Abstract

Nuclear magnetic resonance spectroscopy of fluorine-19 nucleus (¹⁹F-NMR) emerges as a powerful tool because of the high sensitivity due to its high natural abundance, broad spectral range, and the simplicity of a spin-half system. However, it is still seldom utilized in the chemistry classroom or research. This article thus aims to demonstrate the power of NMR by investigating the kinetics when a ¹⁹F – tag reacts with individual amino acids (AA) and eventually utilizing the approach to identify and quantify various AAs from a complex mixture such as a metabolomics sample. The ¹⁹F – tag named 2,5-dioxopyrrolidin-1-yl-2-(trifluoromethyl)benzoate was synthesized following a previously established method. The reaction kinetics of the tag was then continuously measured using ¹⁹F NMR in the presence of selected AAs. The estimated reaction rate constants to form the ¹⁹F – tags with each AA differ, which could be used as an identification tool. The tag formations were typically completed in 24–48 h in water for all the samples. These demonstrations suggest that ¹⁹F – tags could form the basis for chemical kinetics and AA detection using ¹⁹F-NMR.

Keywords

Nuclear Magnetic Resonance (NMR); Fluorine-19; Amino acid; Kinetics; Mixture analysis

1. Introduction

Nuclear magnetic resonance (NMR) has taken a central role in both education and research, as evidenced by the excellent investigations collected in the four comprehensive volumes

by the American Chemical Society Symposium Series [1–4]. Proton (¹H) and carbon (¹³C)-NMR are routinely utilized for structure identification and characterization in research laboratories and industries. In contrast, ¹⁹F nucleus is underutilized in the field of NMR, even though the same spectrometer that is used to detect¹H- and ¹³C can perform the experiments for ¹⁹F. It is worth noting that the 100% natural abundance of ¹⁹F with a high gyromagnetic ratio (3.7 times higher than ¹³C and 90% of ¹H) results in increased sensitivity of the nuclear spin of ½, allowing for a straight-forward interpretation of the ¹⁹F-NMR spectra [5,6]. In addition to providing reliable quantification similar to ¹H NMR, a fluorine nucleus is surrounded by 9 electrons, leading to a broader range of chemical shift dispersion (¹⁹F ~350 ppm, in comparison to ¹³C ~ 200 ppm, and ¹H ~ 12 ppm) and explains the higher sensitivity of fluorine chemical shifts to the local environment. ¹⁹F-NMR has also been used in biomolecular applications [7–11] and teaching laboratories [11–13], including structure-activity relationship studies [14].

Identifying and quantifying small molecules, particularly in samples with complex mixtures (e.g., in a metabolomics study), is an emerging area of NMR spectroscopy [15–17]. Amino acids (AA) are among the most valuable metabolites to identify under such criteria because they are vital components in protein synthesis and are crucial for many metabolic reactions [18]. For instance, the abundance of certain AAs (e.g., leucine, alanine, or proline) in plant tissue can serve as abiotic stress factors, including dehydration, osmotic imbalance, or hypersaline soil [18–20]. However, spectral signal overlap among the various AA in complex mixture analysis, such as in metabolomics studies, poses a challenge in identifying and quantifying different AAs. One approach to overcome the challenge is chemically modifying protein amino groups with reactive ¹⁹F – tags containing an *N*-hydroxysuccinimide ester (NHS) moiety [21]. The said approach has recently been adopted to modify the AAs [22–24].

This study intends to demonstrate the utilization of one-dimensional ¹⁹F NMR spectroscopy in AA identification and quantification. A fluorine tag named 2,5-*dioxopytrolidin*-1-yl-2-(trifluoromethyl)benzoate was synthesized with accordance to the synthetic procedure established by Chen et al. [23] and used to label the *N*-terminus of the AAs (Fig. 1). A given AA's chemical modification reaction process allows continuous real-time NMR spectral monitoring. Since each AA has a unique side chain, each side chain provides a unique chemical environment that influences the fluorine moiety's chemical shift. This investigation further leverages this technique to measure the rate constants of the reaction of the fluorine tag with a select set of AAs. The rate constants are distinctly different among the different AAs. We aim to provide reliable methodologies for synthesizing the fluorine tag, measuring the reaction kinetics of tag modification of AAs, and quantifying tag-labeled AAs with ¹⁹F NMR spectroscopy.

2. Experimental design

2.1. Chemical synthesis and sample preparation

Chemicals: The following chemicals were purchased from Fisher Scientific for direct use in the experiments without further purification. Chemicals used in the synthesis of the 19 F – tag: 3-chloro-2-fluorobenzoic acid (CAS: 161,957–55–7, 97%), 2- (trifluoromethyl)benzoic acid (CAS: 433–97–6, 98%), *N*-hydroxysuccinimide (CAS: 6066–82–6, 98+%), and *N*,*N*-dicyclohexyl carbodiimide (CAS: 538–75–0, 99%). Solvents, buffers, and reference used in the NMR experiments: Deuterium oxide (CAS: 7789–20–0, 99.95%), potassium phosphate monobasic (CAS: 7778–77–0, 99+%), and acetic acid-d₄ (CAS: 1186–52–3, 99.5%). Amino acids used in the experiments: asparagine (CAS: 70–47–3, 99%), leucine (CAS: 61–90–5, 99%), cysteine (CAS: 52–90–4, 99%), hydroxyproline (CAS: 51–35–4, 99%), and proline (CAS: 609–36–9, 99%).

The general procedure of the experimental approach is illustrated in Fig. 1. First, the ¹⁹F - tag (2,5-dioxopyrrolidin-1-yl-2-(trifluoromethyl) benzoate) was prepared by treating 2-(trifluoromethyl)benzoic acid with N-hydroxysuccinimide in dichloromethane mediated by DCC (N.N-dicyclohexyl carbodiimide) adhering to the procedure described by Chen et al. [23]. Typically, most NMR experiments require a percentage of the solvent in the form of a deuterated solvent to lock the magnetic field (feedback control of the deuterium NMR signal to keep the resonant frequency adjustment) [25]. The ¹⁹F-NMR allows a significant reduction in the need for a D₂O in the sample. Phosphate buffer was prepared in deuterium oxide (99.95%) with potassium phosphate monobasic (90 mM) and trifluoroacetic acid (0.05 mM, chemical shift reference and for quantification). The AAs (individually or in a mixture) were prepared at a pH of 6.8. To demonstrate the utility of the process, five different AAs (asparagine, cysteine, leucine, trans-4-hydroxy-proline, and proline) were used both individually and in a mixture. The samples (individual AAs or the mixture) were prepared with a concentration of 0.2 mM with 0.05 mM trifluoroacetic acid (TFA) as the internal standard. In all the experiments, the concentration of the tag is at least six times higher than that of the AA concentrations. The NMR experiments were performed immediately after adding the tag to the sample.

2.2. Kinetic NMR experiments

The NMR experiments were performed in six independent samples: each AA separately and a mixture of AAs (without cysteine). Cysteine was not used in the mix as its reaction rate is much faster than the other AAs (*vide infra*). All ¹⁹F-NMR experiments were carried out on a 600 MHz JEOL NMR spectrometer at 30 °C using an HFX-Royal probe.

The qNMR kinetics experiments were performed following the earlier procedure [26]. Each sample was prepared with a small excess volume required for the NMR measurement (~700 μ L) in an Eppendorf tube. Next, the ¹⁹F – tag was added to the Eppendorf tube, defining the start of the experimental clock (*t* = 0). After a quick mixing of the sample, 600 μ L was transferred to an NMR tube. This time difference (delay time) will be added to the first time point when analyzing the data. The kinetic experiments were collected arrayed, with the

spectral data saved after a certain number of transients were completed. One-dimensional ¹⁹F NMR experiments were acquired at an Ernst angle of 70° [27], which optimizes the signal-to-noise ratio to spin-lattice relaxation time (T₁) when multiple scans are needed. For the kinetic measurements, one-dimensional experiments were conducted in an arrayed manner, with each spectrum in the array taking ~25 min. A total of 256 transients were used for each spectrum, with an acquisition time of ~1.0 s and a relaxation delay of 5.0 s between each transient. Previous work by Chen et al. [7] has established the relaxation time of ¹⁹F tagged AAs are less than one second ($1/T_1 = R_1 = 1.16 - 1.33 s^{-1}$, and $1/T_2 = R_2 = 1.86 - 2.0 s^{-1}$). There a combination of Ernst angle with a relaxation delay of 6 s can be considered sufficient for quantification of the ¹⁹F-NMR peak intensities with a high accuracy. The kinetic experiments are typically performed for 24 h to monitor the completeness of the reactions, with some experiments taking up to 48 h.

2.3. Analysis of kinetic NMR experimental data

Time domain NMR data were processed using MestReNova[®] using a standard procedure (zero-filled once with a sine-squared apodization and baseline correction). All the spectra were referenced using TFA at -76.55 ppm. Based on the TFA peak area, the concentration of the AAs indirectly estimated as

$$[AA] = \frac{I_{AA}}{I_{TFA}} \times \frac{N_{TFA}}{N_{AA}} \times [TFA]$$
⁽¹⁾

where [TFA] is the concentration of TFA, and I_{AA} is the peak area of the AA of interest, with N_{TFA} and N_{AA} are the number of fluorine nuclei of TFA and the AAs, respectively.

First, all the kinetics measurements of product formation were subjected to an initial rate estimation (linear region of the curve). Then, the mechanism of formation of tagged AA is assumed to be a bimolecular reaction with one molecule of the ¹⁹F – tag reacting with one molecule of the AA to form the ¹⁹F-tagged AA (¹⁹FAA); The formation of the ¹⁹F-tagged AAs generally requires a second-order rate equation $([^{19}F - tag] + [AA] \rightarrow [^{19}FAA])$ (rate-constant in units of M⁻¹s⁻¹).

$$-\frac{d}{dt}[AA] - \frac{d}{dt} \begin{bmatrix} 19F - tag \end{bmatrix} = \frac{d}{dt} \begin{bmatrix} 19FAA \end{bmatrix} = k[AA] \begin{bmatrix} 19F - tag \end{bmatrix}$$
(2)

Since the concentration of tag was excess (concentration of amino acids used was less than one-sixth of that of tag 2) $[AA] \ll [{}^{19}F - tag]$, the product $k[{}^{19}F - tag]$ can be considered as a constant, thus simplifying the second-order reaction (Eq. (2)) to a pseudo-first-order response (Eq. (3)).

The pseudo-first-order rate constant $k' = k [{}^{19}F - tag]_0$ in the units of s⁻¹, with $[{}^{19}F - tag]_0$ the tag concentration at t = 0. Since the tag concentration was in excess, the formation of the backbone amide product can be regarded as a pseudo-first-order reaction. Therefore, the observed formation of the ¹⁹F-AA as a function of time for this pseudo-first-order process can be written as

$$\begin{bmatrix} 19 \mathrm{F} - \mathrm{AA} \end{bmatrix}(t) = \begin{bmatrix} 19 \mathrm{F} - \mathrm{AA} \end{bmatrix}_{eq} (1 - e^{-k't})$$
(4)

In Eq. (4), $\begin{bmatrix} 19 \\ F - AA \end{bmatrix}_{eq}^{eq}$ is the concentration of the ¹⁹F-tagged AAs when the reaction is complete (t > > 0). Once the concentration of the ¹⁹F-AA is obtained from NMR spectra Eqs. (1), (4) can be utilized to estimate the rate constants using a non-linear least square fitting procedure. Using the initial concentration of the ¹⁹F – tag, a second-order rate was calculated (second – order rate constant = $k/[^{19}F - tag]$ in $M^{-1} s^{-1}$).

For amino acids with other functional groups, such as cysteine, the reaction kinetics tends to be more complex than the pseudo-first-order mechanism (Eq. (4)). Therefore, this paper did not analyze the kinetics data of cysteine tag formation. The data analysis and plots were generated using Microsoft Excel and the R statistical environment [28].

3. Results and discussion

3.1. ¹⁹F-NMR of tagged AAs

Our one-dimensional ¹⁹F-NMR experiments indicate that the reactions of the different AAs with the fluorine tag required different lengths of time to complete. Fig. 2 shows the spectra of all five ¹⁹F-labeled AAs at the end of the reaction. The chemical shifts of the individual ¹⁹F-labeled AA are distinguishable in each spectrum: Cystine (-58.42 ppm), cysteine (-59.05 ppm), asparagine (Asn, -59.09 ppm), leucine (Leu, -59.22 ppm), hydroxy-proline (Hyp, -59.92 ppm) and proline (Pro, -60.60 ppm). Proline and hydroxy-proline residues indicate the existence of other minor products at -60.27 ppm and -60.36 ppm, respectively. The area under the curve from both the major and minor peaks was considered when we estimated the concentration of these two ¹⁹F-labeled AAs. All the spectra showed the ¹⁹F peak for the hydrolysis product (-59.73 ppm), except for the reaction with cysteine, where the reactant was fully converted to the product.

(3)

3.2. Reaction monitoring of ¹⁹F-tagged AAs individually

Product formation of the ¹⁹F-labeled arginine, leucine, hydroxy-proline and proline are included in the supporting information (Fig. S1). An initial rate (linear region of the product formation, <5 hrs.) and pseudo-first-order analyses were performed. Table 1 summarizes the results when the pseudo-first-order rates are converted to a second-order rate constant using the initial concentration of the ¹⁹F – tag (initial concentration 1.2 mM). The second-order rate constant of ¹⁹F-leucine is the fastest (33.61 ± 1.23 mM⁻¹s⁻¹), while the ¹⁹F-hydroxy-proline is the slowest (35.86 ± 2.04 mM⁻¹s⁻¹). The rate constants, however, do not show a large variation (31.99 mM⁻¹s⁻¹ to 38.22 mM⁻¹s⁻¹), suggesting that within the experimental time, the reaction is completed for all the amino acids.

The progress of the conversion from cysteine to ¹⁹F-labeled cysteine is shown in Fig. 3. The internal reference TFA stays constant during the entire process of the experiment as the ¹⁹F – tag converts to the ¹⁹F-labeled cysteine (Fig. 3). An intermolecular interaction between the ¹⁹F-labeled cysteine produced in the reaction continues to form the disulfide bridge to form the ¹⁹F-labeled cystines [29]. The tagged cysteine concentration reduces over time due to the gradual formation of cystine. The sulfur moiety in cysteine rapidly forms the unstable thioester product, followed by the displacement of cysteine to create the amide product. With time, the cystine amide product is formed. A difference in the chemical shift differences between ¹⁹F-labeled cysteine (–59.05 ppm) and ¹⁹F-labeled cystine (–58.42 ppm) enables tracking the two products from the same data. As the formation of ¹⁹F-cysteine/cystine does not follow the proposed pseudo-first order reaction mechanism, rate constants were not estimated.

3.3. Reaction monitoring of ¹⁹F-tagged AAs in a mixture

The application of the ${}^{19}\text{F}$ – tag to identify individual AA in the mixture is demonstrated by performing the reaction of the ${}^{19}\text{F}$ tag with a mixture of AAs (except cysteine). Fig. S2 shows the mixture's corresponding spectra where the ${}^{19}\text{F}$ -tagged AA's chemical shifts closely match those obtained individually (Fig. 1). The real-time monitoring of the ${}^{19}\text{F}$ -tagged AAs is shown in Fig. 4. An initial rate estimation of the ${}^{19}\text{F}$ – tag formation is also summarized in supporting information (Fig. S3). The analysis results in the following rate constants: Asn (22.05 ± 2.46 mM/hr.), Leu (22.97 ± 2.78 mM/hr.), Hyp (15.98 ± 1.64 mM/hr.), and Pro (16.44 ± 1.71 mM/hr.). A pseudo-first order analysis on the mixture of the AAs is the formation rate of each AA in the mix presented as a second order rate is Asn (59.68 ± 1.64 mM⁻¹s⁻¹), Leu (56.64 ± 1.48 mM⁻¹s⁻¹), Hyp (77.11 ± 2.96 mM⁻¹s⁻¹), and Pro (52.75 ± 1.64 mM⁻¹s⁻¹).

Even though the result for the ¹⁹F-tagged cysteine is included in Fig. 4, the rate is not estimated due to the formation of the secondary reaction product (cystine). The reaction rate for each AA in the mixture is generally faster than the corresponding one for the individual AA, but the overall trend to equilibrium is the same (Table 1). The ¹⁹F-tagged cysteine/ cystine reaction rate is much faster than other ¹⁹F-tagged AAs. These results suggest that

the signature chemical shifts of each ¹⁹F-tagged AA and the rate of converting each AA to its ¹⁹F-tagged product can be used to identify the AAs in a complex mixture. The AA peaks were identified with reference to spectral chemical shifts of the amide product for individually tagged AAs ran at a pH of 6.8. Side chain and amide products of lysine, cysteine, and histidine were distinguished by comparing our chemical shifts with those obtained by Chen et al. [23]. The ¹⁹F-tagged cysteine signal is much more intense than the rest in the mixture due to the greater nucleophilic capability of cysteine.

Intriguingly, the chemical shifts of the ¹⁹F-tagged AAs identified in this work at pH 6.8 did not reproduce those reported by Chen et al. at pH 7.5, suggesting that different pH values affect the chemical shits of amide-containing compounds [23]. The pH-dependent chemical shifts for ¹⁹F-tagged AAs have been reported by Huang et al. [24]. Therefore, it is crucial to use an appropriate pH-adjusted buffer to ensure the chemical shifts in the specific sample are not altered from standard data collected at a given sample pH.

4. Conclusion

Considering AAs form a significant subset of metabolites, a proof-of-concept study has been investigated to develop a method for AA identification and quantification using one-dimensional ¹⁹F NMR spectroscopy. The work presented here elucidates a repeatable, feasible technique that can be implemented in laboratories interested in quantifying ¹⁹F-tagged AAs using ¹⁹F NMR spectroscopy. In addition, utilizing ¹⁹F-NMR spectroscopy enables tracking single peaks representing one amino acid instead of many, thus possibly eliminating error. Further, this work exemplifies a method of AAs quantification in complex mixtures, namely for metabolomics. For example, identifying specific chemical shifts with broad pH ranges can aid in developing libraries and programs intended for AA quantification around this method.

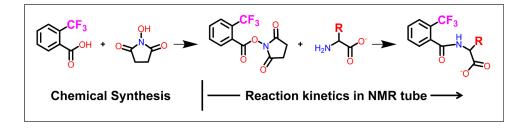

Fig. 1.

Experimental design. The first part of the investigation is the organic synthesis of the 19 F – tag. Next, the reaction kinetics of the tag with the amino acids is monitored in real-time by 19 F -NMR. The 'R' stands for any amino acid side chain.

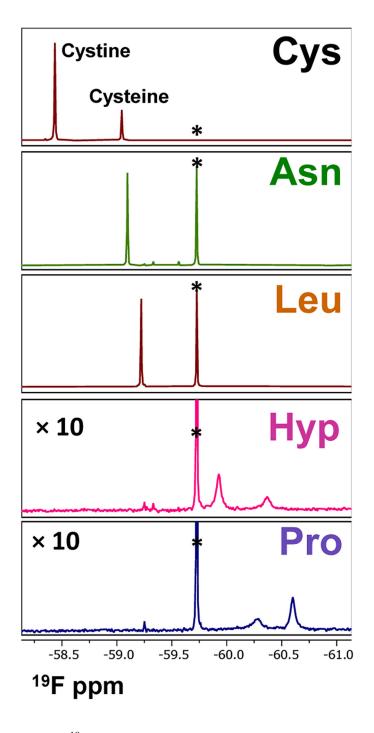

Fig. 2.

¹⁹F-NMR spectra of the ¹⁹F-labeled amino acids that were acquired when the reactions were complete. The three-letter amino acid codes correspond to Cys: cysteine/cystine, Asn: asparagine, Leu: leucine, Hyp: hydroxy-proline, and Pro: proline. The peak position of the ¹⁹F-hydrolysis product is marked by "*'.

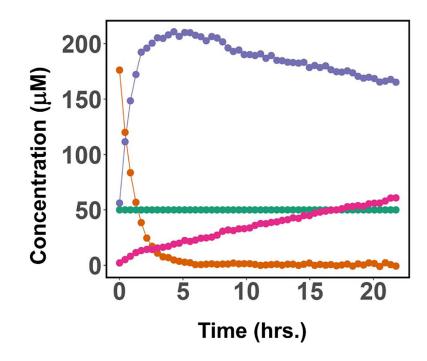

Fig. 3.

Reaction progress monitoring by ¹⁹F-NMR of ¹⁹F-labeled cysteine. The time-dependent change in the various signals when ¹⁹F – tag was reacted with amino acid cysteine. The decay of the reactant thioester product leads first to the formation of the product ¹⁹F-labeled cysteine, which converts into cystine due to the disulfide formation of the cysteines. The concentration of trifluoroacetic acid (TFA) used as a reference remains constant during the reaction.

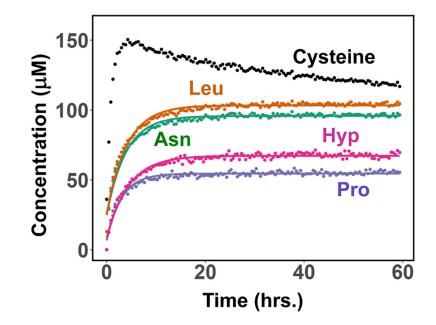

Fig. 4.

Reaction monitoring of ¹⁹F -tagged amino acids. Real-time tracking of the ¹⁹F -tagged amino acids formed when the ¹⁹F tag was added to the mixture of amino acids: Cysteine/ cystine, Asn: asparagine, Leu: leucine, Hyp: hydroxy-proline, and Pro: proline. The experimental values (shown as symbols) are fit to an exponential growth function based on a pseudo-first-order reaction.

Table 1

Kinetics of ¹⁹F-AA formation.

Amino Acid	Individually Rate (mM ⁻¹ s ⁻¹)	Mixture Rate (mM ⁻¹ s ⁻¹)
Asparagine (Asn)	31.99 ± 1.18	59.68 ± 1.64
Leucine (Leu)	33.61 ± 1.23	56.64 ± 1.48
Hydroxy-proline (Hyp)	35.86 ± 2.04	77.11 ± 2.96
Proline (Pro)	38.22 ± 2.13	52.75 ± 1.64
