Abstract

α-crystallins are small heat-shock proteins that act as holdase chaperones. In humans, αA is expressed only in the eye lens, while αB is found in many tissues. α-crystallins have a central domain flanked by flexible extensions and form dynamic, heterogenous oligomers. Structural models show that both the C- and N- terminal extensions are important for controlling oligomerization through domain-swapping. α-crystallin prevents aggregation of damaged $\beta\gamma$-crystallins by binding to the client protein using a variety of binding modes. α-crystallin chaperone activity can be compromised by mutation or post-translational modifications, leading to protein aggregation and cataract. Because of their high solubility and their ability to form large, functional oligomers, α-crystallins are particularly amenable to structure determination by solid-state NMR and solution NMR, as well as cryo-EM.

Keywords

α-crystallin; protein solubility; vertebrate lens protein; molecular chaperone; protein oligomer; intermolecular interactions

1. INTRODUCTION

For the eye lens to function correctly, it must be transparent and refract visible light strongly enough to form an image on the retina. The bulk of this unique tissue is made of layers of densely packed fiber cells filled with very stable proteins called crystallins. Crystallins comprise over 90% of the dry weight of the human eye lens (1). These proteins exhibit a higher refractive index than average proteins, and their refractive power is not a simple function of the amino acid sequence (2). During development, all organelles in fiber cell are degraded to minimize light scattering, leaving these cells without the machinery needed to synthesize new proteins. Thus, the crystallin proteins that are made during development remain soluble under crowded conditions for decades, and are used by the organism

throughout its life. Crystallin proteins exist at very high concentrations in the lens, up to 400 mg/mL in humans (3), and even higher, over 1000 mg/mL in some aquatic species (4). If these proteins aggregate, the light-scattering aggregate formed is called a cataract, the most common cause of blindness (5). To understand how the eye lens works is to understand the physicochemical properties of crystallins, including the molecular basis of their extraordinary solubility, the relationship between sequence and structure, how protein-protein interactions are mediated under conditions of extreme macromolecular crowding, and what happens when this system fails, resulting in cataract.

The study of lens crystallins tracks with the beginning of modern chemistry. In 1830, Berzelius isolated a gelatinous substance from the eye lens that he called crystallin because of its transparency (6). This material was then further fractionated to show that it was in fact made up of more than one substance (7), but it was not until 1894 that the individual protein components were isolated and named a-crystallin and β-crystallin by Mörner (8). Since then great strides have been made in understanding the structure and function of these proteins. The crystallins themselves are categorized into three broad categories in the human lens, the a-, β-, and γ-crystallins. In addition to these ubiquitous vertebrate crystallins, many more taxon-specific crystallins exist in other organisms, but these are beyond the scope of this review. The a-crystallins are chaperone proteins that belong to the small heat-shock protein family (9), while the β- and γ- crystallins are a part of an evolutionarily distinct superfamily of proteins called the $\beta\gamma$-crystallin superfamily (10); they are mentioned here because they are the most common client proteins for a-crystallins in the lens. This review will discuss some history and recent advances in understanding the physical chemistry underpinnings of the unique and extraordinary properties of a-crystallins, with a particular focus on comparisons between human and fish crystallins. We discuss a-crystallin structures, their complex and dynamic oligomerization states, and most importantly, the intermolecular interactions by which they bind to damaged structural crystallins and keep them in solution. Finally, the sidebars provide an introduction to several techniques that are used to obtain this information.

2. a-crystallins are small heat-shock proteins

a-crystallins are small heat-shock proteins (sHSPs) that act as holdase chaperones, meaning they maintain the solubility of damaged client proteins, but are unable to refold them (11, 12). While aA-crystallin is primarily expressed in the lens (13), aB-crystallin is expressed in many tissues throughout the body (14, 15), and alterations to its solubility or substrate binding competence are implicated in a variety of diseases (16). Many studies of a-crystallin function have been performed using zebrafish as a model organism, as the vertebrate crystallin functions (17) and expression patterns (18) are strongly conserved. Furthermore, zebrafish embryos have the advantage of being transparent, enabling detailed studies of the developing lens (19). Mouse a-crystallin promoters were found to drive GFP expression in several organs in the zebrafish, including the lens, notochord, heart, and skeletal muscle, indicating that mammalian a-crystallin promoter activity can also be screened in this model organism (20). In zebrafish, knocking out aB-crystallin causes both lens defects and reduced cardiac stress tolerance (21), while aA was found to have the same function in the lens as it does in other vertebrates (22).

As in other sSHPs, a-crystallins have a β-sheet rich a-crystallin domain flanked by flexible N-terminal and C-terminal extensions (23). A schematic view is shown in Figure 1. The a-crystallin domain is main active part of the protein, containing the region that is responsible for substrate binding; in fact, relatively short peptides from this region, the mini-a-crystallins, display substantial chaperone activity on their own (24, 25). However, the tails also play important roles in controlling the activity, oligomeric state, and substrate recognition (26, 27), as illustrated by the different binding surfaces, corresponding to different sequence regions, that recognize amorphous aggregates and amyloid fibrils (28). Structures of truncated a-crystallins show the primary dimer interface, which is in the middle of an extended β-sheet, but also reveal how the C-terminal extensions can participate in domain-swapping, leading to oligomers of differing sizes (29). The N-terminal extension has also been implicated in binding of specific substrates (28).

3. Polydispersity is central to a-crystallin function

Understanding how a-crystallins recognize client proteins and maintain their structural integrity requires high-resolution structures not only for the monomeric proteins, but also their complexes. a-crystallins exist as polydisperse mixtures of 10–40-mers (30, 31), with the most common species in the range of 24–28 (32). Characterizing the equilibrium of oligomeric states is central to gaining full mechanistic insight into a-crystallin activity: NMR experiments have shown that polyhedra of varying sizes form, providing different environments for client proteins (33). Heterogeneous interactions are observed even in constructs of the isolated a-crystallin domain, as key residues display resonances at more than one chemical shift position, indicating multiple conformations (34). However, the importance of the C- and N-terminal extensions for controlling oligomerization has been demonstrated in several studies. The IPI motif on the C-terminal domain, embedded in the palindromic sequence "ERTIPITRE" can interact bidirectionally with the β4/β8 surface of the a-domain, and these interactions control both the oligomeric state and the ability of the protein to chaperone amyloid clients (35, 36). Peptides mimicking this sequence readily bind to the a-crystallin domain in solution, providing support for the importance of this motif for protein-protein interactions (37). Polydispersity appears to be central to a-crystallin function: not only does the formation of variable oligomers discourage crystallization or other deleterious interactions between the a-crystallin molecules themselves, but the ability of these molecules to self-organize into constantly shifting polyhedra provides a variety of surfaces that are presented to client proteins of differing sizes and shapes.

Solving the structures of a-crystallins in biologically relevant complexes is a challenging endeavor. Their dynamic and polydisperse nature makes them particularly suitable for NMR (38, 39), and in many cases hybrid structural methods are used to integrate information across different length scales. Various combinations of experimental and molecular modeling techniques have been used to model a-crystallin oligomers, sometimes with inconsistent results, possibly reflecting differences in protein constructs or sample preparation methods, or true heterogeneity.

For example, building on solid-state and solution NMR structures of smaller oligomers (40, 41), cryo-EM, solid-state NMR, and small-angle x-ray scattering (SAXS) were used to

generate a model of symmetric aB-crystallin 24-mers (42) (Figure 2A). These oligomers are built using a hierarchical progression where dimers connected by the β-sheet interface assemble via their C-terminal extensions to form hexamers, which in turn associate via their N-terminal regions to create higher-order structures. Another hybrid structure of aB-crystallin 24-mers was generated using a combination of cryo-EM, solid-state NMR, and molecular modeling also came to the conclusion that the building blocks are dimers, which then associate to form hexamers (43). This structure also identifies two different dimer arrangements, consistent with the variable interactions between the palindromic sequence of one monomer and hydrophobic residues of the other observed in the crystal structures (35), but in contrast to solution-state NMR data showing only a single set of chemical shifts, suggesting that all monomers adopt the same conformation (33).

In addition to the most common species, the 24-mers, oligomers ranging from 6-mers to 48-mers have also been observed in solution. These data and the closed, spherical shape of the higher-order oligomers suggest that the highly symmetric complexes may be for storage, whereas the binding-competent species are either smaller complexes (perhaps dimers) or incomplete spheres allowing room for client proteins. Solution NMR indicates that ms-timescale dynamics in the C-terminal extensions regulate the oligomerization state (44). Some details of the dynamic equilibrium among these complexes were revealed using deuteration-assisted small-angle neutron scattering (DA-SANS) in conjunction with electrospray ionization (ESI) native mass spectrometry (nMS): exchange of subunits between complexes was common, however oligomer collapse did not appear to occur, even for a subset of the population (45). Thus, the dynamic quaternary structure of aB-crystallin appears to be mediated by small oligomers dissociating from and re-associating with larger complexes. Other studies have suggested that monomers are present under physiological conditions (46) and have chaperone activity (32), but are compromised from a solubility standpoint (47). Beyond the size of the oligomers, the morphology of the a-crystallin oligomers can also affect chaperone function. a-crystallins can retain function after forming amyloid fibrils or amorphous aggregates, with amyloid fibrils even showing enhanced affinity for particular clients (48).

The first structural models of the lens-specific chaperone aA-crystallin in 12-, 16- and 20-mers were generated recently using a combination of cryo-EM, mass spectrometry with cross-linking, NMR spectroscopy, and molecular modeling (49)(Figure 2B). This model suggests that for aA-crystallin, the building block for oligomerization is a tetramer. As in the case of aB-crystallin, the exact extent of oligomerization is governed in part by the extent of C-terminal domain swapping (50, 51, 52), although the N-terminus is also involved in oligomerization, as its truncation shifts the equilibrium to favor smaller oligomers (53, 54). Domain-swapped oligomers are found in multimers larger than 12, whereas the dodecameric species can form without any interactions with the C-terminus (49). These results are consistent with earlier crystal structures of truncated versions of vertebrate aA-crystallins that showed conformations both with (29) and without domain-swapping (55). Recently, an alternative splicing variant of human aA-crystallin with a truncated N-terminal sequence was discovered. On its own, this isoform has only weak chaperone activity and makes only small oligomers, but it is capable of integrating into larger oligomers of the more common canonical variant, modulating oligomer size and chaperone activity (56). In

contrast, an alternative splicing variant found in rodents (αA^{ins}) has a longer N-terminal domain, and has enhanced activity relative to the standard isoform (57)

4.   Cataract-related α-crystallin variants can be aggregation-prone or have altered chaperone activity

Many cataract-associated variants of α-crystallins feature an altered α-domain, which results in structural changes and/or compromised chaperone activity. The αB-R69C and D109H variants are implicated in human disease, including cataract (58, 59). Both cause considerable structural changes, reduced chaperone activity, and increased aggregation propensity *in vitro* (60). The D109H variant is particularly disruptive, probably because the loss of the negative charge at position 109 disrupts a critical salt bridge that is required for proper formation of the anti-parallel sheet dimer interface, as does the R120G variant (61). The R12C variant of αA-crystallin is more prone to aggregation than WT, especially in the presence of calcium ions (62). Both the αA-G98R and αA-R21Q variants show decreased function, but when mutated together to make an αA-G98R/R12Q double variant, compensating for the difference in charge, much of the function and stability of the protein is rescued (63).

In other cases, the major driving force of cataract formation is how mutations in α-crystallin affect the aggregation of other proteins. For example, the R49C and R116C variants of αA-crystallin have differing affinities for the aggregation-prone client protein I4F γD-crystallin (64). The higher affinity R49C variant results in increased aggregation of γD-I4F, possibly through simple mass action, as the folded form is sequestered by the chaperone protein, thus pushing the equilibrium toward formation of the denatured form (64). In mouse models, knocking out αA and αB-crystallin leads to increased abundance and cross-linking of βB2-crystallin (65) the αB-R120G and the αA-R49C variants lead to decreased protein degradation in the lens during development (66), which may lead to an increased propensity for cataract formation, or alternatively might be an effect of cataract formation. However, not all mutations are deleterious; for example the R12C variant of αB-crystallin exhibits increased chaperone activity in addition to changes in the oligomeric state of the protein with increased population of a dimer form that is favored as a result of a disulfide bond (67). This variant also resists thermal and calcium-induced aggregation compared to WT. However, when exposed to calcium ions the chaperone activity of the variant is decreased, potentially due to structural changes, as the R12C variant shows altered chemical environments of its tryptophan residues, suggesting partial unfolding (67).

5. α-crystallins bind divalent cations, with complex effects on their function

Human αB-crystallin binds one equivalent of Cu^{2+}, and its chaperone activity is enhanced by this interaction (68, 69, 70). αB is able to prevent aggregation and co-precipitation of Cu^{2+} and human γD at all Cu^{2+}:γD ratios, suggesting that αB is acting as a chaperone rather than a chelator in this situation (71). However, there is also evidence of metal ion homeostasis through sequestration. Increasing the amount of α-crystallin bound to the client

protein γD, which would occur naturally with age, results in an increase in free iron and calcium ions (72), which would increase the susceptibility of the eye lens to oxidation. Schiff bases and rutin, a naturally occurring flavonoid, were shown to inhibit copper-induced aggregation of human γD and promote the chaperone activity of aB, suggesting a possible role as a cataract therapeutic (73, 74).

In the case of Zn^{2+}, aB-crystallin was again able to prevent metal ion-induced aggregation, but here it appears to act as a chelator rather than a chaperone, because higher concentrations of Zn^{2+} were still able to cause aggregation (75). Zinc ions mitigated diabetic cataract in mouse models due to their antioxidant properties and positive interactions with a-crystallin (76, 77, 78). Zn^{2+} interactions with a-crystallin do not restructure the protein's secondary or tertiary arrangement, but they do increase its surface hydrophobicity, thereby enhancing the chaperone activity (76). In human lens epithelial cells, treatment with Cd^{2+} or Cu^{2+} promoted the expression of aB-crystallin, whereas Cu^{2+} promoted the expression of aA-crystallin (79).

6. a-crystallin post-translational modifications can cause age-related cataract

The majority of cases of cataract are caused by aging: most people are born with healthy lens proteins, which accumulate post-translational modifications (PTMs) over time, leading to cataract (80, 81). UV irradiation is associated with the formation of cataract (82). In aA-crystallin, UV damage leads to increased hydrophobic exposure, secondary structure changes, and diminished chaperone activity (83). Backbone cleavage can lead to the accumulation of insoluble peptides in the lens, providing nucleation sites for the growth of aggregates. For example, a 15-residue peptide derived from aA-crystallin aggregates in aging lenses, recruiting full-length protein and forming β-sheet rich fibril structures (84).

One of the most common PTMs in the lens is isomerization (85), which is difficult to detect because it does not change the protein mass. Serine and aspartic acid can epimerize to form their D-counterparts, and Asp can also convert to L- or D-isoAsp (86). These modifications can alter the protein structure, sometimes causing disruption that goes beyond the mutation site (87). In the eye lens, Asp isomerization increases with age, with aA-crystallin being more susceptible to isomerization than aB-crystallin (88). Isomerization in aA changes the relative populations of different oligomers (89) In aB, isomerization of Asp109 disrupts a critical salt bridge at the dimer interface, negatively impacting its solubility, while epimerization of Ser162 significantly weakens the dimerization interface between the palindromic sequence and the β4-β8 groove (90). Glycation, particularly of lysine side chains, can also occur in the crystallins, linking cataract and diabetes (91). In mice, L-lysine treatment has been shown to reduce glycation in a-crystallin after treatment with glucose (92). PTMs have even been shown to enhance a-crystallin activity. Acetylation of lysine residues have been linked to higher hydrophobic exposure and increased chaperone activity in a-crystallin (93). Recently, the link between the aA-crystallin oxidation state and oligomerization and function has been characterized. When aA-crystallin is oxidized, a destabilizing disulfide bond is formed, dispersing higher-order oligomers (49).

Another important post-translational modification that impacts the regulation of protein function is phosphorylation, which happens to a-crystallins under stress conditions. In aB-crystallin, phosophorylation occurs in a heterogenous manner, with mixed populations of proteins phosphorylated at different sites. Overall phosphorylation efficiency is low, due to the inability of kinases to act on monomers that are part of a large complex; phosphorylation appears to happen during subunit exchange (94). Phosphorylation of aB-crystallin is mostly localized to three serine residues: 19, 45, and 59 (95, 96). When these sites are phosphorylated, aB-crystallin forms smaller oligomeric complexes, and shows preferential binding to different client proteins (97). An aB-crystallin variant mimicking hyperphosphorylation of these residues showed increased chaperone function relative to wild-type, using insulin as a client (98). Low levels of phosphorylation appear to improve chaperone activity and reduce aggregation propensity, whereas hyperphosphorylation, which sometimes happens to variant proteins *in vivo*, leads to increased aggregation (99). Consistent with this observation, extensive phosphorylation at S45 resulted in uncontrolled aggregation in vitro (100). Epimerization and phosphorylation can also interact to alter the protein's behavior: phosphorylation of Ser59, is precluded by epimerization of this residue, and reduced by the isomerization of the nearby residue Asp62 (90). Despite the many advances in understanding a-crystallin function since Horwitz first discovered its molecular chaperone properties, studies such as these underscore the importance of recognizing that a-crystallins may behave differently in dilute, homogenous solutions than they do in the messy, crowded environment of the cell (101).

7. Client-chaperone interactions

Recognition of misfolded, partially unfolded, or otherwise solubility-compromised proteins is central to a-crystallin function. Although the exact mechanisms of client recognition are not yet fully understood, the size, charge, size, and exposed hydrophobic surface of the client protein all appear to play a role (102). All-atom molecular dynamics (MD) simulations were used to probe the interactions of monomers and oligomers of a small peptide implicated in Alzheimer's disease-related plaques ($A\beta_{17-42}$) with an aB-crystallin ACD dimer. The dimer bound more strongly to oligomers of $A\beta_{17-42}$ relative to monomers, as each peptide has only limited number of contacts with the ACD dimer, resulting in weak and transient interactions. However, oligomer formation locks the peptides into a more rigid conformation, resulting in a larger interaction surface (103). Particular residues in aA, such as D69 (104) and F71 (105) have all been proposed as being critical to chaperone activity, as have the C-terminal (106) and N-terminal tails (107). An important step in understanding what governs these protein-protein interactions was the discovery of small peptides derived from the a-crystallin domain that are active as chaperones. For example, the peptide "KFVIFLDVKHFSPEDLTVK" from aA-crystallin has chaperone activity and was thus named mini-aA-crystallin (108). In aB-crystallin a similar peptide, "DRFSVNLD-VKHFSPEELKVK" was identified, and has been called mini-aB-crystallin (see Figure 1B) (109). The discovery of these peptides has allowed for more focused probing of the molecular mechanism of the client-chaperone interaction involving the a-crystallin domain.

A common finding when investigating a-crystallin binding interactions is the importance of hydrophobic interactions. Mini aA-crystallin is notably hydrophobic, and its confirmed site

of interaction with human γD-crystallin specifically involves several hydrophobic residues (110). In human γD-crystallin, both the I4F and V76D variants stabilize an aggregation-prone intermediate, leading to early onset cataract. However aB-crystallin does not recognize either of these variants, whereas it does bind the I4F/V76D double variant (111), suggesting that a minimum amount of unfolding is needed to trigger a-crystallin activity. More evidence that full-length aB-crystallin can select between native-like and strongly aggregation-prone proteins with very similar, folded structures is provided by the difference between aB-crystallin's robust binding to the G18V variant of human γS-crystallin, but not the G18A variant, which is likewise thermally destabilized, albeit to a lesser extent (112). Similarly, hydrophobic residues in melittin mediate the interaction of full-length aA-crystallin with this peptide (113). Although hydrophobic interactions are clearly important, there is also more to the story. In aB-crystallin alone there are at least 13 peptide sequences related to chaperone activity (114), and each of these could reveal unique mechanisms that explain aB-crystallin's prodigious ability to chaperone diverse client proteins. A schematic illustrating the general binding modes is given in Figure 3A; Figure 3B shows the location of the mini-aA peptide and several other key residues on the a-crystallin monomer.

One area of current interest is how a-crystallin interacts with UV-damaged client proteins. Current work has shown that a-crystallin forms very large complexes when binding β_L-crystallin, and that the size of the complex is positively correlated with the content of UV-damaged protein (115). High-resolution structural studies are needed to resolve the details of these complexes. So far studies have all mostly focused on the role and mechanism of the a-crystallin domain, but the N- and C- terminal extensions are also important, possibly for initial client recognition (116), in addition to their role in mediating oligomerization.

7.1. Species-specific adaptations

a-crystallins have species-specific adaptations that enable them to recognize particular client proteins: bovine a-crystallin effectively protects cow γ-crystallins from aggregation, while failing to interact with structural crystallins from the Antarctic toothfish, and even a-crystallins from the bigeye tuna only partially protected toothfish γ-crystallins under heat stress conditions (117). The cold adaptations required for the lifestyle of the Antarctic toothfish, which lives at a temperature of −2°C year-round provide some clues to this exquisite specificity. Like humans, the toothfish has two a-crystallin paralogs, aA and aB, although its lens protein mixture is more complicated due to the much larger number of γ-crystallin paralogs (118). Sequence comparison shows that a-crystallins from cold-adapted fish have more hydrophobic residues than their warm-water counterparts, and mutating key residues in zebrafish aA-crystallin with their counterparts in the toothfish protein altered surface hydrophobicity (measured using bis-ANS binding), oligomerization, and chaperone activity (119). Unlike humans and toothfish, zebrafish have two aB-crystallins, aBa and aBb (120). aBb is the more similar to human aB, whereas aBa has unusual oligomerization behavior and superior chaperone activity against a panel of destabilized T4 lysozyme variants (57).

7.2. Human a-crystallin chaperone activity as as a biomedical and therapeutic target

An important reason for studying the molecular mechanisms of a-crystallin chaperone action and aggregation is the long-term goal of using this information in a therapeutic context. a-crystallin itself is potentially useful as a therapeutic agent against protein deposition diseases, particularly the a-crystallin domain and component peptides. The a-crystallin domain binds to, and prevents the fibrillization of $A\beta_{1-42}$ (121), a protein found in amyloid plaques in Alzheimer's disease. The ability of a-crystallin to bind amyloid fibrils in a therapeutic context has also been examined in the context of Multiple Sclerosis (MS). MS symptoms are linked to the formation of amyloid fibrils of fibronectin, contributing to the formation of an MS lesion, so maintaining the solubility of these proteins could lead to an effective treatment for MS. In a clinical trial, doses of aB-crystallin were shown to reduce the number of MS lesions by 76% over a 9 month period (122). Delivery remains a problem with this approach: it is difficult to get a-crystallin into the cell efficiently. aB-crystallin can be fused to the glycoprotein C cell penetrating peptide, followed by stimulation of cell uptake by applying heparan sulfate (123).

Of course a-crystallin is also associated with disease states, and so it is itself a target for therapeutics. Attempts at treating a-crystallin associated cataract typically focus on resolubilizing the protein, as protein turnover in the lens is negligible so degradation in not a viable option. Aspirin nanorods have shown effectiveness in maintaining a-crystallin solubility *in vitro*, allowing for the possibility of an aspirin-based cataract treatment (124). Mouse models of hereditary and age-related cataract have been successfully treated with small molecules, with one compound in particular, 29, 5-cholesten-3b,25-diol, improving the solubility of a-crystallin by 63% (125). RNA aptamers can act as molecular switches to control the activity of the targeted proteins. RNA aptamers have been developed that bind specifically to aB-crystallin while not targeting the very similar aA-crystallin (126). This work marks an important first step toward selectively and specifically controlling the activity of aB-crystallin.

8. Conclusion and outlook

We have presented an overview of the current state of knowledge of the molecular mechanisms of a-crystallin oligomerization and chaperone activity. Much of this information has come from combinations of complementary methodologies, notably solid-state and solution NMR with cryo-EM. Future progress toward understanding native a-crystallin oligomers and their interactions with client proteins will require advanced biomolecular simulations. MD simulations provide a detailed picture of how proteins move, leading to insights into protein folding, enzyme activity, and solvent interactions (127, 128). MD is also an integral part of the process of refining macromolecular structures based on X-ray crystallographic (129) and NMR (130) data. MD simulations are often performed using a detailed structural model containing all the atoms in the protein as well as atomically detailed solvent molecules, although coarse-grained approaches and implicit solvent treatments are also available. Monte Carlo simulations can be used to study the equilibrium behavior of a wide range of physical systems. In this method, the system starts in an arbitrary configuration, and a perturbation is applied. Depending on whether the new

configuration is lower or higher in energy, the move is accepted or rejected (131), and a wide range of thermodynamic properties can then be explored. In the context of systems containing many proteins, rigid-body models are often used to reduce the computational cost (132). Multiconformation Monte Carlo simulations can reintroduce some conformational complexity at low additional cost by using a library of predetermined protein conformations (133). For systems that are characterized by complex interactions among a large number of monomers, another alternative to computationally expensive all-atom simulations is the network Hamiltonian dynamics approach, a coarse-grained method in which a network Hamiltonian is written strictly in terms of connectivity among the protein monomers, eliding the molecular-level details. The properties being simulated are therefore characteristic of the entire system rather than of the structural details of any particular protein, allowing long-timescale simulation of systems comprising hundreds to thousands of monomers. This approach has been used to recapitulate all known types of amyloid fibrils observed in the Protein Data Bank (134) and to model the formation kinetics of several different fibrillization pathways (135). It may also provide a modeling framework for understanding α-crystallin oligomerization and the dynamic equilibrium among oligomers of different sizes, even before detailed all-atom simulations for the full system can be obtained. α-Crystallin forms complex, heterogeneous oligomers that are built up in a modular fashion based on domain-swapping interactions with its N- and C-terminal extensions. The full picture of α-crystallin chaperone behavior is very complicated, with different parts of the chaperone contact- ing its aggregation-prone substrate depending on specific properties of the client. A clear future direction in this area is the continued exploration of α-crystallin interactions with a greater variety of misfolded or destabilized proteins, as the full range of α-crystallin activity has probably not yet been characterized. Many different client protein modifications have been observed, ranging from amino acid substitutions to PTMs such as phosphorylation and isomerization. A pattern that emerges from all of these studies is that there are multiple pathways for aggregation depending on the nature of the modification. As these aggregates are formed by different mechanisms and may have different physicochemical properties, pharmaceutical interventions for medical conditions caused by these modifications will require either tailored treatments or a general solution that encompasses all of the α-crystallin functionalities observed in nature. In contrast, understanding α-crystallin properties and crystallin–crystallin interactions can also lead to improved designs for artificial lenses that more closely mimic the functionality of the biological lens.

8.1. Sidebars and Margin Notes

CRYO-EM—A major advantage of cryo-EM is that it enables structure determination of large complexes, even for proteins that resist crystallization. Smaller proteins are problematic as the current theoretical limit for high resolution cryo-EM structures is thought to be 38 kDa for single particles (136), any smaller and the noise overcomes the signal. The basic principle involves freezing a protein sample in vitreous ice. Then, the sample is bombarded with electrons and an image is generated of separated single particles of the protein or complex of interest. The individual particles are then classified based on the orientation of the sample by a computer. Each class is then averaged to generate a sharp image of that orientation. By combining all the different orientations, a 3-D model can be

generated. For success with this technique, a few things are required: 1. Particles in the sample must be identical for the class averages to generate a sharp image. 2. Particles in the sample must take many different orientations, because a bias towards a certain orientations will lead to lower resolution for the less well-represented orientations.

SOLUTION-STATE NMR—Because the solubility of the crystallin proteins is so central to their function, solution-state NMR is a natural choice for solving structures of these proteins under native-like conditions. NMR makes use of the nuclear magnetic moment of atoms that have an odd number of protons or neutrons (137, 138, 139). When placed in an external magnetic field, the magnetic moment of the nucleus will precess about the external magnetic field at a characteristic frequency that is influenced by the unique magnetic environment around that atom. This includes the local magnetic fields produced by electrons in the chemical bonds as well as other nearby atoms, a phenomenon known as the chemical shift. Here, obtaining a high-resolution spectrum depends on the rapid, isotropic tumbling of the molecules of interest relative to the timescale of the experiment. This is the case for relatively small proteins (up to about 30 kDa), although specialized pulse sequences and labeling schemes can be used to extend the size range of solution-state NMR to much larger proteins or complexes (140, 141).

NMR ASSIGNMENTS AND STRUCTURE DETERMINATION—For small organic molecules, assigning each chemical shift to the atom that gives rise to it is relatively straightforward, but this is a daunting task for a protein, which has thousands of atoms. Nonetheless, the first stage in the structure determination process is to obtain a characteristic frequency for every ^{1}H, ^{13}C, and ^{15}N in the protein. This process is greatly facilitated by using recombinant expression, inducing bacteria, yeast, or cell cultures to produce isotopically labeled proteins in sufficient quantities for NMR. Protein samples can be uniformly labeled with ^{13}C and ^{15}N, can be fully or partially deuterated, or can incorporate more specialized labeling schemes (142, 143, 144). In addition to increasing sensitivity, isotopic enrichment is crucial because it enables multidimensional experiments (145) in which two or more correlated Fourier dimensions reveal connectivity along the protein backbone (146). After the assignments are complete, pairs of intermolecular distances are measured, either indirectly via cross-relaxation effects (147), or directly through dipolar couplings in a partially oriented sample (148). These distance restraints, along with other parameters derived from the chemical shift and the protein sequence (149), are used to constrain a molecular dynamics simulation to obtain the final structure (150, 151).

SOLID-STATE NMR—Despite its utility for studying the structure and dynamics of small, soluble proteins, an obvious limitation of solution-state NMR is that the molecules of interest must be dispersed through the sample and rotating freely. For large or insoluble protein complexes, solid-state NMR is a better choice. Here, anisotropic interactions, such as chemical shift anisotropy and dipolar coupling are not averaged out. These interactions contain valuable orientational information, but the broadening they impose on the spectra present a challenge. A static solid-state NMR spectrum can be described by a "powder pattern," which is very broad for each equivalent atom as the chemical shift, for example, can vary greatly in different orientations. In principle, fitting each powder pattern provides a

wealth of detailed orientational information, however this becomes infeasible for even relatively small spin systems.

In solution NMR, anisotropic interactions are averaged to zero by the free rotation of molecules in solution. In solid-state NMR, it is possible to mimic this rotation by mechanically rotating the sample at the magic angle, 54.74° relative to the external magnetic field (152). The speed of rotation is chosen based on the instrumentation used as well as the frequency of the interaction to be averaged out; for example a 12 kHz dipolar coupling would require a rotation rate faster than 12 kHz (in practice, radiofrequency decoupling is also used to average this interaction away. Of course, the liquid-like spectra are obtained at the cost of losing the information found in the powder pattern. However, this information can be recovered using a variety of dipolar recoupling methods, including a vast library pulse sequences and switched angle spinning, which uses mechanical reorientation to selectively recover this information. Under magic angle spinning, multidimensional experiments can be used to obtain assignments and distance restraints, as in solution-state NMR (153, 154, 155, 156). Although the practical details and spin transfer pathways are different, the experiments and structure determination algorithms are conceptually very similar.

SUMMARY POINTS

1. Summary point 1. α-crystallins bind to damaged structural proteins and maintain their solubility.

2. Summary point 2. The dynamic and heterogeneous oligomerization state of α-crystallins is critical to their functionality.

3. Summary point 3. Multiple sequence regions and structural features are required for complex formation.

4. Summary point 4. The high solubility and complex oligomerization behavior of these proteins make them particularly amenable to study by NMR and cryo-EM.

FUTURE ISSUES

1. Future issue 1. Although we are beginning to understand how α-crystallin recognizes and solubilizes its client proteins, more molecular-level studies are required to develop a general model for its holdase chaperone activity.

2. Future issue 2. The activity of α-crystallin monomers, dimers, and larger oligomers needs further study to determine what is the most active species, or if different assemblies play different roles.

3. Future issue 3. The physicochemical impact of post-translational modifications under in vivo conditions is only beginning to be understood.

4. Future issue 4. The mini-α-crystallin peptides or even more minimal chaperones derived from them may provide a basis for development of future therapeutics against protein aggregation diseases.
Figure 1. α-crystallin binding to client protein.
(A) The initial recognition of the client protein sometimes occurs at the N- terminal extension of the α-crystallin (116). (B) Mini αA-crystallin contains many hydrophobic residues that bind to the client protein through hydrophobic interactions (110). (C) αA-crystallin tightly binds the client protein, keeping it in solution.
Figure 2.
Oligomeric states of a-crystallins. (A) The Jehle (top) (31, 42) and Braun (bottom, PDB: 2YGD) (43) aB 24mer pseudoatomic models. Homodimers (left) are formed through ACD (yellow) contacts. Dimers combine to form a hexameric species (middle) through NTR (green) and ACD contacts. The C-terminal domain is highlighted in blue. Hexamers combine to form the dominant 24-mer structures (right).
(B) Pseudoatomic models of a 16-mer of wild-type reduced human aA-crystallin(49). Top: aA-crystallin monomers (blue and red) forming the β7-interface dimer. Dimers via interactions between N-terminal extensions, to form z-shaped tetramers that stack to make up the pillars of the hollow oligomer. Bottom: Monomers (red) binding through N-terminal interactions. (C) Cryo-EM density maps from the Electron Microscopy Database (EMD) (49) of the (top) 12-mer (EMD-4895), (middle) 16-mer (EMD-4894), and (bottom) 20-mer (EMD 4896) with three, four, and five-fold symmetry, respectively, from the apical axis

(right). All oligomers are formed from a z-shaped tetrameric building block. Abbreviations: ACD, α-crystallin domain; cryo-EM, cryo-electron microscopy; EMD, Electron Microscopy Database; NTR, N-terminal region; PDB, Protein Data Bank.
Figure 3.

A A schematic of the interaction modes of αB-crystallin with client proteins. There are several different possible paths for client recognition and chaperone activity. Both the N-(green) and C-terminal extensions (blue) can act as site for initial recognition or even as the active holdase region. In the case of initial recognition, the client initially binds the flexible extension and then becomes bound to the α-crystallin domain. The α-crystallin domain itself can also directly interact with client proteins for holdase activity, without intermediate binding. **B**. Many specific residues and sequence regions are implicated in αB-crystallin holdase activity. The mini-αB peptide is highlighted in red, while the other key residues throughout the protein are labeled. These residues are D2, F24, F27 (107), R56 (157), D109 (59), R120(158), R157 (159), K82, K90, K92, K121, K166, K174, K175 (160). Abbreviation: PDB, Protein Data Bank.
