Empirical Exchange Rate Models of the Nineties: Are Any Fit to Survive?

Abstract

Previous assessments of forecasting performance of exchange rate models have focused upon a narrow set of models typically of the 1970's vintage. The canonical papers in this literature are by Meese and Rogoff (1983, 1988), who examined monetary and portfolio balance models. Succeeding works by Mark (1995) and Chinn and Meese (1995) focused on similar models. In this paper we re-assess exchange rate prediction using a wider set of models that have been proposed in the last decade: interest rate parity, productivity based models, and a composite specification incorporating the real interest differential, portfolio balance and nontradables price channels. The performance of these models is compared against two reference specifications – the purchasing power parity and the Dornbusch-Frankel sticky price monetary model. The models are estimated in error correction and first-difference specifications. Rather than estimating the cointegrating vector over the entire sample and treating it as part of the *ex ante* information set as is commonly done in the literature, we also update the cointegrating vector, thereby generating true *ex ante* forecasts. We examine model performance at various forecast horizons (1 quarter, 4 quarters, 20 quarters) using differing metrics (mean squared error, direction of change), as well as the “consistency” test of Cheung and Chinn (1998). No model consistently outperforms a random walk, by a mean squared error measure; however, along a direction-of-change dimension, certain structural models do outperform a random walk with statistical significance. Moreover, one finds that these forecasts are cointegrated with the actual values of exchange rates, although in a large number of cases, the elasticity of the forecasts with respect to the actual values is different from unity. Overall, model/specification/currency combinations that work well in one period will not necessarily work well in another period.

Key words: exchange rates, monetary model, productivity, interest rate parity, purchasing power parity, forecasting performance

JEL classification: F31, F47

1. Introduction

The recent movements in the dollar and the euro have appeared seemingly inexplicable in the context of standard models. While the dollar may not have been “dazzling” – as it was described in the mid-1980's – it has been characterized as overly “darling.”¹ And the euro’s ability to repeatedly confound predictions needs little re-emphasizing.

It is against this backdrop that several new models have been forwarded in the past decade. Some explanations are motivated by findings in the empirical and theoretical literature, such as the correlation between net foreign asset positions and real exchange rates and those based on productivity differences. None of these models, however, have been subjected to rigorous examination of the sort that Meese and Rogoff conducted in their seminal work, the original title of which we have appropriated and amended for this study.²

We believe that a systematic examination of these newer empirical models is long overdue, for a number of reasons. First, while these models have become prominent in policy and financial circles, they have not been subjected to the sort systematic out-of-sample testing conducted in academic studies. For instance, productivity did not make an appearance in earlier comparative studies, but has been tapped as an important determinant of the euro/dollar exchange rate (Owen, 2001; Rosenberg, 2000).³

Second, most of the recent academic treatments exchange rate forecasting performance rely upon a single model – such as the monetary model – or some other limited set of models of 1970’s vintage, such as purchasing power parity or real interest differential model.

Third, the same criteria are often used, neglecting alternative dimensions of model forecast performance. That is, the first and second moment metrics such as mean error and mean squared error are considered, while other aspects that might be of greater importance are often

¹ Frankel (1985) and *The Economist* (2001), respectively.

² Meese and Rogoff (1983) was based upon work in “Empirical exchange rate models of the seventies: are any fit to survive?” *International Finance Discussion Paper* No. 184 (Board of Governors of the Federal Reserve System, 1981).

³ Similarly, behavioral equilibrium exchange rate (BEER) models – essentially combinations of real interest differential, nontraded goods and portfolio balance models – have been used in estimating the “equilibrium” values of the euro. See Morgan Stanley (Fels and Yilmaz, 2001), Bundesbank (Clostermann and Schnatz, 2000), ECB (Maeso-Fernandez *et al.*, 2001), and IMF (Alberola, *et al.*, 1999). A corresponding study for the dollar is Yilmaz and Jen

neglected. We have in mind the direction of change – perhaps more important from a market timing perspective – and other indicators of forecast attributes.

In this study, we extend the forecast comparison of exchange rate models in several dimensions.

- Five models are compared against the random walk. Purchasing power parity is included because of its importance in international finance and the fact that the parity condition is commonly used to gauge the degree of exchange rate misalignment. The sticky-price monetary model of Dornbusch and Frankel is the only structural model that has been the subject of previous systematic analyses. The other models include one incorporating productivity differentials, an interest rate parity specification, and a composite specification incorporating a number of channels identified in differing theoretical models.
- The behavior of US dollar-based exchange rates of the Canadian dollar, British pound, Deutsche mark and Japanese yen are examined. We also examine the corresponding yen-based rates, to insure that our conclusions are not driven by dollar specific results.
- The models are estimated in two ways: in first-difference and error correction specifications.
- Forecasting performance is evaluated at several horizons (1-, 4- and 20-quarter horizons) and two sample periods (post-Louvre Accord and post-1982).
- We augment the conventional metrics with a direction of change statistic and the “consistency” criterion of Cheung and Chinn (1998).

Before proceeding further, it may prove worthwhile to emphasize why we focus on out of sample prediction as our basis of judging the relative merits of the models. It is not that we believe that we can necessarily out-forecast the market in real time. Indeed, our forecasting exercises are in the nature of ex post simulations, where in many instances contemporaneous values of the right hand side variables are used to predict future exchange rates. Rather, we construe the exercise as a means of protecting against data mining that might occur when relying solely on in-sample inference.⁴

The exchange rate models considered in the exercise are summarized in Section 2.

(2001).

⁴ There is an enormous literature on data mining. See Inoue and Kilian (2003) for some recent thoughts on the usefulness of out of sample versus in sample tests.

Section 3 discusses the data, the estimation methods, and the criteria used to compare forecasting performance. The forecasting results are reported in Section 4. Section 5 concludes.

2. Theoretical Models

The universe of empirical models that have been examined over the floating rate period is enormous. Consequently any evaluation of these models must necessarily be selective. Our criteria require that the models are (1) prominent in the economic and policy literature, (2) readily implementable and replicable, and (3) not previously evaluated in a systematic fashion. We use the random walk model as our benchmark naive model, in line with previous work, but we also select the purchasing power parity and the basic Dornbusch (1976) and Frankel (1979) model as two comparator specifications, as they still provide the fundamental intuition for how flexible exchange rates behave. The purchasing power parity condition examined in this study is given by

$$(1) \quad s_t = \beta_0 + \hat{p}_t ,$$

where s is the log exchange rate, p is the log price level (CPI), and “ $\hat{}$ ” denotes the intercountry difference. Strictly speaking, (1) is the relative purchasing power parity condition. The relative version is examined because price indexes rather than the actual price levels are considered.

The sticky price monetary model can be expressed as follows:

$$(2) \quad s_t = \beta_0 + \beta_1 \hat{m}_t + \beta_2 \hat{y}_t + \beta_3 \hat{i}_t + \beta_4 \hat{\pi}_t + u_t ,$$

where m is log money, y is log real GDP, i and π are the interest and inflation rate, respectively, and u_t is an error term. The characteristics of this model are well known, so we will not devote time to discussing the theory behind the equation. We note, however, that the list of variables included in (2) encompasses those employed in the flexible price version of the monetary model, as well as the micro-based general equilibrium models of Stockman (1980) and Lucas (1982). In addition, two observations are in order. First, the sticky price model can be interpreted as an extension of equation (1) such the price variables are replaced by macro variables that capture money demand and overshooting effects. Second, we do not impose coefficient restrictions in equation (2) because theory gives us little guidance regarding the exact values of all the

parameters.

Next, we assess models that are in the Balassa-Samuelson vein, in that they accord a central role to productivity differentials to explaining movements in real, and hence also nominal, exchange rates. Real versions of the model can be traced to DeGregorio and Wolf (1994), while nominal versions include Clements and Frenkel (1980) and Chinn (1997). Such models drop the purchasing power parity assumption for broad price indices, and allow the real exchange rate to depend upon the relative price of nontradables, itself a function of productivity (z) differentials. A generic productivity differential exchange rate equation is

$$(3) \quad s_t = \beta_0 + \beta_1 \hat{m}_t + \beta_2 \hat{y}_t + \beta_3 \hat{i}_t + \beta_5 \hat{z}_t + u_t.$$

Although equations (2) and (3) bear a superficial resemblance, the two expressions embody quite different economic and statistical implications. The central difference is that (2) assumes PPP holds in the long run, while the productivity based model makes no such presumption. In fact the nominal exchange rate can drift infinitely far away from PPP, although the path is determined in this model by productivity differentials.

The fourth model is a composite model that incorporates a number of familiar relationships. A typical specification is:

$$(4) \quad s_t = \beta_0 + \hat{p}_t + \beta_5 \hat{\omega}_t + \beta_6 \hat{r}_t + \beta_7 \hat{gdebt}_t + \beta_8 \hat{tot}_t + \beta_9 \hat{nfa}_t + u_t,$$

where ω is the relative price of nontradables, r is the real interest rate, $gdebt$ the government debt to GDP ratio, tot the log terms of trade, and nfa is the net foreign asset. Note that we impose a unitary coefficient on the inter-country log price level \hat{p} , so that (4) could be re-expressed as determining the real exchange rate.

Although this particular specification closely resembles the behavioral equilibrium exchange rate (BEER) model of Clark and MacDonald (1999), it also shares attributes with the NATREX model of Stein (1999) and the real equilibrium exchange rate model of Edwards (1989), as well as a number of other approaches. Consequently, we will henceforth refer to this specification as the “composite” model. Again, relative to (1), the composite model incorporates the Balassa-Samuelson effect (via ω), the overshooting effect (r), and the portfolio balance effect ($gdebt, nfa$).⁵

⁵ On this latter channel, Cavallo and Ghironi (2002) provide a role for net foreign assets in

Models based upon this framework have been the predominant approach to determining the rate at which currencies will gravitate to over some intermediate horizon, especially in the context of policy issues. For instance, the behavioral equilibrium exchange rate approach is the model that is most often used to determine the long-term value of the euro.⁶

The final specification assessed is not a model *per se*; rather it is an arbitrage relationship – uncovered interest rate parity:

$$(5) \quad s_{t+k} = s_t + \hat{i}_{t,k}$$

where $i_{t,k}$ is the interest rate of maturity k . Similar to the relative purchasing power parity (1), this relation need not be estimated in order to generate predictions.

The interest rate parity is included in the forecast comparison exercise mainly because it has recently gathered empirical support at long horizons (Alexius, 2001 and Meredith and Chinn, 1998), in contrast to the disappointing results at the shorter horizons. MacDonald and Nagayasu (2000) have also demonstrated that long-run interest rates appear to predict exchange rate levels. On the basis of these findings, we anticipate that this specification will perform better at the longer horizons than at shorter.⁷

3. Data, Estimation and Forecasting Comparison

3.1 Data

The analysis uses quarterly data for the United States, Canada, UK, Japan, Germany, and Switzerland over the 1973q2 to 2000q4 period. The exchange rate, money, price and income variables are drawn primarily from the IMF's *International Financial Statistics*. The productivity data were obtained from the Bank for International Settlements, while the interest rates used to

the determination of exchange rates in the sticky-price optimizing framework of Obstfeld and Rogoff (1995).

⁶ We do not examine a closely related approach, the internal-external balance approach of the IMF (see Faruquee, Isard and Masson, 1999). The IMF approach requires extensive judgments regarding the trend level of output, and the impact of demographic variables upon various macroeconomic aggregates. We did not believe it would be possible to subject this methodology to the same out of sample forecasting exercise applied to the others.

⁷ Despite this finding, there is little evidence that long-term interest rate differentials – or equivalently long-dated forward rates – have been used for forecasting at the horizons we are investigating. One exception from the non-academic literature is Rosenberg (2001).

conduct the interest rate parity forecasts are essentially the same as those used in Meredith and Chinn (1998). See the Data Appendix for a more detailed description.

Two out-of-sample periods are used to assess model performance: 1987q2-2000q4 and 1983q1-2000q4. The former period conforms to the post-Louvre Accord period, while the latter spans the period after the end of monetary targeting in the U.S. Figures 1 and 2 depict, respectively, the dollar-based Deutschemark and yen exchange rates, with the right-most line indicating the beginning of the first out-of-sample period, and the left-most line indicating the second. The shorter out-of-sample period (1987-2000) spans a period of *relative* dollar stability (and appreciation in the case of the mark). The longer out-of-sample period subjects the models to a more rigorous test, in that the prediction takes place over a large dollar appreciation and subsequent depreciation (against the mark) and a large dollar depreciation (from 250 to 150 yen per dollar). In other words, this longer span encompasses more than one “dollar cycle.” The use of this long out-of-sample forecasting period has the added advantage that it ensures that there are many forecast observations to conduct inference upon.

3.2 Estimation and Forecasting

We adopt the convention in the empirical exchange rate modeling literature of implementing “rolling regressions” established by Meese and Rogoff. That is, estimates are applied over a given data sample, out-of-sample forecasts produced, then the sample is moved up, or “rolled” forward one observation before the procedure is repeated. This process continues until all the out-of-sample observations are exhausted. While the rolling regressions do not incorporate possible efficiency gains as the sample moves forward through time, the procedure has the potential benefit of alleviating parameter instability effects over time – which is a commonly conceived phenomenon in exchange rate modeling.

Two specifications of these theoretical models were estimated: (1) an error correction specification, and (2) a first differences specification. These two specifications entail different implications for interactions between exchange rates and their determinants. It is well known that both the exchange rate and its economic determinants are $I(1)$. The error correction specification explicitly allows for the long-run interaction effect of these variables (as captured by the error correction term) in generating forecast. On the other hand, the first differences model emphasizes

on the effects of changes in the macro variables on exchange rates. If the variables are cointegrated, then the former specification is more efficient than the latter one and is expected to forecast better in long horizons. If the variables are not cointegrated, the error correction specification can lead to spurious results. Because it is not easy to determine unambiguously whether these variables are cointegrated or not, we consider both specifications.

Since implementation of the error correction specification is relatively involved, we will address the first-difference specification to begin with. Consider the general expression for the relationship between the exchange rate and fundamentals:

$$(6) \quad s_t = X_t \Gamma + \varepsilon_t,$$

where X_t is a vector of fundamental variables under consideration. The first-difference specification involves the following regression:

$$(7) \quad \Delta s_t = \Delta X_t \Gamma + u_t.$$

These estimates are then used to generate one- and multi-quarter ahead forecasts.⁸ Since these exchange rate models imply joint determination of all variables in the equations, it makes sense to apply instrumental variables. However, previous experience indicates that the gains in consistency are far outweighed by the loss in efficiency, in terms of prediction (Chinn and Meese, 1995). Hence, we rely solely on OLS.

The error correction estimation involves a two-step procedure. In the first step, the long-run cointegrating relation implied by (6) is identified using the Johansen procedure. The estimated cointegrating vector ($\tilde{\Gamma}$) is incorporated into the error correction term, and the resulting equation

$$(8) \quad s_t - s_{t-k} = \delta_0 + \delta_1 (s_{t-k} - X_{t-k} \tilde{\Gamma}) + u_t$$

is estimated via OLS. Equation (8) can be thought of as an error correction model stripped of short run dynamics. A similar approach was used in Mark (1995) and Chinn and Meese (1995), except for the fact that in those two cases, the cointegrating vector was imposed *a priori*. The use of this specification is motivated by the difficulty in estimating the short run dynamics in

⁸ Only contemporaneous changes are involved in (7). While this is a somewhat restrictive assumption, it is not clear that allowing more lags would result in improved prediction. Moreover, implementation of a specification procedure based upon some lag-selection criterion

exchange rate equations.⁹

One key difference between our implementation of the error correction specification and that undertaken in some other studies involves the treatment of the cointegrating vector. In some other prominent studies (MacDonald and Taylor, 1993), the cointegrating relationship is estimated over the entire sample, and then out of sample forecasting undertaken, where the short run dynamics are treated as time varying *but the long-run relationship is not*. While there are good reasons for adopting this approach – in particular one wants to use as much information as possible to obtain estimates of the cointegrating relationships – the asymmetry in estimation approach is troublesome, and makes it difficult to distinguish quasi-ex ante forecasts from true ex ante forecasts. Consequently, our estimates of the *long-run* cointegrating relationship vary as the data window moves.¹⁰

It is also useful to stress the difference between the error correction specification forecasts and the first-difference specification forecasts. In the latter, *ex post* values of the right hand side variables are used to generate the predicted exchange rate change. In the former, contemporaneous values of the right hand side variables are not necessary, and the error correction predictions are true *ex ante* forecasts. Hence, we are affording the first-difference specifications a tremendous informational advantage in forecasting.

3.3 Forecast Comparison

To evaluate the forecasting accuracy of the different structural models, the ratio between the mean squared error (MSE) of the structural models and a driftless random walk is used. A value smaller (larger) than one indicates a better performance of the structural model (random walk). We also explicitly test the null hypothesis of no difference in the accuracy of the two

would be much too cumbersome to implement in this context.

⁹ We opted to exclude short-run dynamics in equation (8) because a) the use of equation (8) yields true *ex ante* forecasts and makes our exercise directly comparable with, for example, Mark (1995), Chinn and Meese (1995) and Groen (2000), and b) the inclusion of short-run dynamics creates additional demands on the generation of the right-hand-side variables and the stability of the short-run dynamics that complicate the forecast comparison exercise beyond a manageable level.

¹⁰ Restrictions on the β -parameters in (2), (3) and (4) are not imposed because in many cases we do not have strong priors on the exact values of the coefficients.

competing forecasts (i.e. structural model vs. driftless random walk). In particular, we use the Diebold-Mariano statistic (Diebold and Mariano, 1995) which is defined as the ratio between the sample mean loss differential and an estimate of its standard error; this ratio is asymptotically distributed as a standard normal.¹¹ The loss differential is defined as the difference between the squared forecast error of the structural models and that of the random walk. A consistent estimate of the standard deviation can be constructed from a weighted sum of the available sample autocovariances of the loss differential vector. Following Andrews (1991), a quadratic spectral kernel is employed, together with a data-dependent bandwidth selection procedure.¹²

We also examine the predictive power of the various models along different dimensions. One might be tempted to conclude that we are merely changing the well-established “rules of the game” by doing so. However, there are very good reasons to use other evaluation criteria. First, there is the intuitively appealing rationale that minimizing the mean squared error (or relatedly mean absolute error) may not be important from an economic standpoint. A less pedestrian motivation is that the typical mean squared error criterion may miss out on important aspects of predictions, especially at long horizons. Christoffersen and Diebold (1998) point out that the standard mean squared error criterion indicates no improvement of predictions that take into account cointegrating relationships *vis à vis* univariate predictions. But surely, any reasonable criteria would put some weight the tendency for predictions from cointegrated systems to “hang together”.

Hence, our first alternative evaluation metric for the relative forecast performance of the structural models is the direction of change statistic, which is computed as the number of correct predictions of the direction of change over the total number of predictions. A value above (below) 50 per cent indicates a better (worse) forecasting performance than a naive model that

¹¹ In using the Diebold Mariano test, we are relying upon asymptotic results, which may or may not be appropriate for our sample. However, generating finite sample critical values for the large number of cases we deal with would be computationally infeasible. More importantly, the most likely outcome of such an exercise would be to make detection of statistically significant out-performance even more rare, and leaving our basic conclusion intact.

¹² We also experimented with the Bartlett kernel and the deterministic bandwidth selection method. The results from these methods are qualitatively very similar. Appendix 2 contains a more detailed discussion of the forecast comparison tests.

predicts the exchange rate has an equal chance to go up or down. Again, Diebold and Mariano (1995) provide a test statistic for the null of no forecasting performance of the structural model. The statistic follows a binomial distribution, and its studentized version is asymptotically distributed as a standard normal. Not only does the direction of change statistic constitute an alternative metric, Leitch and Tanner (1991), for instance, argue that a direction of change criterion may be more relevant for profitability and economic concerns, and hence a more appropriate metric than others based on purely statistical motivations. The criterion is also related to tests for market timing ability (Cumby and Modest, 1987).

The third metric we used to evaluate forecast performance is the consistency criterion proposed in Cheung and Chinn (1998). This metric focuses on the time-series properties of the forecast. The forecast of a given spot exchange rate is labeled as consistent if (1) the two series have the same order of integration, (2) they are cointegrated, and (3) the cointegration vector satisfies the unitary elasticity of expectations condition. Loosely speaking, a forecast is consistent if it moves in tandem with the spot exchange rate in the long run. While the two previous criteria focus on the precision of the forecast, the consistency requirement is concerned with the long-run relative variation between forecasts and actual realizations. One may argue that the criterion is less demanding than the MSE and direction of change metrics. A forecast that satisfies the consistency criterion can (1) have a MSE larger than that of the random walk model, (2) have a direction of change statistic less than $\frac{1}{2}$, or (3) generate forecast errors that are serially correlated. However, given the problems related to modeling, estimation, and data quality, the consistency criterion can be a more flexible way to evaluate a forecast. Cheung and Chinn (1998) provide a more detailed discussion on the consistency criterion and its implementation.

It is not obvious which one of the three evaluation criteria is better as they each have a different focus. The MSE is a standard evaluation criterion, the direction of change metric emphasizes the ability to predict directional changes, and the consistency test is concerned about the long-run interactions between forecasts and their realizations. Instead of arguing one criterion is better than the other, we consider the use of these criteria as complementary and providing a multifaceted picture of the forecast performance of these structural models. Of course, depending on the purpose of a specific exercise, one may favor one metric over the other.

4. Comparing the Forecast Performance

4.1 The MSE Criterion

The comparison of forecasting performance based on MSE ratios is summarized in Table 1. The table contains MSE ratios and the p-values from five dollar-based currency pairs, five model specifications, the error correction and first-difference specifications, three forecasting horizons, and two forecasting samples. Each cell in the table has two entries. The first one is the MSE ratio (the MSEs of a structural model to the random walk specification). The entry underneath the MSE ratio is the p-value of the hypothesis that the MSEs of the structural and random walk models are the same. Because of the lack of data, the composite model is not estimated for the dollar-Swiss franc and dollar-yen exchange rates. Altogether, there are 216 MSE ratios, which spread evenly across the two forecasting samples. Of these 216 ratios, 138 are computed from the error correction specification and 78 from the first-difference one.

Note that in the tables, only “error correction specification” entries are reported for the purchasing power parity and interest rate parity models. In fact, the two models are not estimated; rather the predicted spot rate is calculated using the parity conditions. To the extent that the deviation from a parity condition can be considered the error correction term, we believe this categorization is most appropriate.

Overall, the MSE results are not favorable to the structural models. Of the 216 MSE ratios, 151 are not significant (at the 10 percent significance level) and 65 are significant. That is, for the majority cases one cannot differentiate the forecasting performance between a structural model and a random walk model. For the 65 significant cases, there are 63 cases in which the random walk model is significantly better than the competing structural models and only 2 cases in which the opposite is true. The significant cases are quite evenly distributed across the two forecasting periods. As 10 percent is the size of the test and 2 cases constitute less than 10 percent of the total of 216 cases, the empirical evidence can hardly be interpreted as supportive of the superior forecasting performance of the structural models.

Inspection of the MSE ratios, does not reveal many consistent patterns in terms of outperformance. It appears that the productivity model does not do particularly badly for the dollar-mark rate at the 1- and 4-quarter horizons. The MSE ratios of the purchasing power parity

and interest rate parity models are less than unity (even though not significant) only at the 20-quarter horizon – a finding consistent with the perception that these parity conditions work better at long rather than at short horizons.

The MSE results derived from the yen-based exchange rates are provided in Table 2, which has a format similar to that of Table 1. As we lack data to estimate the composite model for yen-based exchange rates, Table 2 contains only 180 MSE ratios and the p-values of the hypothesis that the MSEs of the structural and random walk models are the same. Again, the structural models do not deliver a better forecasting performance than a random walk model. Indeed, compared with the dollar-based exchange rates, the yen-based exchange rates have a larger fraction of cases in which one cannot differentiate the forecasting performance between a structural model and a random walk model. In 138 out of 180 cases, the statistic is not significant. Of the significant cases, the random walk model outperforms in 37 cases and the competing structural models do better in 5 cases. Again, the frequency of observing a structural model forecast better than a random walk model is lower than that implied by the size of the test.

Consistent with the existing literature, our results are supportive of the assertion that it is very difficult to find forecasts from a structural model that can consistently beat the random walk model using the MSE criterion. The current exercise further strengthens the assertion as it covers both dollar- and yen-based exchange rates, two different forecasting periods, and some structural models that have not been extensively studied before.

4.2 The Direction of Change Criterion

Table 3 reports the proportion of forecasts that correctly predict the direction of the dollar exchange rate movement and, underneath these sample proportions, the p-values for the hypothesis that the reported proportion is significantly different from $\frac{1}{2}$. When the proportion statistic is significantly larger than $\frac{1}{2}$, the forecast is said to have the ability to predict the direction of change. On the other hand, if the statistic is significantly less than $\frac{1}{2}$, the forecast tends to give the wrong direction of change. For trading purposes, information regarding the significance of incorrect prediction can be used to derive a potentially profitable trading rule by going against the prediction generated by the model. Following this argument, one might consider the cases in which the proportion of “correct” forecasts is larger than or less than $\frac{1}{2}$ contain the

same information. However, in evaluating the ability of the model to describe exchange rate behavior, we separate the two cases.

There is mixed evidence on the ability of the structural models to correctly predict the direction of change. Among the 216 direction of change statistics, 50 (23) are significantly larger (less) than $\frac{1}{2}$ at the 10 percent level. The occurrence of the significant outperformance cases is higher (23 percent) than the one implied by the 10 percent level of the test. The results indicate that the structural model forecasts *can* correctly predict the direction of the change, while the proportion of cases where a random walk outperforms the competing models is only about what one would expect if they occurred randomly.

Let us take a closer look at the incidences in which the forecasts are in the right direction. Approximately 58% of the 50 cases are associated with the error correction model and the remainder with the first difference specification. Thus, the error correction specification – which incorporates the empirical long-run relationship – provides a slightly better specification for the models under consideration. The forecasting period does not have a major impact on forecasting performance, since exactly half of the successful cases are in each forecasting period.

Among the five models under consideration, the purchasing power parity specification has the highest number (18) of forecasts that give the correct direction of change prediction, followed by the sticky-price, composite, and productivity models (10, 9, and 8 respectively), and the interest rate parity model (5). Thus, at least on this count, the newer exchange rate models do not edge out the “old fashioned” purchasing power parity doctrine and the sticky-price model. Because there are differing numbers of forecasts due to data limitations and specifications, the proportions do not exactly match up with the numbers. Proportionately, the purchasing power model does the best.

Interestingly, the success of direction of change prediction appears to be currency specific. The dollar-yen exchange rate yields 13 out of 50 forecasts that give the correct direction of change prediction. In contrast, the dollar-pound has only 4 out of 50 forecasts that produce the correct direction of change prediction.

The cases of correct direction prediction appear to cluster at the long forecast horizon. The 20-quarter horizon accounts for 22 of the 50 cases while the 4-quarter and 1-quarter horizons have 18 and 10 direction of change statistics that are significantly larger than $\frac{1}{2}$. Since

there have not been many studies utilizing the direction of change statistic in similar contexts, it is difficult to make comparisons. Chinn and Meese (1995) apply the direction of change statistic to 3 year horizons for three conventional models, and find that performance is largely currency-specific: the no change prediction is outperformed in the case of the dollar-yen exchange rate, while all models are outperformed in the case of the dollar-pound rate. In contrast, in our study at the 20-quarter horizon, the positive results appear to be fairly evenly distributed across the currencies, with the exception of the dollar-pound rate.¹³ Mirroring the MSE results, it is interesting to note that the direction of change statistic works for the purchasing power parity at the 4-quarter and 20-quarter horizons and for the interest rate parity model only at the 20-quarter horizon. This pattern is entirely consistent with the findings that the two parity conditions hold better at long horizons.¹⁴

The direction of change results derived from the yen-based exchange rates are summarized in Table 4. Of the 180 yen-based direction of change statistics, 60 (or 33 percent) are significantly larger than $\frac{1}{2}$ while 7 are significantly smaller. The purchasing power parity specification accounts for 23 of the 60 cases in which the forecasts give correct direction of change predictions. The remaining cases distribute evenly across the three models (sticky price, interest rate parity, and productivity differential) under consideration. On a proportional basis, the purchasing parity and interest rate parity models garner the two highest success ratios (77 percent and 37 percent, respectively). Similar to the dollar-based data, the direction of change results appear to be currency specific and the outperformance is concentrated in the pound-yen exchange rate. Among the 60 cases in which the structure models correctly predict the direction of change, the 20-quarter ahead forecast horizon accounts for 29 cases while the 1-quarter and 4-quarter ahead forecast horizons have 10 and 21 cases respectively. The direction of change outperformance is more pronounced at long horizons. This is in line with the results of Mark (1995) and Chinn and Meese (1995).

¹³ Using Markov switching models, Engel (1994) obtains some success along the direction of change dimension at horizons of up to one year. However, his results are not statistically significant.

¹⁴ Flood and Taylor (1997) noted the tendency for PPP to hold better at longer horizons. Mark and Moh (2001) document the gradual currency appreciation in response to a short term interest differential, contrary to the predictions of uncovered interest parity.

4.3 The Consistency Criterion

The consistency criterion only requires the forecast and actual realization comove one-to-one in the long run. In assessing the consistency, we first test if the forecast and the realization are cointegrated.¹⁵ If they are cointegrated, then we test if the cointegrating vector satisfies the (1, -1) requirement. The cointegration results are reported in Tables 5 and 6. The test results for the (1, -1) restriction are reported in Tables 7 and 8.

For the dollar-based exchange rate data, 67 of 216 cases reject the null hypothesis of no cointegration at the 10 percent significance level. Thus, 67 forecast series (31 percent of the total number) are cointegrated with the corresponding spot exchange rates. The error correction specification accounts for 39 of the 67 cointegrated cases and the first-difference specification accounts for the remaining 28 cases. There is some evidence that the error correction specification gives better forecasting performance than the first-difference specification. These 67 cointegrated cases are slightly more concentrated in the longer of the two forecasting periods – 30 for the post-Louvre Accord period and 37 for the post-1983 period.

Interestingly, the sticky-price model garners the largest number of cointegrated cases. There are 60 forecast series generated under the sticky-price model. 26 of these 60 series (that is, 43 percent) are cointegrated with the corresponding spot rates. The composite model has the second highest frequency of cointegrated forecast series – 39 percent of 36 series. 37 percent of the productivity differential model forecast series, 33 percent of the purchasing power parity model, and 0 percent of the interest rate parity model are cointegrated with the spot rates. Apparently, we do not find evidence that the recently developed exchange rate models outperform the “old” vintage sticky-price model.

The dollar-pound and dollar-Canadian dollar, each have between 19 and 17 forecast series that are cointegrated with their respective spot rates. The dollar-mark pair, which yields

¹⁵ The Johansen method is used to test the null hypothesis of no cointegration. The maximum eigenvalue statistics are reported in the manuscript. Results based on the trace statistics are essentially the same. Before implementing the cointegration test, both the forecast and exchange rate series were checked for the I(1) property. For brevity, the I(1) test results and the trace statistics are not reported.

relatively good forecasts according to the direction of change metric, has only 12 cointegrated forecast series. Evidently, the forecasting performance is not just currency specific; it also depends on the evaluation criterion. The distribution of the cointegrated cases across forecasting horizons is puzzling. The frequency of occurrence is inversely proportional to the forecasting horizons. There are 35 of 67 one-quarter ahead forecast series that are cointegrated with the spot rates. However, there are only 20 of the four-quarter ahead and 12 of the 20-quarter ahead forecast series that are cointegrated with the spot rates. One possible explanation for this result is that there are fewer observations in the 20-quarter ahead forecast series and this affects the power of the cointegration test.

The yen-based cointegration test results are presented in Table 6. The yen-based exchange rates yield a substantially larger proportion of significant cases. Of the 180 forecast series, 79 (or 44 percent) series move together with the spot exchange rates in the long run. The yen-based data display better forecasting performance of the error correction vs. first-difference specifications – the former specification has 49 cointegrated forecast series and the latter has 30.

The productivity and sticky-price models produce the largest number of cointegrated forecast series (28 and 27 respectively). Interestingly, along this cointegration dimension, productivity-based models fare better than along the MSE or direction of change dimensions.

Among the five yen-based exchange rates, the occurrence of cointegrated forecast series ranges from the low of 9 series in the yen-dollar case to the high of 19 series in the yen-mark case. Regarding the forecasting horizon, the yen-based results are quite similar to the dollar-based ones. The cointegrated forecast series are mostly found in the one-quarter ahead forecasting horizon. In fact, it accounts for 41 of the 79 cases. The 20-quarter ahead forecast horizon only has 11 cointegrated forecast series.

The results of testing for the long-run unitary elasticity of expectations at the 10 percent significance level are reported in Table 7 (dollar-based exchange rates) and Table 8 (yen-based exchange rates). The condition of long-run unitary elasticity of expectations; that is the (1,-1) restriction on the cointegrating vector, is rejected by the data quite frequently. For the dollar-based exchange rates, the (1,-1) restriction is rejected in 48 of the 67 cointegration cases. That is 28 percent of the cointegrated cases display long-run unitary elasticity of expectations. Taking both the cointegration and restriction test results together, 9 percent of the 216 cases of the

dollar-based exchange rate forecast series meet the consistency criterion. The yen-based exchange rates yield similar results. The (1,-1) restriction is rejected in 57 of the 79 cointegration cases. This leads to the conclusion that 12 percent of the yen-based exchange rate forecast series meet the consistency criterion.

4.4 Discussion

Several aspects of the foregoing analysis merit discussion. To begin with, even at long horizons, the performance of the structural models is less than impressive along the MSE dimension. This result is consistent with those in other recent studies, although we have documented this finding for a wider set of models and specifications. Groen (2000) restricted his attention to a flexible price monetary model, while Faust *et al.* (2003) examined a portfolio balance model as well; both remained within the MSE evaluation framework.

Setting aside issues of statistical significance, it is interesting that long horizon error correction specifications are over-represented in the set of cases where a random walk is outperformed. Indeed, the purchasing power parity and interest rate parity models at the 20-quarter horizon account for many of the MSE ratio entries that are less than unity (13 of 23 error correction dollar-based entries, and 14 of 33 yen-based entries).

The fact that out-performance of the random walk benchmark occurs at the long horizons is consistent with other recent work. As Engel and West (2003) have noted, if the discount factor is near unity, and at least one of the driving variables follows a near unit root process, the exchange rate may appear to be very close to a random walk, and exhibit very little predictability at short horizons. But at longer horizons, this characterization may be less apt, especially if it is the case that exchange rates are not weakly exogenous with respect to the cointegrating vector.¹⁶

Expanding the set of criteria does yield some interesting surprises. In particular, the direction of change statistics indicate more evidence that structural models can outperform a random walk. However, the basic conclusion that no specific economic model is consistently

¹⁶ Engel and West (2003) use Granger causality tests to conduct their inference. Since they fail to find cointegration of the exchange rate with the monetary fundamentals, they do not conduct tests for weak exogeneity. However, other studies, spanning different sample periods and models, have detected both cointegration; see for instance MacDonald and Marsh (1999) and Chinn (1997), among others.

more successful than the others remains intact. This, we believe, is a new finding.¹⁷

Even if we cannot glean from this analysis a consistent “winner”, it may still be of interest to note the best and worst performing combinations of model/specification/currency. The interest rate parity model at the 20-quarter horizon for the Canadian dollar-yen exchange rate (post-1982) performs well according to the MSE criterion, with a MSE ratio of 0.48 (p-value of 0.04). Figure 3 plots the actual Canadian dollar-yen exchange rate, 20-quarters interest rate parity and random walk forecasts. The graph shows that forecast performance of the interest parity model varies across time. Forecasts from the interest rate parity condition track the actual exchange rate movements pretty well during 1985-1990 and 1993-1997. The random walk, however, forecasts better in the other periods.

Note, however, that the superior performance of a particular model/specification/currency combination does not necessarily carry over from one out-of-sample period to the other. That is the lowest dollar-based MSE ratio during the 1987q2-2000q4 period is for the Deutsche mark composite model in first differences, while the corresponding entry for the 1983q1-2000q4 period is the for the yen interest parity model.

Aside from the purchasing power parity specification, the worst performances are associated with first-difference specifications; in this case the highest MSE ratio is for the first differences specification of the composite model at the 20-quarter horizon for the pound- dollar exchange rate over the post-Louvre period. However, the other catastrophic failures in prediction performance are distributed across the various models estimated in first differences, so (taking into account the fact that these predictions utilize *ex post* realizations of the right hand side variables) the key determinant in this pattern of results appears to be the difficulty in estimating *stable* short run dynamics.

That being said, we do not wish to overplay the stability of the long run estimates we obtain. In a companion study (Cheung, Chinn and Garcia Pascual, 2003), we do not find a definite relationship between in-sample fit and out-of-sample forecast performance. Moreover,

¹⁷ An interesting research topic, as suggested by a referee, is to investigate whether the forecasts of these models can generate profitable trading strategies. The issue, which is beyond the scope of the current exercise, would involve obtaining different vintages of macro data to use as future variables in generating forecasts.

the estimates exhibit wide variation over time. Even in cases where the structural model does reasonably well, there is quite substantial time-variation in the estimate of the rate at which the exchange rate responds to disequilibria. A similar observation applies to the coefficient estimates of the parameters of the cointegrating vector. Thus, an interesting future research topic is to further investigate the effect of imposing parameter restrictions and the interaction between parameter instability and forecast performance.

One question that might occur to the reader is whether our results are sensitive to the out-of-sample period we have selected. In fact, it is possible to *improve* the performance of the models according to a MSE criterion by selecting a shorter out-of-sample forecasting period. In another set of results (Cheung, Chinn and Garcia Pascual, 2003), we implemented the same exercises for a 1993q1-2000q4 period, and found somewhat greater success for dollar-based rates according to the MSE criterion, and somewhat less success along the direction of change dimension. We believe that the difference in results is an artifact of the long upswing in the dollar during the 1990's that gives an advantage to structural models over the no-change forecast embodied in the random walk model when using the most recent eight years of the floating rate period as the prediction sample. This conjecture is buttressed by the fact that the yen-based exchange rates did not exhibit a similar pattern of results. Thus, in using fairly long out-of-sample periods, as we have done, we have given maximum advantage to the random walk characterization.

5. Concluding Remarks

This paper has systematically assessed the predictive capabilities of models developed during the 1990's. These models have been compared along a number of dimensions, including econometric specification, currencies, out-of-sample prediction periods, and differing metrics. The differences in forecast evaluations from different evaluation criteria, for instance, illustrate the potential limitation of using a single criterion such as the popular MSE metric. Clearly, the evaluation criteria could have been expanded further. For instance, recently Abhyankar et al. (2002) have proposed a utility-based metric based upon the portfolio allocation problem. They find that the relative performance of the structural model increases when using this metric. To the extent that this is a general finding, one can interpret our approach as being conservative with respect to finding superior model performance.¹⁸

At this juncture, it may also be useful to outline the boundaries of this study with respect to models and specifications. Firstly, we have only evaluated linear models, eschewing functional nonlinearities (Meese and Rose, 1991; Kilian and Taylor, 2003) and regime switching (Engel and Hamilton, 1990). Nor have we employed panel regression techniques in conjunction with long run relationships, despite the fact that recent evidence suggests the potential usefulness of such approaches (Mark and Sul, 2001). Further, we did not undertake systems-based estimation that has been found in certain circumstances to yield superior forecast performance, even at short horizons (e.g., MacDonald and Marsh, 1997). Such a methodology would have proven much too cumbersome to implement in the cross-currency recursive framework employed in this study. Finally, the current study examines the forecasting performance and the results are not necessarily indicative of the abilities of these models to explain exchange rate behavior. For instance, Clement and Hendry (2001) show that an incorrect but simple model may outperform a correct model in forecasting. Consequently, one could view this exercise as a first pass examination of these newer exchange rate models.

In summarizing the evidence from this extensive analysis, we conclude that the answer to the question posed in the title of this paper is a bold "perhaps." That is, the results do not point to any given model/specification combination as being very successful. On the other hand, some

¹⁸ McCracken and Sapp (2002) forward an encompassing test for nested models. Since not all of our models can be nested in a general specification, we do not implement this approach.

models seem to do well at certain horizons, for certain criteria. And indeed, it may be that one model will do well for one exchange rate, and not for another. For instance, the productivity model does well for the mark-yen rate along the direction of change and consistency dimensions (although not by the MSE criterion); but that same conclusion cannot be applied to any other exchange rate. Perhaps it is in this sense that the results from this study set the stage for future research.

Appendix 1: Data

Unless otherwise stated, we use seasonally-adjusted quarterly data from the *IMF International Financial Statistics* ranging from the second quarter of 1973 to the last quarter of 2000. The exchange rate data are end of period exchange rates. The output data are measured in constant 1990 prices. The consumer and producer price indexes also use 1990 as base year. Inflation rates are calculated as 4-quarter log differences of the CPI. Real interest rates are calculated by subtracting the lagged inflation rate from the 3 month nominal interest rates.

The three-month, annual and five-year interest rates are end-of-period constant maturity interest rates, and are obtained from the IMF country desks. See Meredith and Chinn (1998) for details. Five year interest rate data were unavailable for Japan and Switzerland; hence data from Global Financial Data <http://www.globalfindata.com/> were used, specifically, 5-year government note yields for Switzerland and 5-year discounted bonds for Japan.

The productivity series are labor productivity indices, measured as real GDP per employee, converted to indices (1995=100). These data are drawn from the Bank for International Settlements database.

The net foreign asset (NFA) series is computed as follows. Using stock data for year 1995 on NFA (Lane and Milesi-Ferretti, 2001) at <http://econserv2.bess.tcd.ie/plane/data.html>, and flow quarterly data from the IFS statistics on the current account, we generated quarterly stocks for the NFA series (with the exception of Japan, for which there is no quarterly data available on the current account).

To generate quarterly government debt data we follow a similar strategy. We use annual debt data from the IFS statistics, combined with quarterly government deficit (surplus) data. The data source for Canadian government debt is the Bank of Canada. For the UK, the IFS data are updated with government debt data from the public sector accounts of the UK Statistical Office (for Japan and Switzerland we have very incomplete data sets, and hence no composite models are estimated for these two countries).

Appendix 2: Evaluating Forecast Accuracy

The Diebold-Mariano statistics (Diebold and Mariano, 1995) are used to evaluate the forecast performance of the different model specifications relative to that of the *naive* random walk. Given the exchange rate series x_t and the forecast series y_t , the loss function L for the mean square error is defined as:

$$(A1) \quad L(y_t) = (y_t - x_t)^2.$$

Testing whether the performance of the forecast series is different from that of the naive random walk forecast z_t , it is equivalent to testing whether the population mean of the loss differential series d_t is zero. The loss differential is defined as

$$(A2) \quad d_t = L(y_t) - L(z_t).$$

Under the assumptions of covariance stationarity and short-memory for d_t , the large-sample statistic for the null of equal forecast performance is distributed as a standard normal, and can be expressed as

$$(A3) \quad \frac{\bar{d}}{\sqrt{2\pi \sum_{\tau=-(T-1)}^{(T-1)} l(\tau/S(T)) \sum_{t=|\tau|+1}^T (d_t - \bar{d})(d_{t-|\tau|} - \bar{d})}},$$

where $l(\tau/S(T))$ is the lag window, $S(T)$ is the truncation lag, and T is the number of observations. Different lag-window specifications can be applied, such as the Barlett or the quadratic spectral kernels, in combination with a data-dependent lag-selection procedure (Andrews, 1991).

For the direction of change statistic, the loss differential series is defined as follows: d_t takes a value of one if the forecast series correctly predicts the direction of change, otherwise it will take a value of zero. Hence, a value of \bar{d} significantly larger than 0.5 indicates that the forecast has the ability to predict the direction of change; on the other hand, if the statistic is significantly less than 0.5, the forecast tends to give the wrong direction of change. In large samples, the studentized version of the test statistic,

$$(A4) \quad \frac{\bar{d} - 0.5}{\sqrt{0.25/T}},$$

is distributed as a standard Normal.

Table 1: The MSE Ratios from the Dollar-Based Exchange Rates

Specification	Horizon	Sample 1: 1987 Q2 - 2000 Q4					Sample 2: 1983 Q1-2000 Q4

Note: The results are based on dollar-based exchange rates and their forecasts. Each cell in the Table has two entries. The first one is the MSE ratio (the MSEs of a structural model to the random walk specification). The entry underneath the MSE ratio is the p-value of the hypothesis that the MSEs of the structural and random walk models are the same (Diebold and Mariano, 1995). The notation used in the table is ECM: error correction specification; FD: first-difference specification; PPP: purchasing power parity model; S-P: sticky-price model; IRP: interest rate parity model; PROD: productivity differential model; and COMP: composite model. The forecasting horizons (in quarters) are listed under the heading "Horizon." The results for the post-Louvre Accord forecasting period are given under the label "Sample 1" and those for the post-1983 forecasting period are given under the label "Sample 2." A "." indicates the statistics are not generated due to unavailability of data.

Note: Table 3 reports the proportion of forecasts that correctly predict the direction of the dollar exchange rate movement. Underneath each direction of change statistic, the p-values for the hypothesis that the reported proportion is significantly different from $\frac{1}{2}$ is listed. When the statistic is significantly larger than $\frac{1}{2}$, the forecast is said to have the ability to predict the direction of change. If the statistic is significantly less than $\frac{1}{2}$, the forecast tends to give the wrong direction of change. The notation used in the table is ECM: error correction specification; FD: first-difference specification; PPP: purchasing power parity model; S-P: sticky-price model; IRP: interest rate parity model; PROD: productivity differential model; and COMP: composite model. The forecasting horizons (in quarters) are listed under the heading "Horizon." The results for the post-Louvre Accord forecasting period are given under the label "Sample 1" and those for the post-1983 forecasting period are given under the label "Sample 2." A "." indicates the statistics are not generated due to unavailability of data.

Note: The likelihood ratio test statistic for the restriction of (1, -1) on the cointegrating vector and its p-value are reported. The test is only applied to the cointegration cases present in Table 5. The notation used in the table is ECM: error correction specification; FD: first-difference specification; PPP: purchasing power parity model; S-P: sticky-price model; IRP: interest rate parity model; PROD: productivity differential model; and COMP: composite model. The forecasting horizons (in quarters) are listed under the heading "Horizon." The results for the post-Louvre Accord forecasting period are given under the label "Sample 1" and those for the post-1983 forecasting period are given under the label "Sample 2." A "." indicates the statistics are not generated due to unavailability of data.

Note: Note: The likelihood ratio test statistic for the restriction of (1, -1) on the cointegrating vector and its p-value are reported. The test is only applied to the cointegration cases present in Table 6. The notation used in the table is ECM: error correction specification; FD: first-difference specification; PPP: purchasing power parity model; S-P: sticky-price model; IRP: interest rate parity model; PROD: productivity differential model; and COMP: composite model. The forecasting horizons (in quarters) are listed under the heading "Horizon." The results for the post-Louvre Accord forecasting period are given under the label "Sample 1" and those for the post-1983 forecasting period are given under the label "Sample 2."
