December 1984

<sup>\*</sup> The work described in this report was funded by the Assistant Secretary for Conservation and Renewable Energy, Office of Building Energy Research and Development, Buildings Systems Division of the U.S. Department of Energy under Contract No. DE-AC03-76SF00098.

Initial results from the Buildings Energy Use Compilation and Analysis (BECA) project on existing retrofitted homes were published in *Energy and Buildings*, 5 (1983) 151-170. Other BECA studies published in *Energy and Buildings* include results from low-energy new homes (BECA-A), *Vol. 3* (1981) 315-332, and retrofitted commercial buildings (BECA-CR), *Vol. 5* (1983) 171-196.

#### ABSTRACT

This study summarizes *measured* data on energy savings from conservation retrofits in existing residential buildings. We have compiled building performance data on approximately 115 retrofit projects (almost twice the size of the initial study) that we put into four general categories: utility-sponsored conservation programs, low-income weatherization programs, research studies, and multifamily buildings. The sample size for each project varies widely, ranging from individual buildings to 33,000 homes. Retrofits to the building shell, principally insulation of exterior surfaces, window treatments, and infiltration-reduction measures, are the most popular, although data on various heating system retrofits are now available. The average retrofit investment per unit in multifamily buildings is approximately \$695, far lower than the average of \$1350 spent in single-family residences. The median annual space heat savings in the four categories range from 15 to 38 GJ. Savings achieved are typically 20 to 30 percent of pre-retrofit space heating energy use although large variations are observed both in energy savings and in costs per unit of energy saved. Even given the wide range in savings, most retrofit projects are cost-effective. Approximately 75-80 percent of the retrofit projects have costs of conserved energy below their respective space heating fuel or electricity prices.

#### INTRODUCTION

A recent Office of Technology Assessment (OTA) report has concluded that "despite considerable theoretical analysis and thousands of audits, there is still very little documented information on the results of actual retrofits on different types of buildings."[1] The OTA report stresses that improved data on the results of individual retrofits, retrofit packages, and actual savings compared to predicted could help alleviate building owners' concerns regarding retrofit expense and outcome.

The BECA project addresses the lack of monitored building performance data by collecting and analyzing *measured* data that document the energy savings and cost-effectiveness of conservation measures and practices. This study focuses on retrofitted residential buildings. Updated results from approximately 115 retrofit projects are presented, nearly twice as many as in the previous compilation.[2]

Analysis of a large data base (totaling 60,000 households) provides a fairly broad picture of retrofit performance under varying conditions, although this compilation is not a representative survey of the fraction of the housing stock that has been retrofitted in recent years. In this study, we examine factors that account for variation in energy savings among households installing similar measures. We also report on those building types, specifically multi-unit buildings, for which there is now more detailed coverage. Finally, we identify major data gaps and suggest possible research that could provide an improved picture of the effects of conservation in occupied residential buildings.

#### DATA SOURCES

We obtained information on retrofit projects from research organizations, utilities and government agencies that sponsor conservation programs, and firms that provide building energy services. The data collected in these studies typically included metered energy consumption, installed retrofit measures and their cost, and, in some cases, a brief description of the physical characteristics of the buildings along with demographic information on the occupants. Each project was placed in one of four broad categories (utility-sponsored conservation programs, low-income weatherization programs, research studies, retrofits of multifamily buildings) to permit a consistent and useful treatment of results (see Appendix A, Summary Data Table).

Utility-sponsored conservation programs are mostly large-scale efforts that retrofit thousands of homes. They typically reach single-family, mostly middle-income homeowners whose homes are structurally sound. Utility programs usually offer low- or zero-interest loans to finance recommended conservation measures. Our sample has a distinct regional bias. Thirteen of the 19 conservation programs (approximately 68%) were sponsored by utilities located in the Pacific Northwest or California, and fourteen were directed at electrically-heated homes.

The Department of Energy (DOE) Low-Income Weatherization Assistance Program, the CSA/NBS Weatherization Demonstration Research Project, and pilot retrofit projects for oilfired heating systems funded by the Low-Income Energy Assistance Program are included in the low-income weatherization category. Data from a number of the DOE Weatherization Program evaluations are of questionable quality. Often, only annual utility bills or energy data for a fraction of the heating season are available, and cost data include only the cost of materials, not labor. Despite these limitations, we include the results because of the program's scope (nearly one million homes have been weatherized) and because it targets a housing sector where potential increases in energy efficiency are great.[3,4] The CSA/NBS project involved extensive retrofitting of 142 homes in 12 different locations with detailed monitoring of energy consumption and cost data.[5]

Research studies often test innovative retrofit measures or strategies. For example, Claridge et al. examined results from 26 Colorado homes that participated in the 50/50 Program, a DOE-conceived effort to speed implementation of a large number of low-cost energy conservation measures by making them available as a package.[6] Sample size for research studies tends to be small (fewer than 25 homes) and a comparison or control group is usually

-1-

employed as part of the experimental design. A few studies collected sub-metered end-use data in the post-retrofit period but most research projects relied exclusively on utility billing data.

Retrofit activity in multifamily buildings lags far behind retrofits of single-family homes for a variety of institutional and technical reasons. Almost 85 percent of multifamily housing units are renter-occupied, producing the problem of "split incentives." Landlords have little incentive to invest in energy-saving improvements in cases where tenants pay their own utility bills and tenants are seldom inclined to make investments in property they do not own. The U.S. multi-unit buildings included in the data base are all located in the Northeast or Midwest. The buildings range in size from 5 to 1790 units; 68 percent of the buildings are larger than 50 units. The inhabitants are mostly renters and are often low-income. Fifty percent of the buildings are part of public housing projects. Three buildings were retrofitted by energy service companies who contract with building owners to manage building energy systems.[7]

#### METHODOLOGY

The installation of conservation measures is just one of many factors that affect a building's energy consumption. Some factors will have a small effect while others such as seasonal weather variation and occupancy changes, must be accounted for explicitly. The building energy data that we encountered typically consisted of utility bills that include heating energy usage along with other ("baseline") uses of the same fuel. In research studies, the CSA/NBS weatherization project, and some utility program evaluations, the data were analyzed using a linear model:[8-10]

$$E_{i} = \alpha + \beta \left( DD_{R} \right)_{i}$$
<sup>[1]</sup>

where  $E_j$  is the average daily energy consumption over period j, and  $DD_R$  is heating degree days per day over period j (calculated using reference temperature R).

The regression was done using heating degree-days to either a fixed (base  $18.3^{\circ}C$ ) or variable reference temperature. The reference temperature represents the outside temperature below which the building's heating system is demanded. The parameter  $\alpha$  (energy use/day) is an estimate of the weather-independent usage (i.e., baseload) while  $\beta$ , the heat-loss rate, gives the amount of energy required for each incremental drop in outside temperature below the reference temperature.[8] These parameters, together with the normal-year heating degree days to the best-fit reference temperature, are used to calculate a weather-normalized annual consumption (NAC) for the pre- and post-retrofit periods.

In most cases we had to make one or more adjustments to reported consumption data. If monthly utility billing and local weather data were readily available, we did the analysis using the regression model with a variable reference temperature for each house. Some studies, however, used a different weather-adjustment procedure or reported only annual consumption data. In these cases, we corrected for the varying severity of winter in different years by scaling space heat energy use before and after retrofit by the ratio of normal-to-actual year heating degreedays. We also estimated the space heating portion of total usage for each project by subtracting an estimated baseload usage. The non-space heating portion was derived either from the regression coefficient ( $\alpha$ ), calculated by scaling summer fuel use to a full year, or estimated from regional and utility data.

Only 40% of the retrofit projects in this compilation included a control or comparison group (see Appendix A). Control groups also differed significantly between projects. For example, method of selection, knowledge of the experiment, and level of retrofit activity 'independent' of a program varied widely. In almost all cases, control-group residents were not restricted to maintaining their homes at 'pre-retrofit' status during the study. For these reasons, energy savings in a comparison group were not subtracted from savings achieved in the retrofit group in the energy and economic analysis.

Retrofit cost data were 'standardized' based on the direct costs to the homeowner of contractor-installed measures. An equivalent contractor cost was estimated in cases where only materials costs were known. Costs at the time of retrofit were converted to constant dollars (1983\$), using the GNP Implicit Price Deflators. Three economic indicators were calculated:

simple payback time (SPT), cost of conserved energy (CCE), and internal rate of return (IRR).[11,12] A real (or constant dollar) discount rate of 7 percent is used in the economic analysis. For multifamily buildings, the present value of projected annual operations and maintenance costs is included in addition to the initial investment (except for the SPT calculation). In calculating IRR, we assume that residential energy prices escalate annually at a real rate of 4 percent.[13] The CCE formula assumes constant (1983\$) energy prices. Conservation investments are amortized over the measures' expected physical lifetimes.

#### RESULTS

#### **Retrofit Strategies**

At present, most residential retrofits are directed towards improving energy efficiency in the two largest end-use areas: space heating and domestic water heating. This overall pattern can be observed in three of our data sub-groups (28 multi-unit buildings, 418 homes that participated in research studies, and 142 low-income homes from the CSA/NBS weatherization project), although there are some striking differences in the relative frequency of "shell" vs "system" retrofits between the groups (Fig. 1). For example, virtually all of the CSA/NBS lowincome homes received "shell" retrofits, yet these measures were installed relatively infrequently in multifamily buildings. Only 15 percent of the multi-unit buildings installed attic insulation. The low implementation rate is due, in some cases, to adequate pre-retrofit insulation levels (e.g., in New York City Housing Authority buildings) or to structural characteristics that make installation exorbitantly expensive (e.g., flat roofs, either clad-or masonry bearingwalls). In contrast, measures designed to improve the performance of existing heating systems (HS) either by modification/replacement of equipment (e.g., burners), altered operations and maintenance (OM) practices, or installation of control systems (HC) were popular retrofit strategies in multifamily buildings.

Conventional retrofits, particularly "shell" measures, window, and hot water retrofits, dominate utility-sponsored and DOE Low-Income Weatherization programs (see Appendix A, column E). For example, attic insulation was the only measure implemented in six of 19 utility-sponsored programs and was an option in every program. Approximately 50 percent of the utility conservation programs financed floor insulation, storm windows and doors, and caulking and weatherstripping.

We believe that the savings from many shell measures are now well-documented for single-family homes, due, in part, to the evaluation efforts and broad scope of these utility and low-income programs. Data are also increasingly available on heating system modifications for both single- and multifamily buildings although additional research is necessary on the optimal combination of shell and system measures for various structures and climates. We also need more empirical data on conservation measures at both extremes of the spectrum: performance data on "super-retrofits" that approach the identified conservation potential as well as savings from low-cost measures.

#### Energy Savings

There is substantial variation in annual space heat energy savings among single-family retrofit projects at any given investment level (Fig. 2). For example, savings differ by a factor of four for an investment of \$2400. Median space heat savings in 19 utility-sponsored conservation programs are 38.4 gigajoules (GJ) and 30.5 GJ in 27 low-income weatherization projects. The data points represent results from over 44,000 homes.

Conservation programs initiated by the Tennessee Valley Authority (TVA) and Puget Sound Power and Light (data points E1.1 and E6.1) achieved high energy savings (74 and 96 GJ) relative to cost (\$700 and \$1450). The TVA pilot program specifically targeted lowincome, high-energy consumers; hence significant improvements in building thermal performance were obtained at low cost.

Average space heating consumption was reduced by more than 20 percent in 27 of 45 (60%) single-family retrofit projects and 22 of 35 (63%) research studies (Figs. 3 and 4).

Approximately 30 percent of the retrofit projects achieved average space heating reductions of 30 percent or more. Average savings were not strongly correlated with pre-retrofit consumption levels although this correlation was most evident in results from the DOE Low-Income Weatherization program. Choice of retrofit strategy clearly influenced savings obtained by residents who participated in the CSA/NBS Project. Median space heat savings were 42 percent of preretrofit levels in the 73 homes (located in 7 cities) that received heating and hot water system retrofits in addition to "shell" measures (see points with x printed over circle in Fig. 3), compared to median savings of 13 percent in the 69 homes that installed only "shell" measures.

Several retrofit strategies employed in multifamily buildings were very successful in reducing energy consumption (Fig. 5). For example, space heat and hot water usage declined by 44 percent at Page Homes, a 159-unit public housing complex in Trenton, New Jersey, after the installation of a microcomputer-based boiler control system. High inside temperatures (average  $28^{\circ}$ C) and the buildings' relative energy-inefficiency before retrofit (a heating factor of 482 kJ/m<sup>2</sup>-DD<sub>C</sub> compared to the U.S. average of 318-353 kJ/m<sup>2</sup>-DD<sub>C</sub> for multi-unit buildings with similar characteristics) help account for the impressive energy savings.[14]

Annual space heat savings were between 26-61 GJ in six of eight gas-heated multi-unit buildings in Chicago that are cooperatively-owned. Remarkable savings (126 GJ/unit) were obtained in another one of these buildings (data point G31.5), a 53 percent reduction from preretrofit levels, for an investment of \$1200 per apartment. This building was extremely energyinefficient before retrofit, with a heating factor of 586 kJ/m<sup>2</sup>-DD<sub>C</sub>. Approximately 60 percent of the savings in the eight buildings were attributed to various heating system retrofits (e.g., derating burners in oversized heating systems, installing temperature-sensing burner controls, and balancing radiators and steam lines).[15] Average space heat energy consumption declined by 14.7 GJ in four New York City Housing Authority (NYCHA) buildings retrofitted with thermostatic radiator valves (data point O8), another example of a successful heating system retrofit.

Lower energy savings per dollar invested were achieved in a NYCHA window retrofit project that installed double-glazed thermal-break aluminum windows in nine apartment complexes. Average savings in the nine buildings were 12.7 GJ for an investment of \$1070 per apartment unit (data point O9). Pre-retrofit space heat levels were already fairly low in these buildings (65-75 GJ) as a result of NYCHA's ongoing energy conservation efforts. Their relative energy-efficiency, compared to other multi-unit buildings in the data base, partially accounts for the lower return on investment.

#### Range of Savings among Households

Large variations in fuel savings are observed among households in the same geographic location that installed similar conservation measures (Fig. 6). Weather-adjusted energy consumption declined in almost 95 percent of the sample, increasing in only 17 of 376 homes. For the middle 50 percent of the homes, the spread in savings is typically  $\pm$ 70 percent of the median. The large range in savings suggests that more detailed monitoring is required if we are to fully understand the relative impact of key determinants. Efforts to interpret these results are hampered by data limitations. Inside temperatures are not available for any home and in a few cases, basic information, such as conditioned floor area, was not collected (e.g., G12, G30).

However, a few preliminary conclusions can be extracted from the data. Energy savings seem to be more variable with some measures than others. For example, the coefficient of variation  $(CV)^*$  in energy savings is between 0.9-1.2 in four groups of Long Island, New York homes that retrofitted conventional burners with other options (Group 5 - vent damper, Group 6 - stack heat exchanger, Group 7 - double setback thermostat, Group 8 - thermostat and boiler temperature programmer). In contrast, savings were generally greater and more *uniform* in two similar groups that received retention head burners. The CV in energy savings is only 0.4 in

-4-

<sup>\*</sup> The coefficient of variation is defined as the ratio of the standard deviation to the sample mean; a low CV means that there is less variability in savings.

homes that received the energy-efficient burners with "optimized" installation techniques (Group 2) and 0.7 in homes where typical installation procedures were used (Group 1).[16]

Energy savings for an identical measure also appear to be more variable in mild than in harsh climates. For example, two utilities, Pacific Gas & Electric (PG&E) and Consolidated Gas of Michigan, evaluated conservation programs in which RSI 3.3 (R-19) attic insulation was installed in previously uninsulated homes.[17,18] The PG&E single-family residences were located in the San Joaquin valley in California, a region with a relatively mild winter climate compared to that in Detroit, Michigan (1215 vs 3477 annual heating degree-days, base 18.3<sup>o</sup>C). At one PG&E site (G12.1), median savings were 10.8 GJ, though 50 percent of the homes saved less than 4.2 GJ or more than 18.8 GJ. In addition, space heating usage increased in four households during the heating season following the retrofit. The coefficient of variation (CV) is 1.07 in this group of homes. In contrast, the CV is 0.64 in the Michigan buildings, suggesting less variability in energy savings, even though the sample contained more varied building types (e.g., single-family, row houses, duplexes) than the California study. There is little information available on occupant behavior in either study but we suspect that differences in indoor temperature preferences contribute to the greater variability in energy savings in the mild climate.

#### Economic Analysis

The prospects for significant retrofit investment in existing residential buildings hinge ultimately on the economic attractiveness of these investments to those responsible for building improvements. Homes in the nineteen conservation programs sponsored by utilities had a median simple payback time (SPT) of 5.7 years with a mean of 10.3 years (Fig. 7).\* The average payback period is greater than 15 years in four programs. Electricity prices at these utilities were extremely low (\$0.01-0.02/kWh) at the time of retrofit. Price increases have far exceeded the general inflation rate in recent years, thus the payback period would be somewhat shorter at today's electricity prices. The mean and median payback periods are 9.2 and 11.4 years, respectively, for 27 low-income weatherization projects. The combination of heating system and shell retrofits was roughly two times more cost-effective than shell measures alone (6.4- versus 13year payback period) for homes in the CSA/NBS Demonstration Project.

The cost of conserved energy (CCE) is defined as the ratio of annualized investment divided by annual energy savings, where annualized investment equals total investment multiplied by a capital recovery factor. The median and mean costs of conserved energy (CCE) in the 19 utility-sponsored programs (\$2.71,2.56/GJ) are significantly lower than that obtained in the 27 low-income weatherization projects (\$4.33,6.33/GJ). Key differences that may account for the varying levels of cost-effectiveness between these two groups include:

- poor workmanship and lack of quality control in homes that were retrofitted during the initial phases of the DOE Weatherization Program.[19]
- systematic variations in the choice of retrofit options for example, caulking and weatherstripping were installed in almost all low-income homes; energy savings from these measures are likely to be small and are directly related to the quality of workmanship.
- a fraction of the total investment in low-income homes, ranging from 0 to 25%, was often spent for energy-related structural repairs (e.g., broken window glass). These expenses raise the cost of conserved energy for these low-income homes relative to middle-income homes.
- possible overestimation of equivalent contractor cost for homes that used 'free' CETA labor in the DOE Low-Income Weatherization Program.

In most cases, retrofit measures that were installed in homes that participated in research studies also turned out to be attractive investments. The median cost of conserved energy for 38 research studies is \$3.62/GJ (Fig. 8). Nineteen of 25 gas-heat data points have a CCE lower than \$5.69/GJ, the national average price for gas, while all eight of the oil-heat data points have

<sup>•</sup> Every project is weighted equally in the calculation of mean and median values. Note that sample size varies within each project.

a CCE below the average price for oil. The cluster of gas-heat data points with a cost of conserved energy of only \$2/GJ at a first-cost of \$400 represent "house-doctor" treatment results from six groups of New Jersey homes that participated in Princeton University's Modular Retrofit Experiment (MRE). This retrofit strategy was also evaluated in research projects conducted by the Bonneville Power Administration and Lawrence Berkeley Laboratory (E8.1 and G27.1). In these studies, the costs of conserved energy were \$4-5/GJ. Researchers concluded that cost-effectiveness could be improved at these mild climate sites by focusing "housedoctoring" efforts on homes with either high infiltration rates or those that could be retrofitted with low-cost non-infiltration measures such as intermittent ignition devices and hot water wraps.

#### CONCLUSIONS

Key findings from this compilation of current retrofit experience in existing residential buildings are shown in Table 1. Energy savings occurred after retrofit in almost all retrofit projects, with average annual savings ranging from 27 to 40 GJ in the four categories. Savings actually achieved were typically 20 to 30 percent of pre-retrofit space heating energy use. These results suggest that most efforts to date have fallen far short of estimates of the identified technical potential.[20] There seem to be few successful, cost-effective retrofits involving expenditures of more than \$2500 per house. The average investment in multifamily buildings is approximately \$695/unit with a maximum of \$1650/unit, far lower than the average of \$1350 spent in single-family residences.

There is substantial variation in energy savings for investments of the same magnitude, even after controlling for pre-retrofit energy intensity, building type (e.g., single- vs. multifamily), and climate. We suspect that the variance in savings is due mainly to differences in occupant behavior, physical differences among houses prior to retrofit, variations in product and installation quality, and to measurement error. It is difficult to accurately estimate space heat savings when given only total billed energy use before and after a retrofit. Program evaluations rarely relied on sub-metered heating energy use or monitoring of inside temperatures. The absence of such monitoring techniques means that changes in the household appliance stock, use of secondary heating equipment, or adjustments in occupant behavior might have gone undetected, masking the actual effect of the retrofit. At a minimum, program evaluations should include a telephone or on-site survey of occupants in order to obtain information on these issues, a technique used in only a fraction of the studies.

Particularly cost-effective retrofit strategies can now be verified based on actual metered consumption data.\* The installation of attic insulation, particularly in homes with little or no insulation, resulted in cost-effective energy savings, irrespective of structural and demographic characteristics or climatic region. Conservation strategies designed to reduce domestic hot water usage, typically tank and pipe insulation and/or reduced-flow fittings, were also sound energy-efficiency investments. Varying packages of "shell" retrofit measures, typically including attic insulation, storm windows and, often, wall or floor insulation, were successful in most single-family electric-space heated homes. In low-income, single-family homes, retrofitting existing gas or oil-fired heating equipment appeared to be a very cost-effective complement to "shell" weatherization measures. Results from several pilot programs (e.g., Philadelphia Oil Furnace Retrofit Project) indicate that the cost-effectiveness of low-income weatherization can be enhanced through the development of administratively simple programs that employ well-trained private contractors to install various heating system retrofits.

The conservation potential in multifamily buildings is large and barely tapped. Improvements in existing heating system performance using such techniques as improved controls, burner de-rating, duct insulation, and balancing distribution systems are attractive energysaving strategies in multi-unit buildings. However, additional retrofit data are needed from

<sup>•</sup> These conclusions are drawn primarily from projects where individual measures or sets of measures were installed in groups of homes with similar structural characteristics in the same geographic location.

\*\* Electric space heat savings are measured in resource energy units, 12.1 MJ/kWh

multifamily buildings located in different climatic regions, and with varying physical characteristics and ownership patterns, to determine whether these preliminary results can be widely duplicated.

Many conservation measures are attractive economic investments from a homeowner's perspective, compared to either other investment possibilities or to maintaining present consumption levels at current residential fuel or electricity prices. The median real rate of return ranged from 6 percent in the 30 low-income weatherization projects to 25 percent in 19 utility-sponsored programs. These rates compare favorably with real rates of return from tax-free bonds (3-5 percent). Approximately 75-80 percent of the retrofit projects have costs of conserved energy below their respective space heating fuel or electricity prices.

Finally, this compilation highlights gaps or limitations in the data currently available on the measured performance of retrofits in existing residential buildings:[21]

- Measured data on retrofit performance in existing multifamily buildings, though increasing in number, are still inadequate. Successful retrofit strategies noted in this study must be tested in other climatic regions and in varying building types.
- Insufficient data are available on energy savings trends over multi-year periods. This information is needed to validate engineering estimates of retrofit lifetime, a factor that can be as crucial to cost-effectiveness as first-year savings. Long-term tracking of occupied buildings, however, magnifies the problem of accounting for changes in operating conditions, occupancy, or the effect of additional retrofits. Successful projects will need stable research funding and will almost surely require direct monitoring of major house-hold end-uses and inside temperatures.
- Few data are available on the effect of retrofits on peak power and cooling energy requirements. We have had limited success obtaining data from regions of the country (i.e., Southeastern and Southwestern U.S.) where cooling accounts for a substantial portion of total residential energy use. There are also less data on retrofits directed at end-uses other than space heating. Studies of active and passive solar retrofits are not properly represented in the data base, often because of insufficient cost data.

XCG 839-7234 A

Fig. 1. Relative frequency with which retrofit measures were installed in research studies, multi-family buildings, and CSA/NBS low-income homes. The measure code key is: IA, attic insulation; IW, wall insulation; IX, insulation of miscellaneous areas or unspecified; CW, caulking and weatherstripping; PI, infiltration reduction using blower door pressurization; HS, heating system improvements; HC or T, HVAC controls or clock thermostats; OM, operations and maintenance actions; WM, window management; WR, window repair or replacement; WH, water heating.

#### XCG 839-7233 B

Fig. 2. Annual space heat energy savings are plotted against the first-cost of the retrofit for utility-sponsored and low-income weatherization programs. The sloping reference lines show the minimum energy savings that must be achieved for each level of investment if the retrofit is to be cost-effective compared to national average fuel and electricity prices. This minimum is calculated as the present value of the energy purchases that would be necessary if the retrofit was not installed, assuming a 15-year lifetime, constant (1983\$) energy prices, and a 7% real discount rate. Note, however, that there are regional variations in the prices of gas and electricity, so that the cost-effectiveness of specific projects may be different from that indicated here. Electricity is measured in resource units of 12.1 MJ per kWh.

# SINGLE-FAMILY RETROFIT PROJECTS

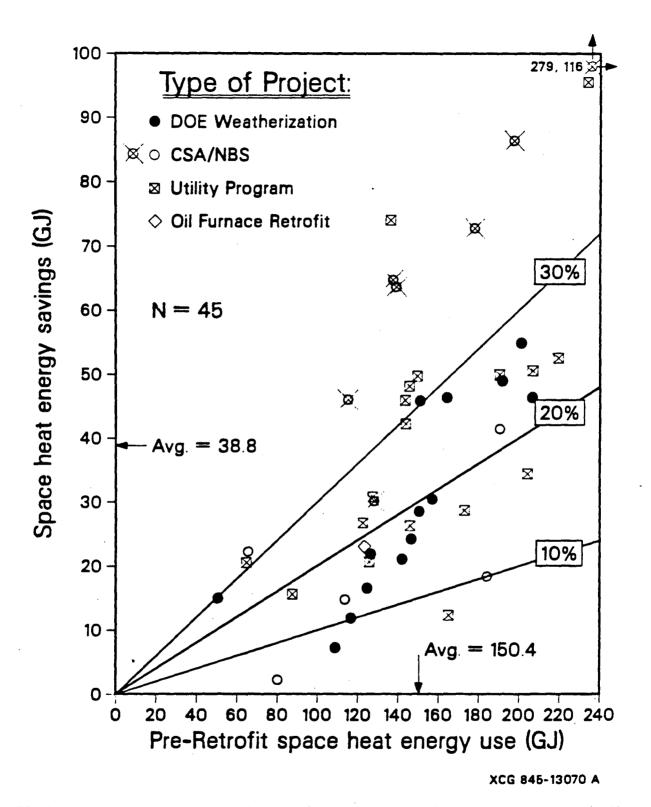

Fig. 3. Annual space heat energy savings as a function of pre-retrofit space heat energy use in 45 single-family retrofit projects. Electricity use is expressed in terms of site energy, 3.6 MJ per kWh (3413 Btu per kWh).

# **RETROFIT RESEARCH STUDIES**

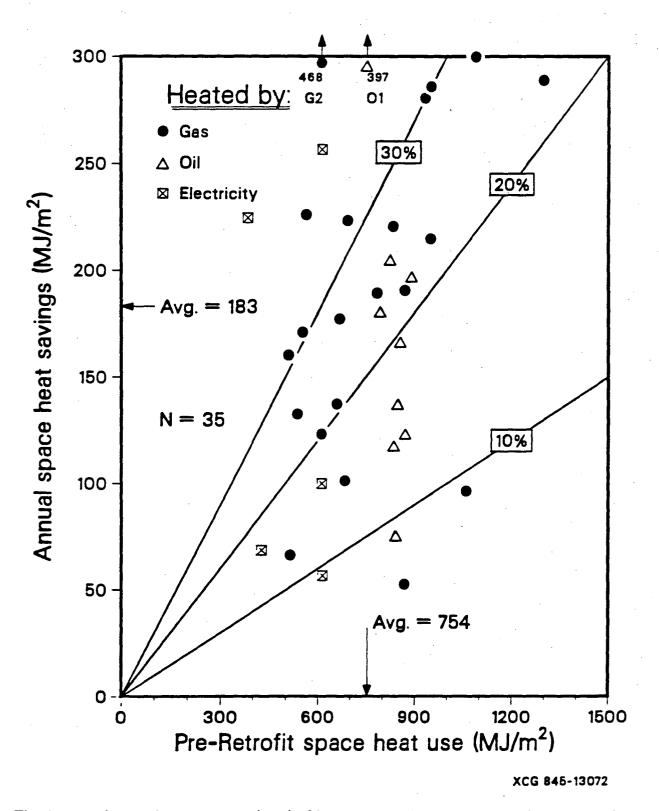

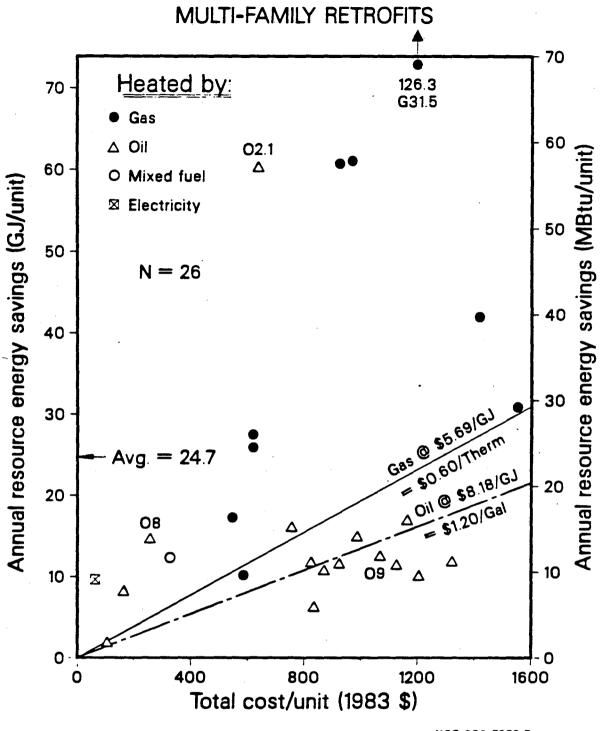

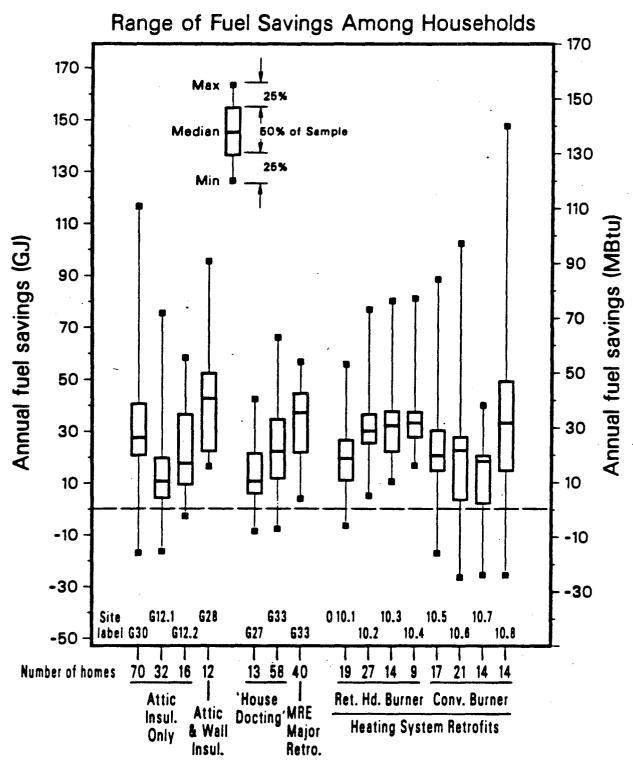

Fig. 4. Annual space heat energy savings in 35 research studies are plotted against pre-retrofit space heat consumption. Usage has been normalized by household floor area. Electricity use is expressed in terms of site energy (3.6 MJ per kWh).

XCG 839-7232 B

Fig. 5. Annual resource energy savings are compared to the total cost of the retrofit investment in 26 multi-unit buildings. Savings and costs are divided by the number of apartment units in that building. In most cases, the savings apply to space heat only, except for five buildings where the retrofit addressed both space heat and domestic hot water usage. In those five cases, we plot the combined savings. Estimated annual maintenance costs are included in the total cost. Price reference lines are defined as in Fig. 2. Electricity is measured in resource units of 12.1 MJ per kWh (12.1 MJ=11,500 Btu).

XCG 841-13003 B

1

Fig. 6. Range in annual fuel savings among households installing similar measures. In most cases, the savings apply to space heat only, except for the heating system retrofits and the "house-doctor" experiments where consumption includes all end-uses of the space heating fuel.

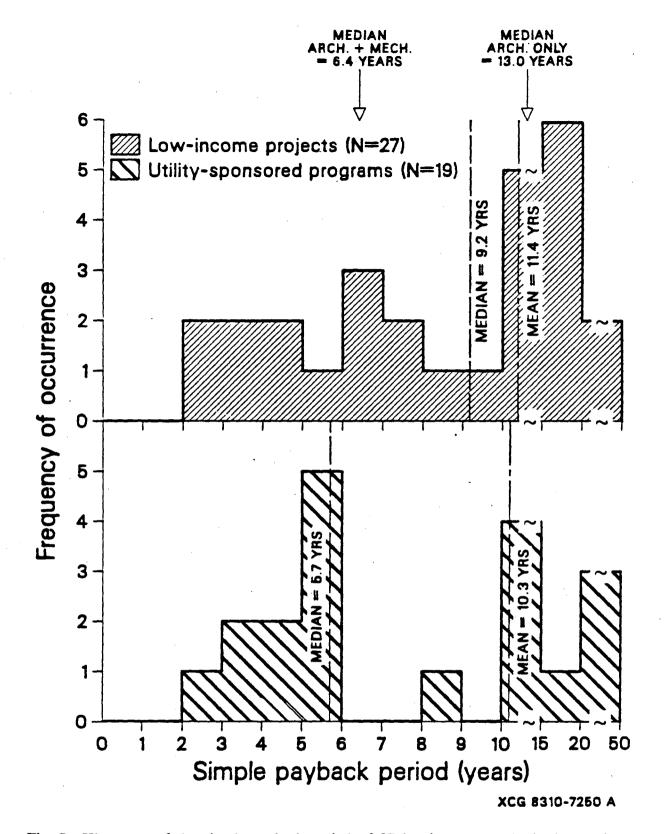

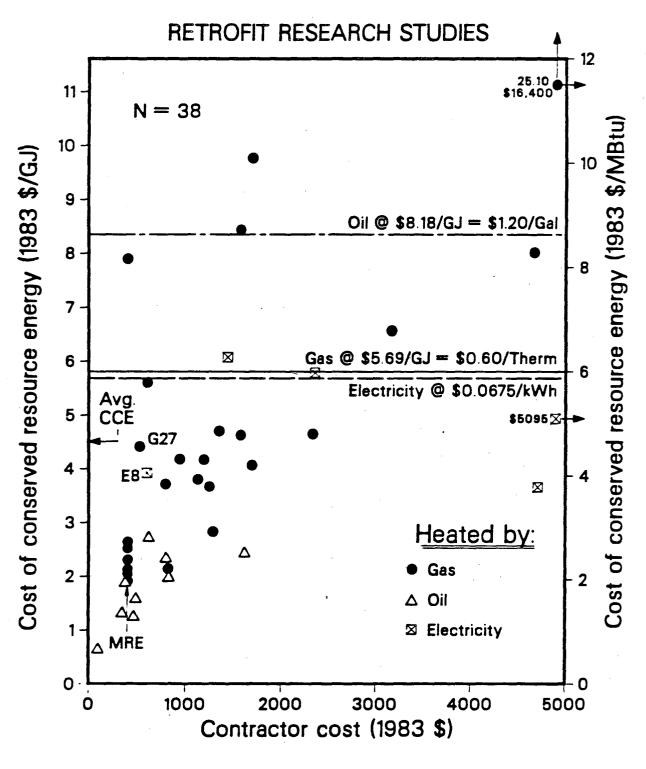

Fig. 7. Histogram of the simple payback period of 27 low-income weatherization projects (represents approximately 850 homes) and 19 utility-sponsored conservation programs (data from 43,730 homes).

XCG 839-7237 C

Fig. 8. The cost of conserved energy as a function of the contractor cost of the retrofit is shown for 38 research studies. The horizontal lines represent national average prices of purchased energy against which conservation retrofits can be compared. Electricity use is expressed in resource terms (12.1 MJ per kWh).

#### Summary Data Table

Explanatory notes on table headings are discussed below:

A: Label is a project's identification number. An asterisk(\*) indicates a new entry to the data base and a plus (+) denotes substantial revision to a previously entered project. The first letter indicates the principal fuel used for space heating ("G" = natural gas "M" = mixed fuel; heating fuel differed from house to house within a study sample "0" = fuel oil "E" = electricity). The number after the initial letter is a counting index that identifies each retrofit project. The number after the decimal point indicates that groups of homes received different retrofit treatments at a particular site. The letter "A" or "B" at the end of the label signifies an "active" or a blind" control group. Example: "G7.3A" signifies gas-heated homes which are part of an active control group at the 7th site.

**B:** Number of Homes in a retrofit project included in the database. The number of apartment units is indicated for each multi-family building.

E: Retrofit Measures. Two-character code used to identify measures installed. The measure must have been implemented in at least 20 percent of the homes in a project to be listed. The retrofit measure code key is: operations & maintenance (OM), heating system retrofits (HS), HVAC controls (HC), clock thermostats (T), heating system replacement (HR), insulation of walls (IW), attic (IA), or floor (IF), caulking & weatherstripping (CW), infiltration-reduction using diagnostic equipment (PI), window management (WM), water heating (WH) storm doors (DR), and lighting system (LS).

F: Heating Degree-Days. The 30-year average of heating degree-days for the retrofit site(s).

G: Year of Retrofit. The actual year of retrofit or the median year in cases where a large sample of homes was retrofitted over several years.

H: Floor Area. Average floor area for homes in the sample. In multi-family buildings, floor area per apartment unit is indicated. A missing value indicates that floor area was not available.

I: Energy Use Code (EUC) indicates the end uses included in Adjusted Total Energy Use (Col. J). The letter code is: "W" = space heating and domestic hot water heating; "F" = all end uses of the space heating fuel (generally includes water heating, cooking, clothes drying, etc.); "B" = non-space heating consumption (baseload); "L" = lighting. The EUC also indicates the energy savings (Col. J2 or K2) used in the economic calculations; space heating ("H") or total usage (either "F" or W").

J1,J2,J3: Adjusted Total Energy Use. Weather-adjusted annual consumption of the heating fuel. Yearly savings in absolute terms and as a percentage of pre-retrofit consumption are shown. Generally, the heating energy data are combined with other ("baseline") uses of the same fuel. Missing values usually indicate that only space heating consumption was available (e.g. EUC = "H"). The space heat portion of consumption is normalized to the long-term average weather at that site. Units are gigajoules (GJ) for fuel-heat homes and kilowatt-hours (kWh) for electric-heat homes (1 GJ = 0.948 MBtu). Percent savings are calculated by taking the mean consumption before and after retrofit for homes in a retrofit project and calculating percent savings for the group as a whole.

K1,K2 and K3: Adjusted Space Heat Use. The weather-adjusted space heating usage. Yearly savings in absolute terms and as a percentage of pre-retrofit space heating consumption are shown. Percent savings are calculated using the method described in Total Energy Use.

L1 and L2: Heating Factor is derived by dividing average space heat usage by the mean floor area and number of normal year heating degree-days (base 18.3°C) at that site. Electricity used for space heating is converted into site energy and that value is divided by 0.67, the average assumed efficiency of existing gas or oil systems (i.e., 3.6 MJ/0.67 or 5.4 MJ per kWh). This adjustment is made to account for the higher site efficiency of electric heating systems, thus

allowing rough comparisons of building shell performance between homes heated with gas and electricity.  $[KJ/m^2-DD_{C} \times 0.049 = Btu/ft^2-DD_{F}]$ 

M: Retrofit Cost. The average first-cost of retrofit (1983\$).

N: Simple Payback Time (SPT) in years.

O: Cost of Conserved Energy (CCE). In calculating the capital recovery rate, a real discount rate of 7 percent is used. Retrofit lifetime estimates (in parentheses) for various measures and programs are: attic insulation only (20), storm windows (15), caulking & weatherstripping (5), measures associated with 'house-doctor' treatment (10), storm doors (10), insulating blanket on hot water heater (10), thermostatic radiator valve (10), heating system improvements (15-20), energy management control system (10), lighting system changes (10), DOE and CSA/NBS low-income weatherization programs (15), utility-sponsored conservation programs (20). Units for CCE are \$/GJ for fuel-heated homes and cents/kwh for electric-heat homes.

**P:** Net Present Value (NPV) of energy savings. Assumptions used in the NPV calculation include: 7% real discount rate; 4% real energy price escalation rate; 15% federal tax credit; expected retrofit lifetime (see Column O); salvage value and maintenance costs for single-family retrofit projects are assumed to be zero; estimated annual maintenance cost depends on measure in multi-unit buildings.

Q: Internal Rate of Return (IRR). Assumptions are the same as for NPV (except that the discount rate is not specified).

**R:** Confidence Level. Assessment of overall reliability of results from a particular retrofit project. Criteria used in ranking are explained below:

- A = high confidence in the data. Consumption data for each house analyzed using linear regression model with variable reference temperature or sub-metered data was collected. Retrofit costs are also well-documented. Often, total costs are itemized by measure or divided into material and labor costs. The experimental design includes a control group.
- B = medium high confidence. Consumption data analyzed using a regression model with reference temperature fixed at 65°F. Baseload usage is determined from the summer months fuel bills. Space heating usage is scaled by the ratio of normal to actual heating degreedays (base 18.3°C) at that site. Retrofit costs are fairly well documented. In some cases, a control group is employed.
- C = average confidence. Often, only annual consumption data are available for each house and no weather or baseload corrections have been made by the original authors. A simplified baseload subtraction is made using either summer months fuel bills or regional estimates Retrofit cost data are barely adequate, in some cases consisting of only materials cost and labor hours.
- D = low confidence. Energy consumption data used in the project evaluation are of poor quality. Retrofit measures and costs are often not indicated. Evaluation methodology is not explained.
- F = no confidence. Very crude data with much missing information. Major flaws exist in the data, e.g., metered consumption data were not collected.
- I = data are incomplete.

(No "F"-level data are included in this study. "D"-level data are shown in the summary data table but are not included in the figures.)
