. Department of Energy, under contract DE-AC02-05CH11231.

${ }^{\text {a }}$ Published cross section (assumed $\mathrm{I}_{\alpha}=1 \%$ [7]) corrected for $\mathrm{I}_{\alpha}=1.8 \%$ [23].
${ }^{\mathrm{b}}$ Geometric mean of $\Gamma_{n} / \Gamma_{\text {tot }}$ at $\mathrm{x}=5,6$.
${ }^{c}$ Cross section measured at a single energy.
${ }^{\mathrm{d}}$ Fixed at average of the other $6 n$ centroids.
${ }^{\mathrm{e}}$ Fixed at average of the other $4 n$ centroids.

FIG. 1. (Color online) Experimental cross sections. $4 n, 5 n$, and $6 n$ exit channels are designated by squares, circles and triangles, respectively. The curves are fits as explained in the text. Large arrows indicate interaction barriers [26,27]. Small arrows show $5 n$ and $6 n$ threshold energies.

FIG. 2. (Color online) $\sigma_{\max }$ (open symbols) as a function of effective fissility [25]. Heavy straight lines (top to bottom) are exponential fits to even-Z $\sigma_{\max }$ for the $5 n, 6 n, 4 n$, and $3 n$ exit channels. Filled symbols connected by dahsed lines are results of HIVAP calculations [15].
