## Supporting Information

**ABSTRACT:** Recent reports on high capacities delivered by Li-excess transition-metal oxide cathodes have triggered intense interest in utilizing reversible oxygen redox for high-energy battery applications. To control oxygen electrochemical activities, fundamental understanding of redox chemistry is essential yet has so far proven challenging. In the present study, micrometer-sized  $\text{Li}_{1.3}\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  single crystals were synthesized for the first time and used as a platform to understand the charge compensation mechanism during Li extraction and insertion. We explicitly demonstrate that the oxidation of  $\text{O}^{2-}$  to  $\text{O}^{n-}$  ( $0 < n < 2$ ) and  $\text{O}_2$  loss from the lattice dominates at 4.5 and 4.7 V, respectively. While both processes occur in the first cycle, only the redox of  $\text{O}^{2-}/\text{O}^{n-}$  participates in the following cycles. The lattice anion redox process triggers irreversible changes in Mn redox, which likely causes the voltage and capacity fade observed on this oxide. Two drastically different redox activity regions, a single-phase behavior involving only  $\text{Mn}^{3+/4+}$  and a two-phase behavior involving  $\text{O}^{2-}/\text{O}^{n-}$  ( $0 \leq n < 2$ ), were found in  $\text{Li}_x\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  ( $0 < x < 1.3$ ). Morphological damage with particle cracking and fracturing was broadly observed when O redox is active, revealing additional challenges in utilizing O redox for high-energy cathode development.

## 1. INTRODUCTION

Lithium-ion batteries (LIBs) have become increasingly important for energy storage in portable electronics, electric vehicles, and stationary application in power grids. Since the discovery of early generations of cathode materials (e.g.,  $\text{LiCoO}_2$  and  $\text{LiMn}_2\text{O}_4$ ) in the 1980s, only a few compounds with other compositions or crystal structures have been reported in the last three decades.<sup>1–3</sup> The conventional wisdom suggests that in O3-type layered oxides, the 3d orbitals of early transition metals (TMs), are partially overlapped with the 2p orbitals of oxygen.<sup>4</sup> As such, only about half of the 3d electrons are available to participate in the redox reaction, which largely limits practical capacity (for example, ~160 mAh/g for  $\text{LiCoO}_2$ ) despite their much higher theoretical capacities. To develop high-energy batteries, cathodes with higher specific capacity (>200 mAh/g) and operating voltage (>4.3 V vs  $\text{Li}^+/\text{Li}$ ) are needed.<sup>1–3</sup>

Recently, approaches to enable high-energy cathodes by utilizing redox reactions of both TM cations and oxygen anions have triggered intense interest.<sup>5–7</sup> One of the most studied examples is the lithium and manganese-rich (LMR) layered

oxides with a general formula of  $\text{Li}_{1+x}\text{Mn}_{1-x-y-z}\text{Ni}_y\text{Co}_z\text{O}_2$ .<sup>8–10</sup> Our recent work showed that, contrary to the common notion of a nanocomposite structure, the oxide has a single monoclinic phase ( $C2/m$ ) with a large number of domains corresponding to different variants.<sup>11</sup> To involve the O 2p electrons in the following electrochemical reactions, the material typically undergoes an initial activation process signaled by a unique charging voltage profile that is much different from those of the subsequent cycles. Recent studies by Luo et al. suggested the formation of  $\text{O}^-$  holes in the intermediates, as evidenced by the progressive growth of a new peak on the O K-edge X-ray absorption spectroscopy (XAS) along with the use of a number of other characterization techniques, including isotopically labeled differential electrochemical mass spectroscopy (DEMS), X-ray absorption near edge structure (XANES), and resonant inelastic X-ray scattering (RIXS).<sup>9</sup> However, this remains controversial as experimental evidence is difficult to

Received: December 1, 2017

Revised: February 9, 2018

Published: February 9, 2018

66 obtain, largely due to their high reactivity toward carbonate-  
67 based electrolyte and/or self-combine to release carbon dioxide  
68 and oxygen gases, respectively. These processes also produce  
69 significant amount of oxide-ion vacancies in the unit cell,  
70 further destabilizing the crystal structure.<sup>12</sup> The activation  
71 process also triggers unfavorable phase transformations,  
72 possibly involving layered  $\rightarrow$  spinel  $\rightarrow$  rock-salt, as the cycling  
73 proceeds, leading to continuous voltage and capacity fades in  
74 the cathode.<sup>12</sup> Various optimization approaches such as  
75 doping,<sup>13,14</sup> surface coating/engineering, and morphology  
76 control<sup>15–18</sup> have been explored as means to mitigate the  
77 degradation, but all were met with limited success.

78 An alternative approach to address the phase instability is to  
79 confine O redox process within a rock-salt structure. This  
80 strategy was rarely used as it is generally believed that  
81 compounds with rock-salt crystal structure lack lithium-ion  
82 conduction pathways and are therefore electrochemically  
83 inactive. In 2003, Shigemura et al. first reported that the Li/  
84 Ti/FeO<sub>2</sub> system can deliver a capacity of ca. 200 mAh/g at a  
85 slow rate of 10 mAh/g.<sup>19,20</sup> Investigation on lithium-ion  
86 conduction pathways in rock-salt Li<sub>1.211</sub>Mo<sub>0.467</sub>Cr<sub>0.3</sub>O<sub>2</sub> was then  
87 reported by Lee et al. in 2014.<sup>21</sup> Using density functional  
88 theory (DFT) calculation, they revealed the percolation of  
89 active diffusion channels in disordered Li-excess materials. In  
90 2015, Yabuuchi et al. reported a new rock-salt  
91 Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> (LNMO) cathode with an impressive  
92 discharge capacity of ca. 300 mAh/g.<sup>22</sup> With the use of soft/  
93 hard X-ray absorption spectroscopy, the authors proposed the  
94 involvement of both Mn<sup>3+/4+</sup> and O<sup>2-/O<sup>-</sup></sup> redox reactions  
95 during charge. However, the detailed charge compensation  
96 mechanism and role of O, particularly the contribution from  
97 oxidation of O<sup>2-</sup> to O<sup>n-</sup> (0 < n < 2) and O loss from the lattice  
98 (in the form of O<sub>2</sub> gas, n = 0), remain unclear. In this study,  
99 well-formed Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> single crystals were synthesized  
100 by a molten-salt method for advanced diagnostic studies. The  
101 use of single crystals allows us to perform additional single-  
102 particle-based studies for systematic comparison of the changes  
103 in crystal structure, chemical state, and microstructure as a  
104 function of lithium content in the sample. The results provide  
105 us important insights on O activities in the oxide sublattice and  
106 how to control/tune them through engineering strategies such  
107 as chemical composition and surface morphology control.

## 2. EXPERIMENTAL SECTION

108 **2.1. Synthesis.** In a typical crystal synthesis procedure,  
109 stoichiometric amounts of Li<sub>2</sub>CO<sub>3</sub>, Nb<sub>2</sub>O<sub>5</sub>, and Mn<sub>2</sub>O<sub>3</sub> precursors  
110 (Sigma-Aldrich, >99%) were milled together with ethanol solvent at  
111 200 rpm for 12 h in a planetary ball mill (RETSCH PM100) using a  
112 zirconia jar with zirconia balls. About 10–15% extra Li<sub>2</sub>CO<sub>3</sub> was used  
113 to compensate Li loss that often occurs during high temperature  
114 heating. The dried powder was further mixed with KCl flux in a molar  
115 ratio of 2.5–5 between the flux and TM precursors (defined as R ratio  
116 hereafter). The obtained mixture was then heated at 950 °C for 12 h in  
117 an Ar atmosphere. A ramp rate of 4 °C/min was used for both heating  
118 and cooling. After the reaction, KCl was dissolved in deionized water,  
119 and the final product was obtained after filtration and thorough  
120 washing with water. Chemical delithiation of Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> was  
121 achieved by reacting the pristine powder with various amounts of 0.1  
122 M nitronium tetrafluoroborate (NO<sub>2</sub>BF<sub>4</sub>) in acetonitrile solution in an  
123 argon filled glovebox (O<sub>2</sub> < 1 ppm and H<sub>2</sub>O < 1 ppm). The reaction  
124 was carried out at room temperature for 1–4 days. The resulting  
125 reaction mixtures were filtered, thoroughly washed with acetonitrile,  
126 and then dried overnight in a vacuum oven.

127 **2.2. Characterization.** Chemical composition of the samples was  
128 determined by an inductively coupled plasma optical emission

spectrometer (ICP-OES 720 Series). Scanning electron microscopy  
(SEM) and energy dispersive X-ray spectroscopy (EDS) images were  
collected on a JEOL JSM-7500F field emission microscope at a 10 kV  
accelerating voltage. Prior to the analysis, the powder samples were  
sputtered with a thin top layer of Au to reduce the charging effect.  
Samples for transmission electron microscopy (TEM) experiments  
were prepared by drop casting a sonicated solution of the crystals in  
anhydrous ethanol onto a carbon coated TEM grid or by sectioning  
using focused ion beam. Selected area electron diffraction (SAED) was  
performed in TEM mode at 300 kV on the sectioned sample, while  
high angle annular dark field (HAADF) imaging was performed on  
dispersed particles in scanning transmission electron microscopy  
(STEM) mode at 120 kV, both using an FEI Titan electron  
microscope.

Phase purity was first analyzed by using laboratory X-ray diffraction  
(XRD) collected on Bruker D2 powder X-ray diffractometer (Cu K $\alpha$ ,  
40 kV, 30 mA). Synchrotron X-ray diffraction patterns were collected  
at ambient temperature at 11-BM at the Advanced Photon Source  
(APS) in Argonne National Laboratory, which operates with a  
monochromatic X-ray of  $\lambda = 0.414$  Å. The scans were collected  
between 0.5° and 50° (2 $\theta$ ) at a step size of 0.0001°. The samples were  
first packed into Kapton capillary tubes before exposing to X-ray for 1  
h. Time-of-flight (TOF) neutron diffraction data were collected at the  
POWGEN diffractometer at the Spallation Neutron Source, Oak  
Ridge National Laboratory. Samples were measured inside the  
vanadium sample cans, and a single bank wave with center wavelengths  
of 1.333 Å (2 h data collection) was used. Monochromatic (1.2 Å)  
neutron diffraction data were obtained using the high resolution  
powder diffractometer at BT1 at National Institute of Standards and  
Technology (NIST) Center for Neutron Research. The refinement of  
the diffraction data was carried out using GSAS/EXPGUI package.<sup>23</sup>

Mn K-edges hard X-ray absorption spectroscopy data were collected  
in transmission mode using a (220) monochromator at SSRL  
beamline 2-2 and 2-3. The crystals were sandwiched between two  
Kapton films for data collection. Higher harmonics in the X-ray beam  
were reduced by detuning the Si (220) monochromator by 50% at the  
Mn edge. Energy calibration was accomplished by using the first  
inflection point at 6539 eV in the spectra of Mn metal foil reference.  
X-ray absorption near edge structure spectra were analyzed by Sam's  
Interface for XAS Package or SIXPACK software, with the  
photoelectron energy origin  $E_0$  determined by the first inflection  
point of the absorption edge jump. Soft X-ray absorption spectroscopy  
measurements were carried out at beamlines 8-2 and 10-1 at SSRL. A  
thin layer of the crystals was spread onto a conductive carbon tape  
which was attached to an aluminum sample holder inside an Ar filled  
glovebox (O<sub>2</sub> < 1 ppm, H<sub>2</sub>O < 1 ppm). Measurements were carried  
out on the 31-pole wiggler beamline 10-1 at SSRL with a ring current  
of 350 mA, a 1000 l mm<sup>-1</sup> spherical grating monochromator with 20  
mm entrance and exit slits, a 0.2 eV energy resolution, and a 1 mm<sup>2</sup>  
beam spot. Data were collected at room temperature under ultrahigh  
vacuum (10<sup>-9</sup> Torr) in a single load using the total electron yield and  
fluorescence yield mode detectors.

**2.3. Electrochemistry.** To prepare the composite electrodes, the  
active material was first ball-milled with acetylene carbon black  
(Denka, 20 wt %) to reduce the particle size and improve its electronic  
conductivity. The mixture was then mixed with acetylene carbon black  
and a polyvinylidene fluoride (PVdF) binder (Kynar 2801) in a 8:1:1  
weight ratio in an NMP solvent. The slurry was spread onto aluminum  
foil and dried overnight at 120 °C under vacuum. Cathode disks with  
an area of 1.6 cm<sup>2</sup> and a typical electrode loading of 2–3 mg cm<sup>-2</sup>  
were cut from the electrode sheets and assembled into 2032-type coin  
cells in an argon-filled glovebox. Lithium foil (Alfa-Aesar) was used as  
counter and reference electrodes, Celgard 2400 polypropylene  
membrane as separators, and 1 M LiPF<sub>6</sub> in 1:1 (v/v) ethylene  
carbonate (EC):diethylene carbonate (DEC) (Novolyte Technologies  
Inc.) as electrolyte. The cells were galvanostatically cycled between 1.5  
and 4.8 V using a VMP3 multichannel potentiostat/galvanostat  
controlled by EC-Lab v10.12 software (BioLogic Science Instru-  
ments). Cyclic voltammetry tests were carried out using the same coin  
cell configuration with Li foil as counter and reference electrodes. The

199 cells were scanned between 1.5 and 4.8 V with a constant scan rate of  
200 5 mV/min. All electrochemical tests were carried out at room  
201 temperature.

202 Differential electrochemical mass spectroscopy measurements were  
203 performed in a customized Swagelok-type cell consisting of a lithium  
204 anode, a liquid electrolyte (1.0 M LiPF<sub>6</sub> in EC/DEC 1:1 v/v), and the  
205 crystal composite as the working positive electrode. The cell was  
206 periodically pulsed with Ar gas at regular intervals to sweep the  
207 evolved gases from the headspace to the mass spectrometer for  
208 analysis. The experimental setup is described in detail elsewhere.<sup>24</sup>  
209 Electrochemical measurements were carried out with a constant  
210 current rate of 25 mA/g between 1.5 and 4.8 V with a rest period of 25  
211 min right after the cells reached the upper or lower cutoff voltages. All  
212 data collection was controlled by a BioLogic SP-300 potentiostat.

### 3. RESULTS AND DISCUSSION

213 **3.1. Synthesis and Characterization of**  
214 **Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> Single Crystals.** Synthesis of polycrystal-  
215 line Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> cathode material was recently carried out  
216 by Yabuuchi et al.<sup>22</sup> The process involved ball-milling  
217 stoichiometric amount of Li<sub>2</sub>CO<sub>3</sub>, Mn<sub>2</sub>O<sub>3</sub>, and Nb<sub>2</sub>O<sub>5</sub>, pressing  
218 the resulting mixture into a pellet, and then heating the pellet in  
219 Ar atmosphere at 900 °C for 24 h. Synthesis of  
220 Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> single crystals, however, has not been  
221 reported in the literature. Here, we adopted a molten-salt  
222 method and systematically varied the synthesis conditions to  
223 obtain phase-pure and discrete Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> single crystals  
224 with uniform morphology and size distribution for the first  
225 time. The following parameters were carefully optimized in our  
226 synthesis: choice of transition-metal precursor salts and flux  
227 salt, the molar ratio between the flux and TM precursors (R  
228 ratio), choice and amount of lithium precursor, heating  
229 temperature and time, and reaction atmosphere. It was found  
230 that the best reaction time and temperature were 12 h and 950  
231 °C, respectively. Li<sub>3</sub>NbO<sub>4</sub> was often obtained as an impurity  
232 when the reaction time was too short or the heating  
233 temperature was below 950 °C. The loss of lithium at elevated  
234 temperature was effectively compensated by using additional  
235 10–15% of the lithium precursor. Various molten salts,  
236 including LiCl, NaCl, KCl, CsCl, KOH, and Li<sub>2</sub>SO<sub>4</sub>, were  
237 used as the flux, but only KCl (mp = 770 °C) led to the  
238 formation of phase-pure samples. The optimized R ratio was  
239 between 2.5 and 5. In addition, the presence of trace O<sub>2</sub> in the  
240 synthesis atmosphere can lead to the formation of Li<sub>2</sub>MnO<sub>3</sub>  
241 and Li<sub>3</sub>NbO<sub>4</sub> impurities.

242 The nominal composition of the as-synthesized oxide was  
243 analyzed by an inductively coupled plasma optical emission  
244 spectrometer, which confirmed the chemical formula of  
245 Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub>. As shown in the scanning electron  
246 microscopy image in Figure 1a and high angle annular dark  
247 field scanning transmission electron microscopy image in  
248 Figure 1b, the particles adopted a large spherical shape with an  
249 average size of ca. 5–8 μm and absence of any grain  
250 boundaries. This suggests that all the facets have similar  
251 thermodynamic stability and grow at a similar rate under  
252 current synthesis conditions. Contrast reversal toward the  
253 center of the particles observed on HAADF STEM images  
254 indicates that the pristine particles are too thick for detailed  
255 analytical electron microscopy. Focused ion beam (FIB) milling  
256 was then used to reduce the thickness and a SAED pattern in  
257 [110] zone axis was taken over an area covering almost entire  
258 single particle (Figure 1c). The pattern matches well with the  
259 one simulated using *Fm* $\bar{3}$ *m* structure with a lattice parameter of  
260 *a* = 4.2 Å (Figure 1d), confirming the single crystal nature of

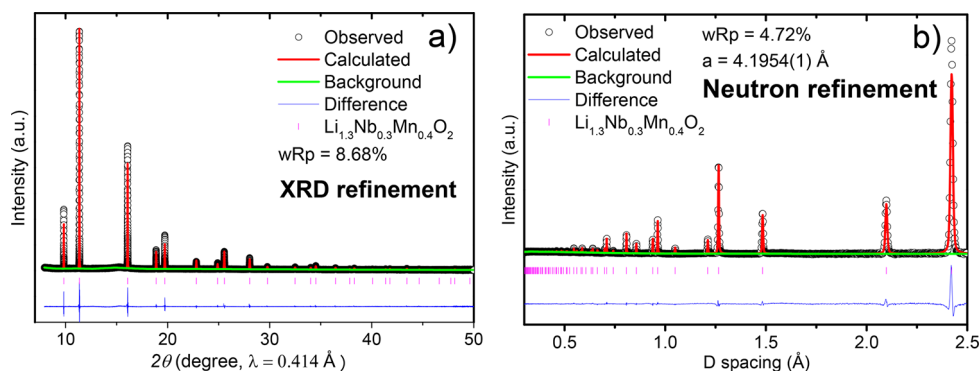

**Figure 1.** Morphology and structure of Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> crystals: (a) secondary electron SEM image, (b) HAADF STEM image, (c) SAED pattern taken in [110] zone axis, and (d) simulated electron diffraction pattern corresponding to panel c.

the particle. It is worth noting that the SAED pattern from this  
particle also shows diffuse scattering effects that are character-  
istic of materials with short-range ordering.<sup>25</sup> At this point, it is  
unclear whether this short-range order occurs broadly in the  
entire sample or if it has any effect on oxide properties and  
behavior. Both of them require further investigation with  
complementary analytical techniques, and the results will be  
reported in a future publication.

Bulk phase purity and crystal structure of the synthesized  
samples were evaluated by using both synchrotron X-ray and  
neutron diffraction studies. Figure 2 shows the Rietveld  
refinement of the diffraction patterns, while Table 1 lists the  
refined structural parameter. In both sets of diffraction patterns,  
the high peak symmetry observed in a wide angular range  
indicates a single phase with high crystallinity. Rietveld  
refinement confirms a rock-salt crystal structure with a lattice  
parameter of 4.1954(1) Å and cell volume of 73.685(1) Å<sup>3</sup>,  
which is in good agreement with the values reported by  
Yabuuchi et al. on polycrystalline samples.<sup>22</sup> All cations (Li, Nb,  
and Mn) were randomly located in the 4a sites, and all M–O  
bonds had the same distance of 2.0965(1) Å, confirming the  
disordered nature of the oxide crystals. The refined occupancies  
agree well with the chemical formula of Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub>.

**3.2. Electrochemical Studies.** The electrochemical  
performance of Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> crystals was evaluated at  
room temperature in a half-cell configuration. Due to high  
resistance and poor utilization of large particles, only limited  
capacities were obtained on composite electrodes made with  
the as-synthesized micrometer-sized crystals. In a modified  
procedure, the crystal size was reduced and electronic  
conductivity improved by ball-milling the oxide crystals  
together with a carbon black additive in a  
Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub>:carbon weight ratio of 80:20. A SEM image  
of the mixture is shown in Figure S1. The mixture was then  
added into the standard carbon and PVdF slurry in an *N*-  
methyl-2-pyrrolidone (NMP) solvent and cast onto the Al

**Figure 2.** Rietveld refinement of (a) XRD and (b) neutron diffraction patterns collected on pristine  $\text{Li}_{1.3}\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  single crystals (PWEGEN). Values in parentheses indicate standard deviation.

<sup>a</sup> $Fm\bar{3}m$ ,  $a$  (Å) = 4.1954(1),  $V$  (Å<sup>3</sup>) = 73.845(1),  $wR_p$  = 9.22%,  $\delta$  = 0.0(0).

297 current collector. The final weight ratio of active material:  
298 al:carbon additive:PVDf binder in the thus-prepared electrodes  
299 was 56:34:10. Electrode disks with a size of 1.6 cm<sup>2</sup> and an

active material loading of ca. 2–3 mg/cm<sup>2</sup> were then cut out 300  
and used as cathodes in coin cells, which were cycled between 301  
1.5 and 4.8 V vs  $\text{Li}^+/\text{Li}$  at a constant current density of 10 mA/  
302 g. Figure 3a shows the voltage profiles of the first four cycles. 303 B  
Similar to what was observed in the LMR oxide cathodes, two 304  
distinct regions, a sloping region and a plateau region, are 305  
present during the first charge. In the sloping region, the 306  
voltage increased steadily from the open circuit voltage (OCV) 307  
of 3.0 to 4.3 V, which delivered a specific capacity of ~115 308  
mAh/g. Whereas in the plateau region, the voltage increased 309  
only slightly from 4.3 to 4.5 V before it rapidly increased to the 310  
cut off voltage of 4.8 V. A specific capacity of ~215 mAh/g was 311  
obtained above 4.3 V on the first cycle, leading to a total charge 312  
capacity of 330 mAh/g. An overall sloping discharge profile was 313  
observed, which delivered a total discharge capacity of ~290 314

**Figure 3.** (a and b) Voltage profiles of  $\text{Li}_{1.3}\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  half-cell cycling. (c) Specific capacity and average voltage as a function of cycle number. (d) Cyclic voltammogram of the first 9 scans at a scan rate of 5 mV/min. Solid symbols and open symbols in panel c represent capacity and voltage, respectively.

315 mAh/g at the cutoff voltage of 1.5 V. The Coulombic efficiency  
316 for the first cycle is therefore  $\sim 88\%$ . Two guidelines, one  
317 showing the theoretical capacity originated from the  $\text{Mn}^{3+}/$   
318  $\text{Mn}^{4+}$  redox couple at 118 mAh/g and the other showing the  
319 theoretical capacity based on Li content at 383 mAh/g are also  
320 shown in Figure 3a. It is clear that both charge and discharge  
321 capacities (330 and 290 mAh/g, respectively) are significantly  
322 larger than the theoretical capacity of the  $\text{Mn}^{3+}/\text{Mn}^{4+}$  redox  
323 (118 mAh/g). The charge capacity obtained in the sloping  
324 region is consistent with the capacity from the  $\text{Mn}^{3+}/\text{Mn}^{4+}$   
325 redox couple, suggesting that  $\text{Mn}^{3+}/\text{Mn}^{4+}$  may be the sole  
326 redox process occurring in this region below 4.3 V.

327 In the second cycle, there is an overall decrease in the  
328 charging voltage of the sloping region, which led to an  
329 increased capacity of  $\sim 180$  mAh/g upon reaching 4.3 V. The  
330 plateau region became somewhat sloping, but voltage increase  
331 remained slow. With cycling, the degree of sloping gradually  
332 increased, and the capacity obtained from this plateau region  
333 continued to decrease. The same trend was also observed on  
334 the discharge capacity, which was reduced to 160 mAh/g after  
335 27 cycles, a loss of nearly 45% (Figures 3b and c). These results  
336 obtained from room-temperature cycling are comparable to  
337 what was obtained at 60 °C by Yabuuchi et al. Although more  
338 carbon was used in our electrode, which likely contributed to  
339 the improved performance, the results may also indicate that  
340 the crystal samples have a kinetic advantage compared to the  
341 polycrystalline samples synthesized using the solid-state  
342 method. Further analysis showed that the oxide experienced  
343 not only capacity fade but also voltage fade. As shown in Figure  
344 3c, the average discharge voltage, obtained by dividing the total  
345 cell energy ( $E$ ) by the cell capacity ( $Q$ ) at 1.5 V, continues to  
346 decrease along with cycling. The extent of decay appears to be  
347 sensitive to the discharge cutoff voltage, and much faster decay  
348 was observed when the cutoff voltage was reduced from 1.5 to  
349 1.0 V.

350 Further insights on the redox activities of  $\text{Li}_{1.3}\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$   
351 crystals were obtained from cyclic voltammetry performed  
352 between 1.5 and 4.8 V at a scan rate of 5 mV/min. Figure 3d  
353 shows the results obtained from the first nine cycles. A broad  
354 peak centered at 3.5 V and a split peak between 4.5 and 4.7 V  
355 were observed during the first oxidation, corresponding to the  
356 sloping and plateau regions on the charging voltage profile,  
357 respectively. In the following scans, the oxidation peak at 3.5 V  
358 gradually moves toward high voltage, and its intensity grew  
359 while that of the peak at 4.5 V decreased, along with the  
360 disappearance of the split peak at 4.7 V after the first cycle. As  
361 the peak around 4.5–4.7 V is often attributed to the oxidation  
362 of  $\text{O}^{2-}$  to  $\text{O}^{n-}$  ( $0 \leq n < 2$ ), the disappearance of the split peak  
363 and the continuous decrease in peak intensity suggest the  
364 complex and irreversible nature of the processes. During the  
365 first reduction, only a single peak was observed around 3.2 V,  
366 which decreased its intensity along with the appearance and  
367 gradual growth of a new peak around 2.2 V in the following  
368 scans. The pair of peaks centered at 3.5 V during oxidation and  
369 3.2 V during reduction is likely associated with the  $\text{Mn}^{3+}/\text{Mn}^{4+}$   
370 redox couple. The growth of the reduction peak at 2.2 V at the  
371 expense of the peak at 3.2 V suggests the gradual trans-  
372 formation of the Mn species and the increasing contribution  
373 from the lower voltage process along with cycling. This  
374 transformation was not observed when the upper cutoff voltage  
375 was limited to 4.0 V, before the onset of the oxygen oxidation  
376 peak. The results suggest that the oxidation of  $\text{O}^{2-}$  to  $\text{O}^{n-}$  at  
377 high voltage may be responsible for the irreversible conversion

of the  $\text{Mn}^{3+}$  redox species, which ultimately led to both capacity 378  
and voltage fade in this oxide cathode. 379

Operando differential electrochemical mass spectroscopy was 380  
used to further examine the oxidation process of  $\text{O}^{2-}$  to  $\text{O}^{n-}$  ( $0 \leq n < 2$ ) 381  
occurring between 4.5 and 4.7 V. Figure 4 shows the 382 44

Figure 4. (a) Voltage profile and (b)  $\text{O}_2$  and  $\text{CO}_2$  gas evolution analyzed by DEMS of a cathode containing 2.66 mg  $\text{Li}_{1.3}\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  active material.

results obtained during the first 2 cycles at a constant current 383  
density of 25 mA/g. The voltage profiles are similar to those 384  
obtained from the coin cell tests, validating the excellent quality 385  
of the in situ electrochemical cell. During the first cycle, both 386  
 $\text{CO}_2$  and  $\text{O}_2$  evolution were detected.  $\text{CO}_2$  evolution began 387  
around 3.8 V during the charge (the first blue guideline in the 388  
figure) and completed around the mid-discharge cycle (the 389  
second blue guideline). There was an increase in intensity 390  
around the midplateau after the onset of  $\text{O}_2$  evolution, and the 391  
peak  $\text{CO}_2$  evolution was reached at the end of charge at 4.8 V. 392  
Oxygen gas was not detected until the midplateau region at 393  
about 4.5 V (the first red guideline in the figure), which also 394  
peaked at the upper cutoff voltage of 4.8 V. Oxygen evolution 395  
completes at the beginning of first discharge after the resting 396  
step (the second red guideline). The cumulative  $\text{CO}_2$  and  $\text{O}_2$  397  
evolved from the first cycle were 1.53 and 0.11  $\mu\text{mol}$ , 398  
respectively, from a cathode that contained 2.66 mg of active 399  
materials. Oxygen evolution, therefore, is much reduced 400  
compared to what was reported on the lithium and 401  
manganese-rich layered oxide system by Luo et al.<sup>9,10</sup> In the 402  
second cycle, the amount of  $\text{CO}_2$  was reduced from 1.53 to 403  
0.46  $\mu\text{mol}$ , while negligible  $\text{O}_2$  evolution was detected. 404

Several sources may contribute to the evolution of  $\text{CO}_2$  gas. 405  
 $\text{Li}_2\text{CO}_3$ , a precursor from synthesis or a byproduct formed 406  
during air exposure of Li-TM oxide samples, can decompose 407  
during charging and release  $\text{CO}_2$  gas. Recent studies confirmed 408  
that in LMR oxide cathodes,<sup>26</sup> all  $\text{CO}_2$  gas evolved during the 409  
first charge in the typical voltage region, results from residual 410  
 $\text{Li}_2\text{CO}_3$  in the samples. Given the similar outgassing behavior of 411  
 $\text{Li}_{1.3}\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  cathode to LMR, we postulate that residual 412  
 $\text{Li}_2\text{CO}_3$  likely accounts for most, if not all,  $\text{CO}_2$  evolution 413  
observed in Figure 4. Nevertheless, carbonate-based electrolytes 414  
are usually unstable at voltages above 4.3 V, especially in the 415  
presence of high valence transition metals (such as  $\text{Mn}^{4+}$ ) that 416  
may catalyze the process and further lower the decomposition 417  
voltage, and a small percentage of  $\text{CO}_2$  evolution at high 418  
potentials may originate from this degradation process. 419  
Carbonate solvent decomposition due to the attack of oxygen 420  
species has also been reported in the context of  $\text{Li}-\text{O}_2$  421  
batteries.<sup>27–29</sup> This represents another possible mechanism 422

423 for lattice oxygen loss in addition to oxygen gas evolution. In  
 424 the simplest case where we safely assume only O atoms in O<sub>2</sub>  
 425 gas originate from Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> cathode material, the total  
 426 lattice O loss from a cathode containing 2.66 mg of active  
 427 materials was 0.11 μmol, which corresponds to 0.38 mol % of  
 428 oxygen ion vacancy in the delithiated cathode and a capacity of  
 429 4.48 mAh/g. Although some of the first charge capacity may  
 430 also come from Li<sub>2</sub>CO<sub>3</sub> oxidizes to CO<sub>2</sub> via a 2 e<sup>-</sup>/CO<sub>2</sub> process  
 431 and side reactions from electrolyte decomposition, it is evident  
 432 that the redox process of O<sup>2-</sup> to O<sup>n-</sup> (0 < n < 2) species  
 433 accounts for the majority of the first charge capacity above 4.3  
 434 V (215 mAh/g) and the first discharge capacity (290 mAh/g)  
 435 in Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> cathode.

436 The DEMS results also reveal that capacity contribution from  
 437 O extraction from the oxide lattice occurs above ~4.5 V. This  
 438 mechanism is active during the first charge which disappears in  
 439 the following cycles. This is consistent with the observation on  
 440 the CV studies, where the oxidation peak centered at 4.7 V was  
 441 observed only during the first scan. The combined results  
 442 suggest that the peak at 4.7 V is likely related to O<sup>2-</sup> oxidation  
 443 to O<sub>2</sub> gas. The peak centering at 4.5 V, therefore, is attributed  
 444 to the oxidation O<sup>2-</sup> anion to O<sup>n-</sup> (0 < n < 2) species. While  
 445 both O<sub>2</sub> gas evolution and lattice oxygen oxidation occur in the  
 446 first charge, the following cycles involve only the redox of O<sup>2-</sup>  
 447 to O<sup>n-</sup> (0 < n < 2) species, signaled by the single oxidation peak  
 448 at 4.5 V. The continuous decrease in peak intensity along with  
 449 scanning indicates that the lattice anion redox process is highly  
 450 irreversible. After merely nine cycles, the O redox process no  
 451 longer participates.

452 **3.3. Structural, Chemical, and Morphological Evolution**  
 453 **during the First Delithiation.** To gain further insights  
 454 on structural and chemical changes during the first charge, we  
 455 resorted to chemical delithiation, which allows for the  
 456 preparation of samples in the large quantity needed for a  
 457 number of analytical techniques. This approach also allows us  
 458 to monitor morphological evolution as large single crystals can  
 459 be used directly without the prior milling process, a necessary  
 460 step to electrochemically charge and discharge the sample.  
 461 Pristine Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> crystals were mixed with various  
 462 amount of nitronium tetrafluoroborate oxidant in acetonitrile to  
 463 prepare a series of Li<sub>x</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> (x = 1.21, 1.1, 1.06, 1.03,  
 464 0.92, 0.87, 0.81, 0.76, 0.64, 0.56, 0.49, 0.40, 0.32, 0.22, 0.13,  
 465 0.01, and 0) samples at different states of charge, which were  
 466 subsequently examined by synchrotron X-ray and neutron  
 467 diffraction, hard and soft X-ray absorption spectroscopy, and  
 468 SEM. While the Li content was determined by ICP  
 469 measurements, the Mn/Nb ratio in each sample was verified  
 470 to be consistent with the calculated value of 1.33 by using  
 471 energy dispersive X-ray spectroscopy. Figure 5a shows the  
 472 powder XRD patterns collected at 11-BM at the Advanced  
 473 Photon Source. As discussed earlier, the pristine  
 474 Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> is phase pure with a rock-salt crystal structure  
 475 (*Fm* $\bar{3}$ *m*; a = 4.1954(1) Å). The 4a sites are occupied by Li, Nb,  
 476 and Mn cations, whereas the 4b sites are occupied only by O  
 477 anions. Oxygen vacancy was not detected in the pristine  
 478 sample. With Li extraction, a single rock-salt phase remained  
 479 when the lithium content is above 0.9 (x > 0.9). Further  
 480 removing Li from the structure led to peak broadening and  
 481 peak shifting toward to high angle, suggesting an overall  
 482 reduction in lattice dimension. Similar results were also  
 483 observed in neutron patterns collected on several samples in  
 484 the series, as shown in Figure 5b. Joint X-ray and neutron  
 485 Rietveld refinement was performed in cases where the same

Figure 5. (a) Synchrotron X-ray diffraction and (b) monochromatic neutron diffraction patterns collected on chemically delithiated Li<sub>x</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> crystals. For neutron measurement, Li<sub>1.3</sub> and Li<sub>0</sub> samples were measured at SNS (POWGEN) using TOF, while Li<sub>1.1</sub>, Li<sub>0.92</sub>, Li<sub>0.7</sub>, Li<sub>0.49</sub>, and Li<sub>0.22</sub> samples were measured at NIST (BT-1) using a single wavelength of λ = 1.19 Å. Note that the Li contents were determined by ICP measurements where an error range of up to ±0.06 is possible.

sample was examined by both techniques. Figure S2 and Table 486 12  
 487 2 show the results obtained from Rietveld refinement of these  
 488 XRD patterns. The structural transformation can be separated  
 489 into two regions: single phase (phase 1) behavior when x > 0.9  
 490 (region I) and a two-phase (phase 2 and 3) behavior when 0 <  
 491 x < 0.9 (region II). The unit cell volume and phase fraction as a  
 492 function of Li content were constructed from the refinement  
 493 and shown in Figures 6a and b, respectively. The Vegard's law  
 494 is only followed in region I, where the total volume change is  
 495 ca. 0.2%. This is consistent with the participation of simple  
 496 cation redox from Mn<sup>3+</sup> to Mn<sup>4+</sup> along with the extraction of  
 497 0.4 Li<sup>+</sup> from the Li<sub>1.3</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2</sub> structure. Complex mixed  
 498 oxygen activities are likely involved in region II, where phases 2  
 499 and 3 with the same rock-salt crystal structure but different  
 500 lattice dimension evolve along with the extraction of Li. Smaller  
 501 sized phase 3 reaches the maximum fraction when x is ~0.5,  
 502 whereas phase 2 becomes the main phase with further Li  
 503 removal. Combining with the results from the electrochemical  
 504 studies, we propose that lattice O<sup>2-</sup> oxidation to O<sup>n-</sup> (0 < n <  
 505 2) mainly occurs in phase 3, whereas loss of O from the lattice  
 506 mainly occurs in phase 2. This was further supported by results  
 507 from the joint X-ray and neutron refinements (Figure S3),  
 508 which revealed that ~2 and 7.8 mol % of oxygen ion vacancies  
 509 exist in the delithiated Li<sub>x</sub>Nb<sub>0.3</sub>Mn<sub>0.4</sub>O<sub>2-δ</sub> with x = 0.2 and 0,  
 510 respectively. Compared to the oxygen ion vacancies in the  
 511 electrochemically charged samples, the much higher concentration  
 512 is likely due to the fact that chemical delithiation was

**Table 2. Summary of Structural Parameters in  $\text{Li}_x\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_{2-\delta}$  ( $0 \leq x \leq 1.3$ ) Determined from Rietveld Refinement of Synchrotron X-ray Diffraction and Neutron Data<sup>a</sup>**

<sup>a</sup> $V_1$ ,  $V_2$ ,  $V_3$ ,  $n_1$ ,  $n_2$ ,  $n_3$ ,  $d_1$ ,  $d_2$ ,  $d_3$ ,  $U_{\text{iso}1}$ ,  $U_{\text{iso}2}$ , and  $U_{\text{iso}3}$  represent the unit cell volume, phase fraction, bond distance of Li/Mn/Nb–O, and thermal factors for Li/Nb/Mn and O in phase 1, 2, and 3, respectively.  $\delta$  represents oxygen anion vacancy in each phase, while  $wR_p$  represent the residual factor of the refinement.

513 performed in an open system that shifts the equilibrium toward  
514 more gas evolution. We also like to point out that protons were  
515 detected on the chemically delithiated oxides based on the  
516 prompt-gamma activation analysis (PGAA). This is likely  
517 molecular in nature as delithiated samples generally have higher  
518 surface area (as shown in the SEM images in Figure 9) and  
519 tend to absorb water during brief air exposure. However, it is  
520 possible that the detected protons may originate from cation  
521 exchange between  $\text{Li}^+$  and  $\text{H}^+$ , as previously reported on the  
522 classic layered oxides.<sup>30</sup> Further analysis is needed to fully  
523 understand the source of protons in these samples.

524 The kinetic properties of delithiation were evaluated by the  
525 relationship between the molar ratio of oxidant/oxide used and  
526 the residual Li content in the sample (Figure 6c), as determined  
527 by ICP. While a linear relationship is apparent in region I,  
528 significant deviation is seen in region II, further confirming the  
529 complex nature of mixed anion activities at lower Li contents.

530 Hard X-ray absorption spectroscopy correlates the changes in  
531 the absorption edge energy to the variations in the average  
532 oxidation state of the absorbing atoms being analyzed in the  
533 bulk material.<sup>31,32</sup> The technique also probes the local and  
534 electronic structures near the absorbing atoms and has the  
535 ability to reveal element-specific structural changes in the  
536 samples. Due to the energy limit of the XAS beamline at SSRL,  
537 Nb spectra were not collected in this study. A previous report  
538 from Yabuuchi et al. indicated that Nb remains at 5+ during the  
539 entire charge/discharge process.<sup>22</sup> The normalized spectra of  
540 Mn *K*-edge and XANES spectra of the chemically delithiated  
541  $\text{Li}_x\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  series are shown in Figures 7a and b,  
542 respectively. The spectrum of pristine  $\text{Li}_{1.3}\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  is  
543 consistent with that of  $\text{Mn}^{3+}$  collected on the standard  
544 reference. Substantial blue-shift of the edge energy was  
545 observed as the lithium content was reduced from 1.3 to 0.9,  
546 consistent with the oxidation of  $\text{Mn}^{3+}$  to  $\text{Mn}^{4+}$ . Negligible  
547 changes were observed in samples with the Li content below  
548 0.9. The edge position, defined by Photoelectron Energy Origin  
549 ( $E_0$ ), is a commonly used parameter for extracting edge energy  
550 level in XANES spectra.<sup>33</sup> Figure 7c compares the edge position

as a function of lithium content in  $\text{Li}_x\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  samples. It  
551 is clear that Mn *K*-edge energy shifts toward higher value in a  
552 near linear fashion when  $x > 0.9$  (region I) whereas it remains  
553 nearly constant when  $0 < x < 0.9$  (region II). This is consistent  
554 with the results from X-ray and neutron diffraction studies,  
555 further confirming that Mn is only redox active in region I.  
556

557 Further changes were observed in the intensity of Mn pre-  
558 edge absorption peaks arising from the dipole forbidden  $1s \rightarrow$   
559  $3d$  electronic transitions, which are typically weak in the  
560 transition metals. In the presence of  $3d$  and  $4p$  orbital  
561 hybridization, often resulting from structural distortion in local  
562 symmetry or noncentrosymmetric environment between the  
563 metal and oxygen coordination, the transitions are made  
564 partially allowed, and the peaks become much stronger.<sup>34–36</sup> As  
565 shown in Figure 7d, the intensity of the pre-edge absorption  
566 peaks is similar in region I, which becomes noticeably stronger  
567 in region II. This suggests that although Mn redox activities are  
568 not involved in region II, the nature of Mn–O bond is altered  
569 in these samples, providing further evidence for oxygen redox  
570 activities in this region as the processes are likely behind the  
571 changes in local symmetry and environment of metal–ligand  
572 coordination. Similar to the edge shift observed in Figures 7a  
573 and b, the absorption energy of the pre-edge peaks also  
574 experienced blue shift in region I while maintaining nearly  
575 constant in region II, corroborating with the observation of Mn  
576 redox activity in region I only.

577 Oxygen redox activities during delithiation of  
578  $\text{Li}_{1.3}\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  were investigated by soft XAS that directly  
579 probes the chemical changes of the element as a function of  
580 penetration depth. The depth profiling from the surface to bulk  
581 were achieved by using two different detectors in total electron  
582 yield (TEY) and fluorescence yield (FY) modes, which have a  
583 typical probing depth of 5 and 50 nm, respectively.<sup>37</sup> Figures 8a  
584 and b show the evolution of TEY and FY O *K*-edge XAS  
585 spectra as a function of Li content in  $\text{Li}_x\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$ . In both  
586 cases, the spectra can be separated into the pre-edge region and  
587 postedge region at the black dashed line (533 eV) shown in the  
588 figures. Features in the postedge region are often attributed to  
589

**Figure 6.** (a and b) Cell volume and phase fraction as a function of  $x$  in delithiated  $\text{Li}_x\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  samples and (c) relationship between the molar ratio of oxidant/oxide and residue Li content in chemically delithiated  $\text{Li}_x\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  samples.

589 O1s  $\rightarrow$  O2p-TM4s4p hybridization, while those in the pre-edge  
 590 region are attributed to O1s  $\rightarrow$  O2p-TM3d hybridization.<sup>38,39</sup>  
 591 Due to the crystal field effect and octahedral coordination of  
 592 oxygen, the pre-edge peaks are often represented by multiplets  
 593 between 528 and 533 eV. As the O2p and TM3d band  
 594 electrons are of most interest to redox activities, we focus on  
 595 the analysis in the pre-edge region. It is clear that as lithium is  
 596 extracted from  $\text{Li}_{1.3}\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$ , both TEY and FY spectra  
 597 exhibit a significant increase in the pre-edge peak intensity. This  
 598 increase is often used as a qualitative measure for the generated  
 599 holes left by electron extraction from either oxygen or TM at  
 600 the O2p-TM3d energy levels.<sup>39–41</sup> A new shoulder peak at  
 601  $\sim$ 529 eV also appeared and gradually grew along with  
 602 delithiation, suggesting the involvement additional O-TM  
 603 hybridization (referred to as  $p$ -band) during the process. Due  
 604 to similarity between the  $p$ -band and the pre-edge absorption  
 605 peak often observed in peroxides and superperoxides,<sup>22,40,42,43</sup>  
 606 we speculate this new O-TM hybridization arises from the  
 607 interaction between oxygen anions as a result of oxygen redox  
 608 activities. Note that similar results were previously reported on  
 609 the LMR cathode materials.<sup>22,40</sup>

To better understand the oxygen redox activities as a  
 610 function of Li content, quantifications of peak features in both  
 611 TEY and FY O  $K$ -edge XAS spectra were performed, and the  
 612 results are shown in Figures 8c and d. The detailed peak fitting  
 613 method is also shown in Figure S4. For both TEY and FY  
 614 spectra, the ratio between the pre-edge peaks and postedge  
 615 peaks continuously increase with lithium extraction, as shown  
 616 in Figure 8c. This confirms electron extraction from O2p and  
 617 TM 3d hybridization and agrees with the previous report by  
 618 Yabuuchi et al.<sup>22</sup> It is, however, unclear on the contribution  
 619 from TM and O due to the hybridization nature between them.  
 620 The quantification on the  $p$ -band intensity, on the other hand,  
 621 provides an opportunity to directly probe oxygen redox  
 622 activities. As shown in Figure 8d, the initial  $p$ -band intensity  
 623 is fairly low in the pristine  $\text{Li}_{1.3}\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  and remains nearly  
 624 constant below Li content of  $\sim$ 0.9, suggesting negligible  
 625 interactions between oxygen anions or oxygen redox activities.  
 626 As  $x$  decreases to below 0.9, there is an increase in the  $p$ -band  
 627 intensity, and the trend continues to full delithiation ( $x = 0$ ).  
 628 The results suggest a continuous increase in oxygen valence  
 629 states in this region and the participation of oxygen redox for  
 630 charge compensation. Combined with the results from the Mn  
 631  $K$  edge XAS spectra which shows that Mn is active when  $x >$   
 632 0.9 and inactive when  $x <$  0.9, the quantification of O  $K$ -edge  
 633 XAS spectra enables the understanding of complete charge  
 634 compensation mechanism during delithiation of  
 635  $\text{Li}_{1.3}\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  crystals. Note that the  $p$ -band intensity in  
 636 the  $x <$  0.9 region is generally higher in the FY mode than that  
 637 in the TEY mode, consistent with a difference in oxygen  
 638 activities, likely enhanced lattice O loss on the surface.  
 639

The evolution of particle morphology during the first  
 640 delithiation is revealed by the SEM images collected on the  
 641 series of delithiated crystal samples (Figure 9). Some surface  
 642 roughing was observed but the particles remain intact when  $x >$   
 643 0.9. With further lithium extraction, large cracks begin to  
 644 appear, which tend to propagate across the entire particle,  
 645 leading to the eventual fracturing of the crystals. The number of  
 646 cracks on each crystal increases along with the decrease in  $x$  but  
 647 appears to reach the maximum at a Li content of 0.5–0.6. This  
 648 coincides with the occurrence of maximum fraction of phase 3,  
 649 as shown in Figure 6b. The change in morphology is also  
 650 consistent with the fact that Mn is redox active when  $x >$  0.9  
 651 while O is redox active when  $x <$  0.9. The participation of  
 652 oxygen redox appears to cause significant morphological  
 653 damage. Our results also suggest that lattice oxidation of  $\text{O}^{2-}$   
 654 to  $\text{O}^{n-}$  ( $0 < n < 2$ ) is more damaging than  $\text{O}_2$  gas evolution,  
 655 although it is possible that particles become more stable when  $x$   
 656 is less than 0.5–0.6 as mechanical stress is released by certain  
 657 cracks and fractures at that point. Further evaluation on oxygen  
 658 oxidation and mechanical damage in Li-excess oxides is  
 659 warranted, but we emphasize that particle cracking and  
 660 fracturing create fresh surfaces which can contribute to  
 661 increased O loss from the lattice and side reactions with the  
 662 electrolyte. Successful surface stabilization strategies such as  
 663 elemental segregation and coating treatment therefore need to  
 664 take consideration in particle morphology evolution during  
 665 cycling.  
 666

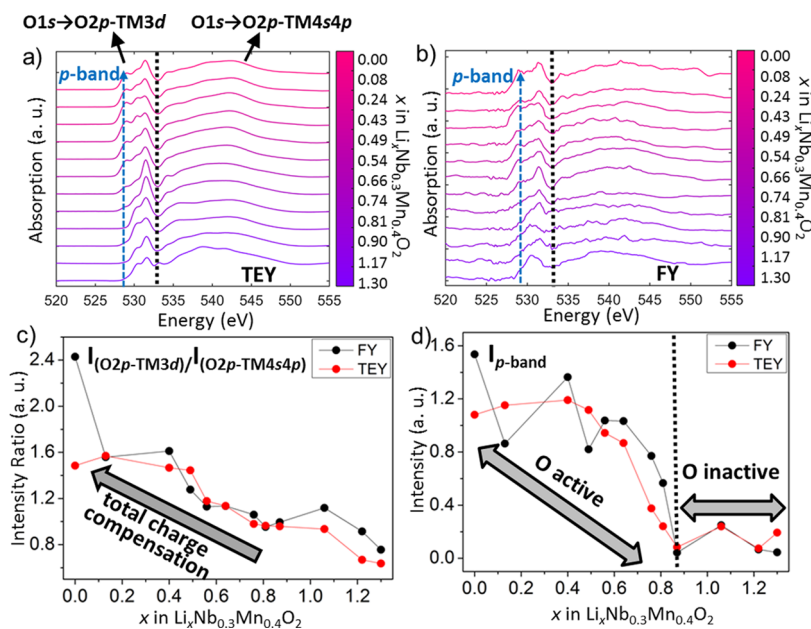

#### 4. CONCLUSION

Disordered, Li-excess transition-metal oxide cathodes are  
 667 capable of delivering high capacities and are promising next-  
 668 generation LIB cathodes. In this study, uniform and phase-pure  
 669  $\text{Li}_{1.3}\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  single crystals were synthesized by a molten-  
 670

**Figure 7.** (a and b) Mn *K*-edge hard XAS and XANES spectra, (c) XANES energy edge ( $E_0$ ) as a function of Li content in  $\text{Li}_x\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  samples, and (d) Mn *K*-edge pre-edge spectra.

**Figure 8.** (a and b) O *K*-edge soft XAS spectra obtained in TEY and FY modes, (c) intensity ratio between the pre-edge and postedge absorption peaks as a function of lithium content, and (d) intensity of the *p*-band as a function of lithium content. In panels a and b, black dashed line divides the pre- and postedge regions, and the blue dashed arrow follows the evolution of the *p*-band intensity.

671 salt method for the first time and used as a diagnostic tool to  
 672 understand the charge compensation mechanism during Li  
 673 extraction and insertion. Electrochemical evaluation suggests  
 674 structural irreversibility after the first cycle, leading to capacity  
 675 and voltage fade of the cathode. Both  $\text{CO}_2$  and  $\text{O}_2$  gas  
 676 evolution was found during the first cycle, with the latter only  
 677 accounting for  $\sim 1\%$  of the charge capacity, in addition to the  
 678 contribution of  $\sim 35\%$  capacity from the  $\text{Mn}^{3+/4+}$  redox couple.  
 679 A large fraction of capacity therefore originates from the redox  
 680 process of  $\text{O}^{2-}/\text{O}^{n-}$  ( $0 < n < 2$ ). Joint refinement on

synchrotron X-ray and neutron diffraction patterns of  
 $\text{Li}_x\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  series showed that the oxide undergoes a  
 single-phase reaction involving  $\text{Mn}^{3+/4+}$  redox reaction when  
 $0.9 < x < 1.3$  and a two-phase reaction involving mixed  $\text{O}^{2-}/$   
 $\text{O}^{n-}$  ( $0 \leq n < 2$ ) reactions when  $0 < x < 0.9$ . For the fully  
 delithiated sample,  $\sim 7.8$  mol % of oxide-ion vacancies were  
 found, resulting from O loss from the lattice. Cracks and  
 fractures initiated and intensified with deep lithium extraction,  
 which serves as a means to release the mechanical stress

**Figure 9.** SEM images of chemically delithiated  $\text{Li}_x\text{Nb}_{0.3}\text{Mn}_{0.4}\text{O}_2$  crystals:  $x =$  (a) 1.3, (b) 1.1, (c) 0.87, (d) 0.76, (e) 0.56, and (f) 0.13.

690 endured by the large crystals during the oxygen redox  
691 processes.
