Plants acclimate to temperature by adjusting their photosynthetic capacity over weeks to months. However, most evidence for photosynthetic acclimation derives from leaf-scale experiments. Here we address the scarcity of evidence for canopy-scale photosynthetic acclimation by examining the correlation between maximum photosynthetic rates ( $A_{\max,2,000}$ ) and growth temperature ( $\overline{T_{\text{air}}}$ ) across a range of concurrent temperatures and canopy foliage quantity, using data from >200 eddy covariance sites. We detect widespread thermal acclimation of canopy-scale photosynthesis, demonstrated by enhanced  $A_{\max,2,000}$  under higher  $\overline{T_{\text{air}}}$ , across flux sites with adequate water availability. A 14-day period is identified as the most relevant timescale for acclimation across all sites, with a range of 12–25 days for different plant functional types. The mean apparent thermal acclimation rate across all ecosystems is 0.41 (–0.38–1.04 for 5th–95th percentile range)  $\mu\text{mol m}^{-2} \text{s}^{-1} \text{ } ^\circ\text{C}^{-1}$ , with croplands showing the largest acclimation rates and grasslands the lowest. Incorporating an optimality-based prediction of leaf photosynthetic capacities into a biochemical photosynthesis model is shown to improve the representation of thermal acclimation. Our results underscore the critical need for enhanced understanding and modelling of canopy-scale photosynthetic capacity to accurately predict plant responses to warmer growing seasons.

The carbon uptake capacity of terrestrial ecosystem photosynthesis shows large spatiotemporal variation<sup>1</sup>. Air temperature ( $T_{\text{air}}$ ) is one of the key factors determining this variation<sup>2</sup>. Given recent warming of 0.1–0.3 °C per decade<sup>3</sup>, a better understanding of ecosystem responses to  $T_{\text{air}}$  is needed. While the instantaneous temperature dependence of photosynthesis has been a major focus of research<sup>4–6</sup> and is represented in vegetation and land surface models<sup>7–9</sup>, the slower process known as thermal acclimation, through which plants maintain or enhance their photosynthetic efficiency in response to warmer growth temperatures<sup>10–14</sup>, is less well understood<sup>15,16</sup>. Several studies have indicated that leaves acclimate to thermal growing conditions within weeks to months, although the relevant timescales for different

plant types remain uncertain<sup>17–20</sup>. The potential mechanisms of this (non-genetic) acclimation include changes in key biochemical parameters (electron-transport potential and carboxylation capacity)<sup>12,14,21</sup>, the sensitivity of stomatal conductance to atmospheric vapour pressure deficit (VPD)<sup>22–24</sup> and enzymatic heat tolerance<sup>10,14</sup>.

Widespread evidence of thermal acclimation at the leaf and canopy scales indicates that the optimal temperature ( $T_{\text{opt}}$ ) of photosynthesis adjusts in accordance with the prevailing  $T_{\text{air}}$  averaged over the time frame most relevant for acclimation ( $\overline{T_{\text{air}}}$ )<sup>12,14,21,25,26</sup>. Yet the extent to which the maximum carbon assimilation rate under high light ( $A_{\max}$ ) acclimates to  $\overline{T_{\text{air}}}$  under natural conditions is less clear, particularly since most experiments are conducted on seedlings under highly

controlled growth conditions<sup>13,27</sup>. Given that  $T_{opt}$  is well-documented to increase with rising  $\overline{T_{air}}$ , it is crucial to understand whether  $A_{max}$  can also acclimate to  $\overline{T_{air}}$ , since only their simultaneous enhancement can lead to consistent increases in photosynthesis<sup>28,29</sup>. While some process-based photosynthetic models have incorporated  $T_{opt}$  acclimation,  $A_{max}$  acclimation has not been adequately represented in models<sup>30,31</sup>. Demonstrating the presence of thermal acclimation at the canopy scale, quantifying its relevant timescales and rates across ecosystems and assessing the accuracy of photosynthetic models in representing these acclimation processes are essential for understanding how thermal acclimation can mitigate the potentially detrimental effects of warming on the future terrestrial carbon sink<sup>16</sup>.

In this study, we define evidence for thermal acclimation of canopy photosynthesis as a positive adjustment in canopy-scale  $A_{max}$  in response to elevated  $\overline{T_{air}}$ . Following the definition used in leaf-scale studies<sup>32</sup>, canopy-scale  $A_{max}$  is defined as the photosynthetic assimilation rate of the canopy measured under high light, ample water and ambient  $CO_2$ . We derive  $A_{max}$  from light response curves of half-hourly or hourly eddy covariance carbon fluxes obtained from >200 FLUXNET2015 flux sites (Methods). While canopy-scale  $T_{opt}$  has been shown to acclimate to elevated  $\overline{T_{air}}$  in several previous studies<sup>25,26,33</sup>, our focus here is solely on thermal acclimation of canopy-scale  $A_{max}$ . To facilitate consistent analysis across different light conditions, we standardize  $A_{max}$  to photosynthetic photon flux density (PPFD) equivalent to 2,000  $\mu mol m^{-2} s^{-1}$  (denoted as  $A_{max,2,000}$ ; Methods). Given the limited number of  $A_{max,2,000}$  samples for individual flux sites, we infer the thermal acclimation of  $A_{max,2,000}$  across spatial gradients by leveraging the large range of climates sampled by the FLUXNET2015 sites. We examine the correlation between  $A_{max,2,000}$  and  $\overline{T_{air}}$  when averaged over different time windows to identify the most relevant timescale ( $\tau$ ) for thermal acclimation, as indicated by peak correlation. Finally, we evaluate a biochemical model of canopy-scale  $C_3$  photosynthesis<sup>4,31</sup>, incorporating recent advances in parameterizing temperature dependence acclimation<sup>12</sup> and modelled optimality-based leaf photosynthetic capacity<sup>34</sup>, to assess its ability to reproduce the observed thermal acclimation rates.

## Results and discussion

### Evidence for thermal acclimation of canopy photosynthesis

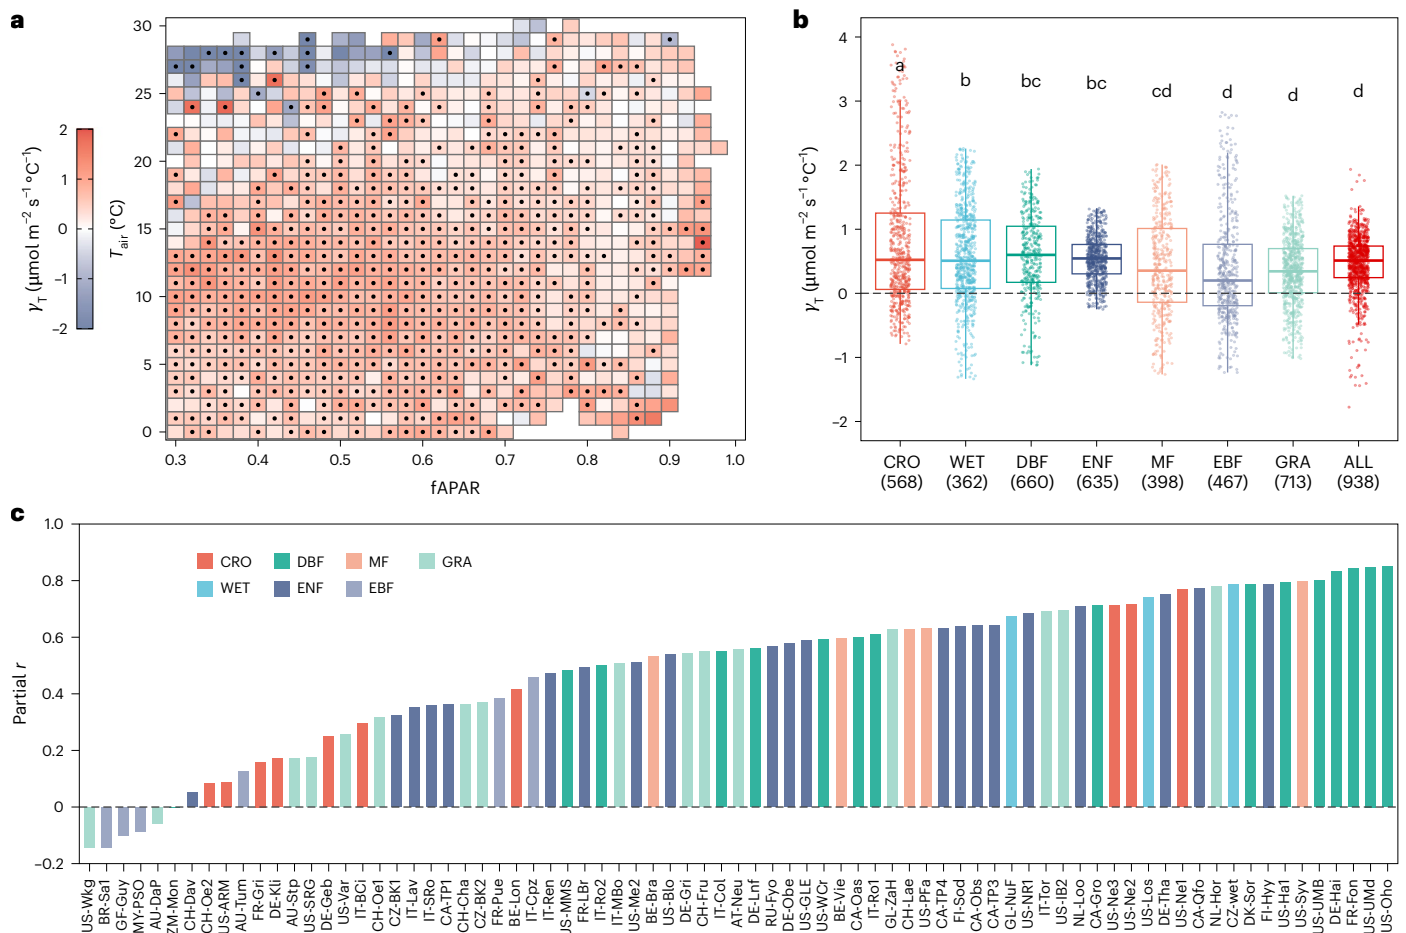

By binning  $T_{air}$  and the fraction of absorbed photosynthetically active radiation (fAPAR) to control for the confounding effects of concurrent temperature and seasonal changes in canopy foliage quantity and the development of the photosynthetic system on  $A_{max,2,000}$ , our analysis reveals a pervasive positive correlation between  $A_{max,2,000}$  and  $\overline{T_{air}}$  (see Methods for the derivations of  $\tau$  for each plant functional type (PFT)) under conditions of adequate water availability as indicated by a high ratio of actual to potential evapotranspiration (ET/PET) (Fig. 1). This correlation is observed both spatially across multiple sites (Fig. 1a) and temporally within individual sites (Fig. 1c). We use linear mixed-effect models (LLMs) to obtain the regression coefficients of  $\overline{T_{air}}$  when estimating  $A_{max,2,000}$  ( $A_{max,2,000} \sim \overline{T_{air}} + (I|site)$ ), which we define as the apparent thermal acclimation rate ( $\gamma_T$ ,  $\mu mol CO_2 m^{-2} s^{-1} ^\circ C^{-1}$ ). The concept of apparent rates is used here as the  $A_{max,2,000}$  response rate to  $\overline{T_{air}}$  may be influenced by other covarying environmental conditions<sup>19</sup>, including the growth PPFD (PPFD) and VPD<sup>35</sup> (Supplementary Fig. 1). To account for the potential impact of adaptation<sup>12</sup>—the modification of  $A_{max,2,000} - \overline{T_{air}}$  relationships across different species and populations within a species growing at different sites—sites are treated as random intercepts within the LLMs (see Extended Data Fig. 1a for an example). Cropland sites are included in the PFT-based analyses but excluded from cross-site analyses.

Detectability of thermal acclimation in canopy photosynthesis is quantified as the percentage of  $T_{air}$ -fAPAR bins showing a positive  $\gamma_T$ . Our cross-site analysis for natural ecosystems finds positive  $\gamma_T$  values in 87% of the  $T_{air}$ -fAPAR bins (938 in total) (Fig. 1a), with 65% of these

positive relationships being statistically significant ( $P < 0.05$ ), indicating that thermal acclimation is widespread across biomes. Averaged over all  $T_{air}$ -fAPAR bins,  $\gamma_T$  is  $0.41 \pm 0.62$  (mean  $\pm$  s.d.)  $\mu mol CO_2 m^{-2} s^{-1} ^\circ C^{-1}$ , with a 5th to 95th percentile range of  $-0.38$ – $1.04 \mu mol CO_2 m^{-2} s^{-1} ^\circ C^{-1}$ . The average of positive  $\gamma_T$  values is  $0.57 \pm 0.30 m^{-2} s^{-1} ^\circ C^{-1}$ . The PFT-based analysis also shows strong evidence of thermal acclimation, with mean  $\gamma_T$  values decreasing as follows: croplands (CRO, 0.81) > deciduous broadleaf forests (DBF, 0.58) > wetlands (WET, 0.57) > evergreen needle-leaf forests (ENF, 0.54) > mixed forests (MF, 0.42) > evergreen broadleaf forests (EBF, 0.39) > grasslands (GRA, 0.34) (Fig. 1b and Extended Data Fig. 3). Furthermore, 92% of FLUXNET2015 sites with observations spanning 6 years or more show positive partial correlations between  $A_{max,2,000}$  and  $\overline{T_{air}}$  after controlling for potential confounding factors of  $\overline{PPFD}$ ,  $T_{air}$  and fAPAR (Fig. 1c), indicating widespread acclimation to seasonal temperature variations at individual flux sites. Sites showing a negative correlation are mainly located in the tropics (Extended Data Fig. 4a).

The potential confounding effect of factors other than  $\overline{T_{air}}$  on  $A_{max,2,000}$  appears to be minimal as the detectability of thermal acclimation remains high across diverse conditions. The binning approach has proved effective in previous studies for analysing relationships between variables of interest while controlling for confounding factors<sup>35–37</sup>. The effects of concurrent  $T_{air}$  and seasonal changes in fAPAR on  $A_{max,2,000}$  under  $T_{air}$ -fAPAR bin pairs are shown to be very weak (Extended Data Fig. 1b,c). To ensure our findings are not skewed by light acclimation<sup>35</sup>, we consider the detectability of thermal acclimation when incorporating  $\overline{PPFD}$  into LLMs (89%; Extended Data Fig. 2a) and controlling for  $\overline{PPFD}$  through partial correlation (85%; Extended Data Fig. 2b). The impact of VPD is probably limited, as its negative effect on  $A_{max}$  has been accounted for during the derivation of  $A_{max}$  (equation (3) in Methods) and has been further mitigated by ET/PET filtering. After filtering, there is a positive relationship between  $A_{max,2,000}$  and VPD (Supplementary Fig. 1c). Any negative VPD impact on  $A_{max,2,000}$  is expected to reinforce, not diminish, the observed widespread thermal acclimation. Diffuse radiation is expected to increase  $A_{max}$  by penetrating into deep canopy layers where light is limited<sup>38,39</sup>. However, this effect does not confound the relationship between  $A_{max,2,000}$  and  $\overline{T_{air}}$  (Supplementary Fig. 2) since the conditions of diffuse radiation on the days of  $A_{max}$  measurements do not necessarily show a strong positive correlation with  $\overline{T_{air}}$  (Supplementary Table 1). Additionally, our findings remain robust with respect to the metric choice; detectability is 88% when  $A_{max}$  is unstandardized to a specific PPFD level and 87% when PFTs are treated as random effects within LLMs (Extended Data Fig. 2c,d).

Thermal acclimation capability can be influenced by the level and variability of  $\overline{T_{air}}$  as well as by species and PFTs<sup>27,40–42</sup>. We observe negative effects of  $\overline{T_{air}}$  on  $A_{max,2,000}$  when fAPAR falls below 0.7 and  $T_{air}$  exceeds 25 °C (Fig. 1a). Limited transpiration, due to a low amount of leaves, may not cool the canopy sufficiently under elevated  $\overline{T_{air}}$ , making ribulose-1,5-bisphosphate (RuBP) regeneration a limiting process for canopy photosynthesis at high canopy temperature<sup>13</sup>. The reduction in  $A_{max,2,000}$  with  $\overline{T_{air}}$  may be attributed to reduced stomatal conductance under high VPD<sup>23</sup> (Supplementary Fig. 3f) and/or decreased maximum quantum yield of photosystem II in response to elevated temperature<sup>5,34,43</sup>. Additionally, under these conditions, the range of  $\overline{T_{air}}$  (the difference between the 90th and 10th percentiles; 3.8 °C) is significantly narrower than among the rest (8.4 °C) (two-tailed  $t$ -test,  $P < 0.01$ ) (Supplementary Fig. 3b). Our site-level analyses also show that the correlation between  $A_{max,2,000}$  and  $\overline{T_{air}}$  is positively associated with  $\overline{T_{air}}$  variability and negatively with  $T_{air}$  (Extended Data Fig. 4b,c), which aligns with previous studies indicating that plants grown under low  $\overline{T_{air}}$  variability and/or high  $\overline{T_{air}}$  show reduced acclimation potential<sup>27,40,44</sup>. Conversely, leaf-scale experiments indicate that the acclimation rates of light-saturated net assimilation rates ( $A_{net}$ ) under different measurement temperatures are similar<sup>41</sup>, suggesting a limited

**Fig. 1** Relationships between  $A_{\max,2,000}$  and  $\overline{T_{\text{air}}}$ . **a**,  $\gamma_T$  values over fAPAR and  $T_{\text{air}}$  bins across flux sites. Black dots indicate significant (two-sided,  $P < 0.05$ ) correlations between  $A_{\max,2,000}$  and  $\overline{T_{\text{air}}}$  in the LMM ( $A_{\max,2,000} \approx \overline{T_{\text{air}}} + (1/\text{site})$ ). **b**, PFT-specific  $\gamma_T$  values. PFTs are arranged in descending order on the basis of their mean  $\gamma_T$  values. In the box plots, the central lines represent the median  $\gamma_T$  values, the upper and lower box limits represent the 75th and 25th percentiles, and the upper and lower whiskers extend to 1.5 times the interquartile range, respectively. Letters represent statistically significant differences in the average

$\gamma_T$  values as determined by Tukey's honestly significant difference test (two-sided,  $P < 0.05$ ), which adjusts for multiple comparisons. The numbers in parentheses represent the sample size for each PFT. **c**, Partial correlation coefficients (partial  $r$ ) between  $A_{\max,2,000}$  and  $\overline{T_{\text{air}}}$ , when controlling for PPFD,  $T_{\text{air}}$  and fAPAR, across individual longer-term (>5 yr) flux sites. Colours in **b** and **c** indicate different PFTs, including CRO, DBF, EBF, ENF, GRA, MF, WET and all natural biomes combined (ALL).

impact of  $T_{\text{air}}$  on  $A_{\max,2,000}$ . Moreover, EBF is the dominant PFT for the bin pairs with high  $T_{\text{air}}$  (Supplementary Fig. 4b). There is some evidence that tropical evergreen forests have a limited capability for physiological acclimation because these forests are adapted to relatively stable thermal conditions and/or thrive under high  $\overline{T_{\text{air}}}$  that is beyond the range limit for acclimation<sup>33,45,46</sup>. The under-representation of EBF in the FLUXNET2015 database<sup>47</sup> may also lead to uncertainties in the estimation of  $\gamma_T$  for this biome.

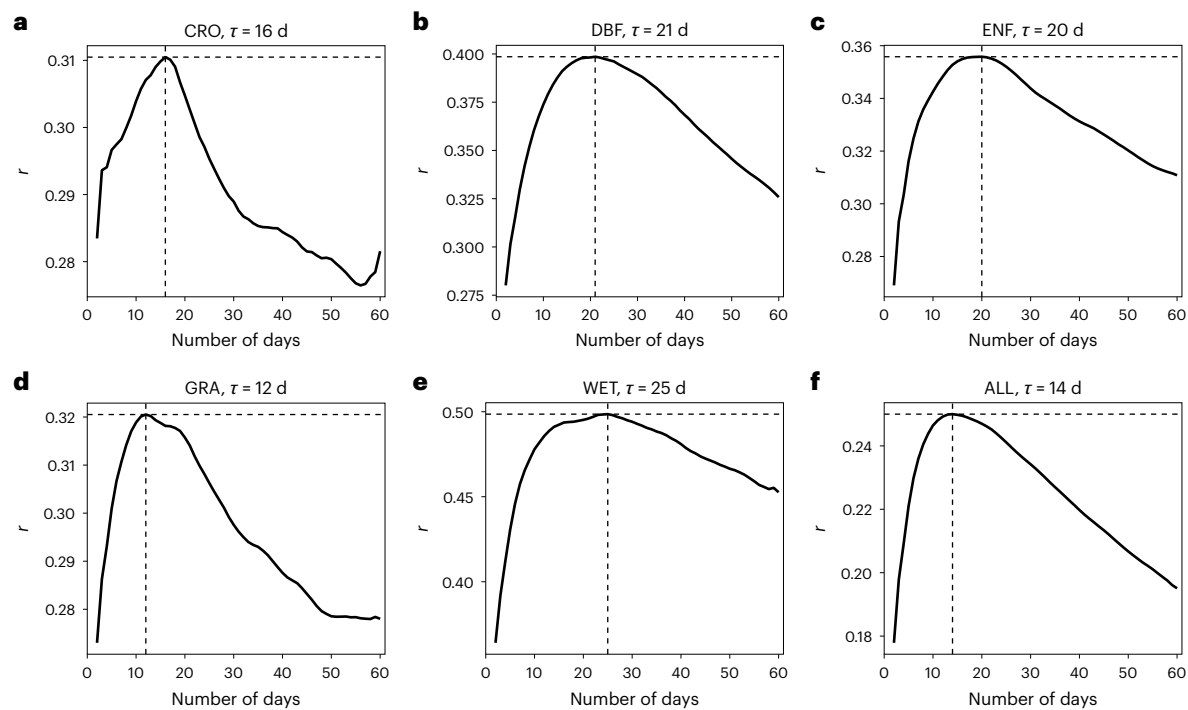

The observed widespread thermal acclimation of  $A_{\max,2,000}$  (Fig. 1) contrasts with the varying sign of the response of leaf  $A_{\text{net}}$  to  $\overline{T_{\text{air}}}$ , which can be positive, negative or neutral<sup>27,40,41,48,49</sup>. This discrepancy may stem from the fact that, unlike  $A_{\max}$ ,  $A_{\text{net}}$  is not necessarily measured under ample water conditions<sup>27,32</sup> and water stress is known to affect the capacities of plant thermal acclimation<sup>22</sup>. In water-limited situations, plants typically reduce water loss through transpiration by decreasing stomatal conductance<sup>50</sup>, resulting in decreased  $A_{\text{net}}$ .

### Timescale of thermal acclimation of canopy photosynthesis

The timescale for canopy photosynthetic acclimation, as measured by the correlation coefficient ( $r$ ) between  $A_{\max,2,000}$  and  $\overline{T_{\text{air}}}$  over different periods within concurrent  $T_{\text{air}}$  and fAPAR bins, varies across PFTs (Fig. 2

and Supplementary Fig. 5), increasing from GRA (12 d) to CRO (16 d), ENF (20 d), DBF (21 d) and finally WET (25 d). The  $\tau$  value obtained across all sites is 14 d (Fig. 2f). For EBF, an optimal  $\tau$  cannot be determined using  $A_{\max,2,000}$ , even over an extended period of 180 d (Supplementary Fig. 5a). The enhanced vegetation index (EVI) that is derived from reflectance data in the near-infrared, red and blue spectral bands can characterize canopy structure, which closely relates with the canopy photosynthetic capacity<sup>51</sup>. We use a  $\tau$  value of 13 d for EBF as identified by remote-sensing EVI for subsequent analysis (Methods and Supplementary Fig. 5b).

Our estimate of an average of 14 d as  $\tau$  for thermal acclimation of canopy photosynthesis falls within the range of leaf-scale  $\tau$ , which varies from days to months depending on species and growth conditions<sup>10,18,20,52</sup>. Studies that identify  $\tau$  for photosynthetic acclimation using observational data across a spectrum of time frames are rare. A modelling study reports that a 15 day timescale for acclimation optimally predicts hourly eddy covariance flux measurements<sup>53</sup>. It is important to note that  $A_{\max,2,000}$  can show positive correlations with  $\overline{T_{\text{air}}}$  over both the optimal  $\tau$  value and other time frames close to the optimal, due to the potentially high correlation among  $\overline{T_{\text{air}}}$  calculated over different short-term periods.

**Fig. 2 | Timescales for thermal acclimation of canopy photosynthesis.** **a–f**, The timescale for CRO (**a**), DBF (**b**), ENF (**c**), GRA (**d**), WET (**e**) and ALL (**f**). The x axes represent the number of days over which  $T_{\text{air}}$  is averaged to derive  $T_{\text{air}}$ .

The y axes represent the 5-day moving average of positive Pearson correlation coefficients ( $r$ ) between  $A_{\text{max},2,000}$  and  $T_{\text{air}}$  over FAPAR and  $T_{\text{air}}$  bins. The  $\tau$  value is the length of time frame for which  $r$  peaks.

The timescale  $\tau$  for photosynthetic acclimation to a changing environment reflects a trade-off between potential benefits (for example, carbon assimilation) and costs (for example, resource re-allocation)<sup>48</sup>. A rapid adjustment in photosynthetic capacities is expected to enhance photosynthetic performance but is accompanied by higher costs in energy and resources<sup>15</sup>. The shorter  $\tau$  observed in GRA and CRO are in line with the expectation that fast-growing plants with a high generation rate of new leaves might show shorter  $\tau$  than slow-growing species due to their greater physiological plasticity<sup>54</sup>. Conversely, we found larger  $\tau$  values in forests and WET, indicating that these ecosystems require more time for acclimation; however, this longer acclimation period is potentially compensated for by a higher acclimation rate (Fig. 1b). The PFT-specific and cross-site  $\tau$  values for the canopy photosynthetic capacity provide a credible basis for explicitly incorporating the timescale of thermal acclimation into vegetation and land surface models.

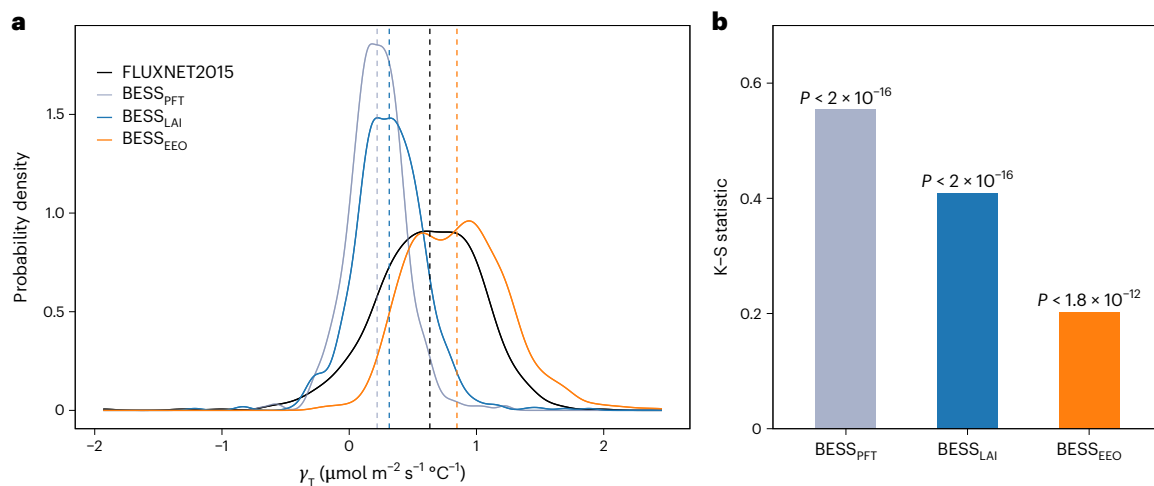

### Representing acclimation in photosynthesis models

We further explore the representation of  $A_{\text{max},2,000}$  thermal acclimation in a biochemical model for  $C_3$  canopy photosynthesis incorporated in the Breathing Earth System Simulator (BESS)<sup>55</sup>, based on the Farquhar–von Caemmerer–Berry (FvCB) model<sup>4</sup> (Methods). We test three alternative approaches, each under different resource-use allocation assumptions, to estimate maximum carboxylation rates ( $V_{\text{cmax}}$ ,  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) standardized to 25 °C ( $V_{\text{cmax}}^{25\text{C}}$ ). These approaches are: (1) assuming a temporally constant and PFT-specific  $V_{\text{cmax}}^{25\text{C}}$  ( $V_{\text{cmax,PFT}}^{25\text{C}}$ ), where plants do not actively regulate  $V_{\text{cmax}}^{25\text{C}}$  through the growing seasons; (2) scaling leaf  $V_{\text{cmax}}^{25\text{C}}$  by canopy phenology, as indicated by leaf area index (LAI) (LAI-scaled  $V_{\text{cmax,LAI}}^{25\text{C}}$ ); and (3) modelling acclimation to prevailing environments based on the eco-evolutionary optimality (EEO) theory<sup>34,56</sup> ( $V_{\text{cmax,EEO}}^{25\text{C}}$ ) (Methods and Supplementary Texts 1 and 2). The FvCB model as applied here incorporates recent advances in parameterizing the temperature dependence of leaf photosynthetic capacities to represent  $T_{\text{opt}}$  acclimation<sup>12</sup> (Supplementary Text 1). We run the model using the site-level forcings from the FLUXNET2015

database and derive  $A_{\text{max},2,000}$  by setting PPFD equivalent to 2,000  $\mu\text{mol m}^{-2} \text{s}^{-1}$ . Canopy temperature is a key uncertainty in modelling canopy-scale photosynthesis<sup>30,57</sup>. We evaluate model performance using three temperature approximations, including  $T_{\text{air}}$ , aerodynamic surface temperature and radiometric surface temperature<sup>58</sup>. We finally use  $T_{\text{air}}$  to represent canopy temperature because it has comparable performance to the other two approximations and greater data availability (Supplementary Text 1 and Supplementary Fig. 8). For further analysis, we select estimated  $A_{\text{max},2,000}$  values from 65  $C_3$  sites excluding CRO and water-limited sites, where all three model variants show acceptable accuracy in estimating  $A_{\text{max},2,000}$  (coefficient of determination ( $R^2$ ) > 0.5) (Supplementary Table 2).

The BESS model variant incorporating optimality-based  $V_{\text{cmax,EEO}}^{25\text{C}}$  more closely approximates the observed  $\gamma_T$  compared to the other two variants,  $V_{\text{cmax,PFT}}^{25\text{C}}$  (BESS<sub>PFT</sub>) and  $V_{\text{cmax,LAI}}^{25\text{C}}$  (BESS<sub>LAI</sub>) (Fig. 3). The Kolmogorov–Smirnov (K–S) test indicates that the cumulative distribution functions of  $\gamma_T$  between BESS<sub>EEO</sub> and FLUXNET2015 observations are more closely aligned, despite significant differences between all three BESS model distributions and observations ( $P < 0.05$ ) (Fig. 3b). BESS<sub>PFT</sub> and BESS<sub>LAI</sub> underestimate the median observed  $\gamma_T$  by 65% and 50%, respectively, while BESS<sub>EEO</sub> overestimates it by 34% (Fig. 3a).

The considerable underestimation of  $\gamma_T$  by BESS<sub>PFT</sub> and BESS<sub>LAI</sub> highlights the limitation in process-based photosynthetic models that incorporate only  $T_{\text{opt}}$  acclimation. To capture  $\gamma_T$  accurately, process-based models must also integrate seasonal variations in photosynthetic capacities resulting from thermal acclimation. The overestimation by BESS<sub>EEO</sub> can be attributed to its higher predicted detectability (99%) of thermal acclimation than observed (92%) (Fig. 3a). When calculating  $V_{\text{cmax,EEO}}^{25\text{C}}$ , we assume that plants are not water-stressed following ET/PET filtering; a water-stress factor is not applied to scale  $V_{\text{cmax}}^{25\text{C}}$  as described in ref. 43 (Supplementary Text 2). Consequently, in this study, the EEO theory represents an idealized condition where carbon assimilation is optimized under the assumption of sufficient water availability. While plant light use efficiency can be reduced by physiological stress due to water scarcity<sup>59</sup>, the absence

**Fig. 3 | Impact of leaf photosynthetic capacities on  $\gamma_T$  estimation. a**, Probability densities of  $\gamma_T$  values derived from FLUXNET2015 and three variants of the BESS model (BESS<sub>PFT</sub>, BESS<sub>LAI</sub> and BESS<sub>EEO</sub>). The vertical lines represent the median  $\gamma_T$  values. **b**, The statistics of the two-sided K–S tests between FLUXNET2015 observations and three model variants.

of such water-stress constraints can lead to an overestimation of  $V_{cmax}^{25C}$ . Although ET/PET is an effective indicator of soil moisture, it may not fully correspond to plant physiological stress. Bridging the gap between existing water availability metrics and actual plant stress responses remains a challenge<sup>60</sup>.

## Conclusion

Photosynthesis can benefit from future warming through thermal acclimation, resulting in increased carbon uptake under conditions where water is not limiting. While leaf-scale acclimation is widely recognized, our study shows that the positive acclimation of canopy-scale photosynthetic capacity to growth temperature is a widespread phenomenon across various terrestrial biomes. We have shown that, on average, the canopy photosynthetic capacity acclimates to the growth thermal conditions of the preceding 14 days. Incorporating seasonal acclimation of photosynthetic capacities (the maximum carboxylation rate and the maximum electron-transport rate) is critical for achieving accurate simulations of photosynthesis in response to variations in temperature at timescales of weeks to months. Despite warmer growing seasons, water availability is increasingly constrained in many regions, potentially forcing plants to reduce photosynthetic capacity as a water conservation strategy. Improving the understanding of canopy-scale photosynthetic thermal acclimation in response to future conditions characterized by warming and variable water availability is therefore important.

## Methods

### Global database of ecosystem-scale carbon fluxes

We derive  $A_{max}$  from >200 eddy covariance sites from the global database FLUXNET2015, which covers a wide range of geospatial locations and PFTs<sup>47,61</sup> (Supplementary Table 2). FLUXNET2015 is an openly accessible database containing data on the net exchange of carbon (NEE), water and energy between the atmosphere and the biosphere and meteorological observations. Uniform processing approaches are implemented for the flux calculation and quality control across the sites<sup>47</sup>. We use half-hourly or hourly NEE (NEE\_VUT\_USTAR50), its corresponding estimation of the uncertainty caused by friction velocity filtering (NEE\_VUT\_USTAR50\_RANDUNC) and gap-filled meteorological observations, including incoming radiation (SW\_IN\_F), air temperature (TA\_F) and VPD (VPD\_F) to derive  $A_{max}$  (refs. 47,62) (described below). Sites are excluded if data are unavailable during the MODIS period from 2002 onwards (for example, US-LWW and US-Me4) or if the uncertainty estimation is missing (for example, CA-Man).

### Derivation of ecosystem-scale $A_{max}$

We derive  $A_{max}$  from light response curves across the FLUXNET2015 sites according to the daytime flux partitioning methods detailed in refs. 35,63. We fit NEE using the following hyperbolic equation:

$$-NEE = \frac{\alpha R_g}{\alpha R_g + \beta} + \gamma \quad (1)$$

where  $\beta$  ( $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) is the target variable of interest. Variables  $\alpha$ ,  $R_g$  and  $\gamma$  represent the ecosystem-scale quantum yield ( $\mu\text{mol C J}^{-1}$ ), global radiation ( $\text{W m}^{-2}$ ) and ecosystem respiration ( $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ), respectively.

To account for the potential influence of high VPD (hPa),  $\beta$  is scaled using an exponential function only when VPD exceeds 10 hPa. Thus, we obtain  $A_{max}$  as follows:

$$A_{max} = \begin{cases} \beta, & \text{VPD} \leq 10 \text{ hPa} \\ \beta \exp(-k(\text{VPD} - 10)), & \text{VPD} > 10 \text{ hPa} \end{cases} \quad (2)$$

where  $\beta$  and  $k$  are fit parameters to the flux data. The ecosystem respiration term in equation (1),  $\gamma$ , is estimated using an Arrhenius-type function describing the temperature dependence of  $\gamma$  (ref. 64), which is applied to night-time data by assuming that night-time NEE is equivalent to ecosystem respiration:

$$NEE = R_{ref} \exp \left\{ E_0 \left( \frac{1}{T_{ref} - T_0} - \frac{1}{T_{air} - T_0} \right) \right\} \quad (3)$$

where  $R_{ref}$  and  $E_0$  are the basal respiration rate ( $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) at a reference temperature ( $T_{ref} = 15^\circ\text{C}$ ) and temperature sensitivity ( $^\circ\text{C}$ ), respectively.  $T_0$  is a constant equal to  $-46.02^\circ\text{C}$  (ref. 65).

In practice,  $E_0$  is first estimated according to equation (3). With a fixed  $E_0$ , the remaining parameters of equations (2) and (3) ( $\alpha$ ,  $\beta$ ,  $k$  and  $R_{ref}$ ) are derived using a time window of 2–14 d. The specific time window depends on data availability and the  $A_{max}$  value is assumed invariant within the same fitting window. On average, 25% of estimated  $A_{max}$  values are flagged as medium or low quality because the parameter ranges are unreasonable and/or the curve fitting is unconstrained (Supplementary Fig. 6b) and are subsequently discarded<sup>35</sup>. Additionally,  $A_{max}$  values that are constant for 14 consecutive days or more are excluded. More than 88% of the  $A_{max}$  values in the remaining dataset are fitted within a 2 d window (Supplementary Fig. 6a), indicating a

sufficient sample size for most fitting. Here we derive  $A_{\max}$  using the REdDyProc R package (<https://github.com/bgctw/REddyProc>)<sup>66</sup>, as  $A_{\max}$  is not provided in the FLUXNET2015 database. We convert PPFD to  $R_g$  using a constant of  $2.1 \mu\text{mol J}^{-1}$  (ref. 67). We standardize  $A_{\max}$  to  $\text{PPFD} = 2,000 \mu\text{mol m}^{-2} \text{s}^{-1}$  ( $A_{\max,2,000}$ ) by setting  $R_g = 952 \text{ W m}^{-2}$  in equation (1) and calculating the corresponding assimilation rate. This approach can avoid any  $A_{\max}$  values obtained from potentially unsaturated light conditions and ensure consistent levels of absorbed PAR<sup>35</sup>.

### Timescale for thermal acclimation of $A_{\max,2,000}$

We hypothesize that the most relevant timescale for thermal acclimation ( $\tau$ ) ranges between 2 and 60 d, according to the coordination hypothesis and observations<sup>18,20,68</sup>. We conduct linear regressions between  $A_{\max,2,000}$  derived from the FLUXNET2015 sites and the daytime  $\overline{T_{\text{air}}}$  averaged over the 2–60 d before the time of  $A_{\max,2,000}$  measurements with a time interval of 1 d. On the basis of a previous study<sup>35</sup>, savanna and shrubland sites are excluded from the analysis because they are frequently subject to water stress. Croplands are excluded from the cross-site analysis. Furthermore, we exclude the  $A_{\max,2,000} - \overline{T_{\text{air}}}$  pairs collected during water-limited conditions, as indicated by the ratio of prevailing actual evapotranspiration to Priestley–Taylor potential evapotranspiration ( $\text{ET}/\text{PET}$ ) < 0.7 (ref. 69) and  $\text{VPD} > 20 \text{ hPa}$ . Additionally, we only focus on growing seasons, characterized by  $\text{fAPAR} > 0.3$  and  $T_{\text{air}}$  and  $\overline{T_{\text{air}}} > 0 \text{ }^\circ\text{C}$ . Daily  $\text{fAPAR}$  and LAI for each site were derived by interpolating the 8 d MODIS MOD15A2H products following ref. 35. Low-quality data affected by cloud contamination are removed<sup>31</sup>. A total of 149,403  $A_{\max,2,000}$  records are used for further analyses.

To remove the potential effects of concurrent  $T_{\text{air}}$  and  $\text{fAPAR}$  on  $A_{\max,2,000}$ , we group  $A_{\max,2,000} - \overline{T_{\text{air}}}$  pairs into different bins of  $T_{\text{air}}$  with  $1 \text{ }^\circ\text{C}$  intervals and  $\text{fAPAR}$  with 0.02 intervals. This approach allows the analysis of changes in  $A_{\max,2,000}$  along  $\overline{T_{\text{air}}}$  gradients to be made while controlling for the instantaneous temperature dependence of photosynthesis and seasonal changes in leaf quantity and the development of the photosynthetic system. Pearson  $r$  between  $A_{\max,2,000}$  and  $\overline{T_{\text{air}}}$  that is averaged over different time frames (that is, 2–60 d with 1 d interval) is calculated for  $T_{\text{air}}$  and  $\text{fAPAR}$  bins. A positive  $r$  indicates the thermal acclimation potential of  $A_{\max,2,000}$ . Only bins with sampling numbers larger than 10 and 20 for PFT-based and cross-site analyses, respectively, are retained. We examine the relationship between the average of the positive  $r$  values obtained from  $T_{\text{air}}$  and  $\text{fAPAR}$  bins and the time frames used to calculate  $\overline{T_{\text{air}}}$  for each PFT and cross sites (Fig. 2). Parameter  $\tau$  is defined as the corresponding time frame when the 5 d moving average of the positive  $r$  reaches its peak. EVI, derived from MODIS reflectance data (MCD43A4) in the near-infrared, red and blue spectral bands<sup>51</sup>, is used to estimate  $\tau$  for EBF for subsequent analysis, as an optimal  $\tau$  cannot be identified for this PFT using  $A_{\max,2,000}$  (Supplementary Fig. 5).

### Evidence for thermal acclimation of $A_{\max,2,000}$

We use PFT-specific  $\tau$  values for aggregating prevailing  $T_{\text{air}}$  to obtain  $\overline{T_{\text{air}}}$  (Fig. 1). We run LMMs, which include a random effect of different sites for removing the site-level adaptation effect, to explore the relationship between  $A_{\max,2,000}$  and PFT-specific  $\overline{T_{\text{air}}}$  (that is,  $A_{\max,2,000} \sim \overline{T_{\text{air}}} + (1|\text{site})$ ) (Extended Data Fig. 1a). The same data selection procedure and  $T_{\text{air}}$  and  $\text{fAPAR}$  binning scheme are used for the cross-site analysis (Fig. 1a and see earlier). The coefficient of  $\overline{T_{\text{air}}}$  estimated from LMMs is defined as thermal acclimation rate ( $\gamma_T$ ). The sampling number, conditional and marginal correlation coefficients for the cross-site analysis are shown in Supplementary Fig. 6. The LMM is conducted with the R package lme4 (ref. 70). For each site, the sampling number of  $A_{\max,2,000} - \overline{T_{\text{air}}}$  pairs is insufficient to support the correlation analysis under the binning scheme<sup>35</sup>. Instead, a partial correlation analysis is run between  $A_{\max,2,000}$  and  $\overline{T_{\text{air}}}$  controlling for PPFD,  $T_{\text{air}}$  and  $\text{fAPAR}$  on flux sites with observation lengths longer than 5 yr (Fig. 1c).

The prevailing conditions of  $T_{\text{air}}$  and PPFD often show a high correlation (Supplementary Fig. 1a). Therefore, we also include PPFD as an additional predictor in the LMM (Extended Data Fig. 2a) and we analyse partial correlations between  $A_{\max,2,000}$  and  $\overline{T_{\text{air}}}$  controlling for PPFD (Extended Data Fig. 2b) to eliminate the confounding effect of light acclimation<sup>35</sup>. Additionally, we repeat LMMs with a different target variable ( $A_{\max}$ ) and random effect (PFT) to examine the robustness of the detectability of thermal acclimation (Extended Data Fig. 2c,d).

### Modelling canopy photosynthesis of $C_3$ plants

We apply the photosynthesis module of the BESS model<sup>57</sup> to estimate canopy photosynthesis ( $A$ ) and subsequently  $A_{\max,2,000}$  for each flux site. This allows a direct comparison to be made of the impacts of different empirical formulations of leaf photosynthetic capacities on thermal acclimation. The photosynthesis module is based on the FvCB model<sup>4</sup>, where  $A$  is determined as the lower  $\text{CO}_2$  assimilation rate between the maximum rate of ribulose-1,5-bisphosphate carboxylase/oxygenase activity when light is saturated ( $A_c$ ) and the electron-transport rate for RuBP regeneration when light is limited ( $A_j$ ). For this study, the two-big-leaf scheme implemented in the BESS model is simplified to a one-big-leaf scheme. We have updated the parameters of temperature dependence of the maximum carboxylation rate ( $V_{\text{cmax}}$ ,  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ), the maximum electron-transport rate ( $J_{\text{max}}$ ,  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ), as well as the ratio of their values at  $25 \text{ }^\circ\text{C}$  following ref. 12. A detailed description of the canopy photosynthesis model can be found in Supplementary Text 1 (also see refs. 31,55,57).

### Leaf photosynthetic capacities

$V_{\text{cmax}}$  is a key parameter in the FvCB model, particularly under light-saturated conditions<sup>4</sup>. Previous studies have shown that leaf biochemical components can acclimate to  $\overline{T_{\text{air}}}$  (refs. 11,12,21). In this study, we compare three empirically derived variants of  $V_{\text{cmax}}$  at  $25 \text{ }^\circ\text{C}$  ( $V_{\text{cmax}}^{25\text{C}}$ ) within the FvCB model to evaluate their effectiveness in simulating the observed  $\gamma_T$ :

- (1)  $V_{\text{cmax,PFT}}^{25\text{C}}$ : this variant assumes a constant  $V_{\text{cmax}}^{25\text{C}}$  value over the growing season, an assumption that is still widely used in vegetation models<sup>16</sup>. The prescribed top leaf  $V_{\text{cmax}}^{25\text{C}}$  values are adopted from a look-up table based on PFTs and climatic zones compiled from the TRY trait database<sup>31,71</sup>.
- (2)  $V_{\text{cmax,LAI}}^{25\text{C}}$ : leaf  $V_{\text{cmax}}^{25\text{C}}$  varies seasonally, with its seasonality following LAI. This scheme, implemented in the previous version of the BESS model<sup>31</sup>, follows equation (4).

$$V_{\text{cmax,LAI}}^{25\text{C}} = a \times V_{\text{cmax,PFT}}^{25\text{C}} + (1 - a) \times V_{\text{cmax,PFT}}^{25\text{C}} \times \frac{\text{LAI} - \text{LAI}_{\min}}{\text{LAI}_{\max} - \text{LAI}_{\min}} \quad (4)$$

where  $\text{LAI}_{\min}$  and  $\text{LAI}_{\max}$  are the 5th and 95th percentile values of LAI over a growing season, respectively, and  $a$  is an empirical parameter set to 0.3 (ref. 57).

- (3)  $V_{\text{cmax,EEO}}^{25\text{C}}$ : the calculation is based on EEO theory<sup>19,34,56</sup>, specifically the coordination hypothesis<sup>17,72</sup> and the least-cost hypothesis<sup>50,73</sup>. The coordination hypothesis proposes that plants actively coordinate resource allocation so that  $A_c$  tends to equal  $A_j$  on weekly to monthly timescales. The least-cost hypothesis proposes that plants minimize the combined costs (per unit assimilation) of maintaining the biochemical capacity for photosynthesis and the water transport capacity required to support it, through stomatal regulation. Combining the two hypotheses results in an optimal intercellular  $\text{CO}_2$  concentration under representative conditions<sup>74</sup>. Here we assume that  $V_{\text{cmax,EEO}}^{25\text{C}}$  acclimates to prevailing conditions following the same timescale as  $A_{\max,2,000}$  (Fig. 2). The calculation is detailed in Supplementary Text 2 and ref. 34.

## Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

## Data availability

The dataset of FLUXNET2015 flux sites under the CC-BY-4.0 policy is publicly available for download at <http://fluxnet.fluxdata.org>. Remote-sensing canopy structure data from the MODIS MCD43A and MOD15A2H products are freely accessible at <https://lpdaac.usgs.gov/products/mcd43a3v006/> and <https://lpdaac.usgs.gov/products/mod15a2hv006/>. BESS flux products are publicly available at <https://www.environment.snu.ac.kr/data/>.

## Code availability

The corresponding R code scripts used in this study are available via Zenodo at <https://doi.org/10.5281/zenodo.13854273> (ref. 75). The code for the deviation of  $A_{\max}$  from the FLUXNET2015 database is available via GitHub at <https://github.com/trevorkeen/inhibitionPaperCode>. The code for modelling optimality-based  $V_{\text{cmax}}$  is available via GitHub at <https://github.com/chongya/SVOM>.

**Extended Data Fig. 1 | An example of the response of  $A_{max,2000}$  to  $\overline{T_{air}}$ ,  $T_{air}$ , and  $fAPAR$  under a  $fAPAR$ - $T_{air}$  bin pair.** Cross-site  $A_{max,2000}$ ,  $\overline{T_{air}}$ ,  $T_{air}$ , and  $fAPAR$  samples are collected when  $0.56 < fAPAR \leq 0.58$  and  $15^\circ C < T_{air} \leq 16^\circ C$ . **a-c**, Relationships between  $A_{max,2000}$  and  $\overline{T_{air}}$  (**a**),  $A_{max,2000}$  and  $T_{air}$  (**b**), and  $A_{max,2000}$  and  $fAPAR$  (**c**). The black lines represent the best fits between  $A_{max,2000}$  and  $\overline{T_{air}}$  as a

linear mixed-effect function ( $A_{max,2000} \sim \overline{T_{air}} + (1|Site)$ , two-sided test,  $P < 0.001$ ) (**a**),  $A_{max,2000}$  and  $T_{air}$  as a linear function ( $A_{max,2000} \sim T_{air}$ , two-sided test,  $P > 0.05$ ) (**b**), and  $A_{max,2000}$  and  $fAPAR$  as a linear function ( $A_{max,2000} \sim fAPAR$ , two-sided test,  $P > 0.05$ ) (**c**).

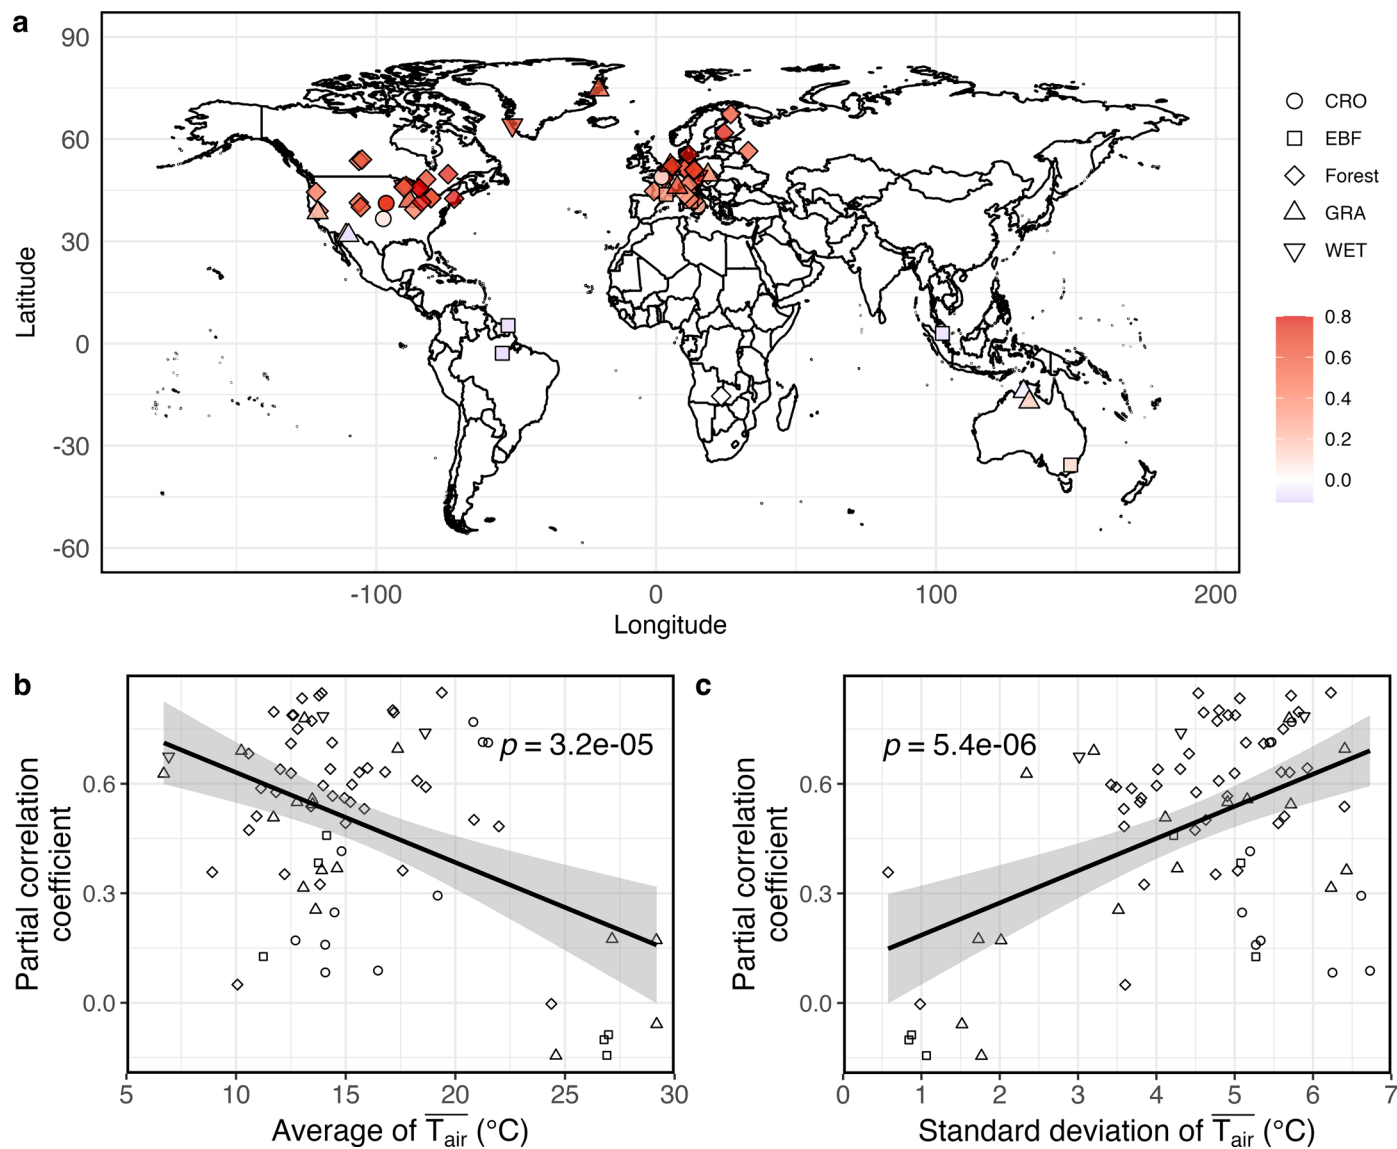

**Extended Data Fig. 2 | The relationships between canopy photosynthetic capacities and  $\overline{T_{air}}$  over fAPAR and  $T_{air}$  bins.** **a**, The partial effect of  $\overline{T_{air}}$  on  $A_{\max,2000}$  when  $\overline{PPFD}$  is also incorporated in the modelling ( $A_{\max,2000} \sim \overline{T_{air}} + \overline{PPFD} + (1|Site)$ ). **b**, Partial correlation coefficients (partial  $r$ ) between  $A_{\max,2000}$  and  $\overline{T_{air}}$  when controlling for  $\overline{PPFD}$  ( $A_{\max,2000} \sim \overline{T_{air}} | \overline{PPFD}$ ). **c**, The cross-site thermal acclimation rate ( $\gamma_T$ ) is calculated based on  $A_{\max}$  ( $A_{\max} \sim$

$\overline{T_{air}} + (1|Site)$ ). **d**, The cross-site  $\gamma_T$  is calculated using plant function types (PFTs) as random intercepts ( $A_{\max,2000} \sim \overline{T_{air}} + (1|PFT)$ ). Numbers (%) in parentheses represent the detectability of positive  $\gamma_T$  values, which is defined as the percentage of the number of bins displaying a positive  $\gamma_T$  over the total number of bins. Black dots indicate significant ( $P < 0.05$ ) correlations.

**Extended Data Fig. 3 | The PFT-specific thermal acclimation rates ( $\gamma_T$ ). a–g,** PFT-specific  $\gamma_T$  for croplands (CRO) (a), deciduous broadleaf forests (DBF) (b), evergreen broadleaf forests (EBF) (c), evergreen needle-leaf forests (ENF) (d), grasslands (GRA) (e), mixed forests (MF) (f), wetlands (WET) (g). Numbers (%) in

parentheses represent the detectability of positive  $\gamma_T$  values, which is defined as the percentage of the number of bins displaying a positive  $\gamma_T$  over the total number of bins. Black dots indicate significant ( $P < 0.05$ ) correlations between  $A_{\max,2000}$  and  $\overline{T_{air}}$ .

**Extended Data Fig. 4 | Analyses of the partial correlation coefficients between  $A_{max,2000}$  and  $\overline{T_{air}}$  derived from long-term flux sites and their relationships with the site-level average  $\overline{T_{air}}$  and variability of  $\overline{T_{air}}$ .** **a**, Geographic distribution of partial correlation coefficients between  $A_{max,2000}$  and  $\overline{T_{air}}$  controlling for  $\overline{PPFD}$ ,  $fAPAR$  and  $T_{air}$  across sites with observations spanning over five years. **b**, Relationship between partial correlation coefficients and the site-level averages of  $\overline{T_{air}}$ . **c**, Relationship between partial correlation coefficients

and the site-level standard deviation of  $\overline{T_{air}}$ . The black lines in **b** and **c** represent the predicted mean values from linear regression models, and the grey shaded areas indicate their 95% confidence intervals.  $P$ -values are determined through two-sided Pearson's correlation significance tests. The "Forest" biome category includes evergreen needle-leaf forests, deciduous broadleaf forests, and mixed forests. Other PFTs are croplands (CRO), evergreen broadleaf forests (EBF), grasslands (GRA), and wetlands (WET).

## Reporting Summary

Nature Portfolio wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Portfolio policies, see our [Editorial Policies](#) and the [Editorial Policy Checklist](#).

### Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a Confirmed

- The exact sample size ( $n$ ) for each experimental group/condition, given as a discrete number and unit of measurement
- A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
- The statistical test(s) used AND whether they are one- or two-sided  
*Only common tests should be described solely by name; describe more complex techniques in the Methods section.*
- A description of all covariates tested
- A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
- A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
- For null hypothesis testing, the test statistic (e.g.  $F$ ,  $t$ ,  $r$ ) with confidence intervals, effect sizes, degrees of freedom and  $P$  value noted  
*Give  $P$  values as exact values whenever suitable.*
- For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
- For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
- Estimates of effect sizes (e.g. Cohen's  $d$ , Pearson's  $r$ ), indicating how they were calculated

*Our web collection on [statistics for biologists](#) contains articles on many of the points above.*

### Software and code

Policy information about [availability of computer code](#)

Data collection

Data analysis

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Portfolio [guidelines for submitting code & software](#) for further information.

## Data

Policy information about [availability of data](#)

All manuscripts must include a [data availability statement](#). This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A description of any restrictions on data availability
- For clinical datasets or third party data, please ensure that the statement adheres to our [policy](#)

The dataset of FLUXNET2015 flux sites under the CC-BY-4.0 policy is publicly available for download at <http://fluxnet.fluxdata.org>. Remote-sensing canopy structure data from the MODIS MCD43A and MOD15A2H products are freely accessible at <https://lpdaac.usgs.gov/products/mcd43a3v006/> and <https://lpdaac.usgs.gov/products/mod15a2hv006/>. BESS flux products are publicly available at <https://www.environment.snu.ac.kr/data/>. PFT-based Vcmax25C is derived from TRY trait database at <https://www.try-db.org/TRYWeb/dp.php>.

## Research involving human participants, their data, or biological material

Policy information about studies with [human participants or human data](#). See also policy information about [sex, gender \(identity/presentation\), and sexual orientation](#) and [race, ethnicity and racism](#).

Reporting on sex and gender	N/A
Reporting on race, ethnicity, or other socially relevant groupings	N/A
Population characteristics	N/A
Recruitment	N/A
Ethics oversight	N/A

Note that full information on the approval of the study protocol must also be provided in the manuscript.

## Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

- Life sciences       Behavioural & social sciences       Ecological, evolutionary & environmental sciences

## Ecological, evolutionary & environmental sciences study design

All studies must disclose on these points even when the disclosure is negative.

Study description	We derive Amax from light response curves of half-hourly or hourly eddy-covariance carbon fluxes obtained from more than 200 FLUXNET2015 flux sites. We examine the correlation between Amax and growth temperature when averaged over different time windows to identify the most relevant time scale for thermal acclimation, as indicated by peak correlation. Finally, we evaluate a biochemical model of canopy-scale C3 photosynthesis, incorporating recent advances in parameterizing temperature dependence acclimation and modelled optimality-based leaf photosynthetic capacity, to assess its ability to reproduce the observed thermal acclimation rates.
Research sample	Half-hourly and hourly net ecosystem exchanges of CO2 and their corresponding environmental conditions were collected from all sites listed on FLUXNET2015. MODIS LAI and fPAR data were also collected for each site.
Sampling strategy	We attempted to derived Amax from all FLUXNET2015 sites under the CC-BY-4.0 policy, though failed on three sites due to missing data variable and mismatched time periods with MODIS.
Data collection	All data were downloaded from their original source through the URLs provided in the data availability statement. The raw data were collected and processed by site PIs. The FLUXNET community standardized the flux data by ONEFlux.
Timing and spatial scale	We focused on the period between 2002 and 2014 when MODIS data were available and overlapped with FLUXNET2015. Daily fAPAR and LAI for each site were derived by interpolating the 8-day MODIS MOD15A2H products. We chose the growing seasons identified by fPAR and air temperature and well-watered conditions according to an aridity index (ET/PET).
Data exclusions	Sites are excluded if data are unavailable during the MODIS period from 2002 onwards (e.g. US-LWW and US-Me4) or if the uncertainty estimation is missing (e.g. CA-Man).

Reproducibility

Blinding

Did the study involve field work?  Yes  No

## Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

### Materials & experimental systems

n/a	Included in the study
<input checked="" type="checkbox"/>	<input type="checkbox"/> Antibodies
<input checked="" type="checkbox"/>	<input type="checkbox"/> Eukaryotic cell lines
<input checked="" type="checkbox"/>	<input type="checkbox"/> Palaeontology and archaeology
<input checked="" type="checkbox"/>	<input type="checkbox"/> Animals and other organisms
<input checked="" type="checkbox"/>	<input type="checkbox"/> Clinical data
<input checked="" type="checkbox"/>	<input type="checkbox"/> Dual use research of concern
<input type="checkbox"/>	<input checked="" type="checkbox"/> Plants

### Methods

n/a	Included in the study
<input checked="" type="checkbox"/>	<input type="checkbox"/> ChIP-seq
<input checked="" type="checkbox"/>	<input type="checkbox"/> Flow cytometry
<input checked="" type="checkbox"/>	<input type="checkbox"/> MRI-based neuroimaging

## Dual use research of concern

Policy information about [dual use research of concern](#)

### Hazards

Could the accidental, deliberate or reckless misuse of agents or technologies generated in the work, or the application of information presented in the manuscript, pose a threat to:

No	Yes
<input checked="" type="checkbox"/>	<input type="checkbox"/> Public health
<input checked="" type="checkbox"/>	<input type="checkbox"/> National security
<input checked="" type="checkbox"/>	<input type="checkbox"/> Crops and/or livestock
<input checked="" type="checkbox"/>	<input type="checkbox"/> Ecosystems
<input checked="" type="checkbox"/>	<input type="checkbox"/> Any other significant area

### Experiments of concern

Does the work involve any of these experiments of concern:

No	Yes
<input checked="" type="checkbox"/>	<input type="checkbox"/> Demonstrate how to render a vaccine ineffective
<input checked="" type="checkbox"/>	<input type="checkbox"/> Confer resistance to therapeutically useful antibiotics or antiviral agents
<input checked="" type="checkbox"/>	<input type="checkbox"/> Enhance the virulence of a pathogen or render a nonpathogen virulent
<input checked="" type="checkbox"/>	<input type="checkbox"/> Increase transmissibility of a pathogen
<input checked="" type="checkbox"/>	<input type="checkbox"/> Alter the host range of a pathogen
<input checked="" type="checkbox"/>	<input type="checkbox"/> Enable evasion of diagnostic/detection modalities
<input checked="" type="checkbox"/>	<input type="checkbox"/> Enable the weaponization of a biological agent or toxin
<input checked="" type="checkbox"/>	<input type="checkbox"/> Any other potentially harmful combination of experiments and agents
