ABSTRACT

An endobronchial mass was found in a main-stem bronchus of a 13-year-old girl with a new-onset “asthma.” Biopsy of the mass revealed mucoepidermoid carcinoma. The condition was completely cured using a sleeve tumor resection and bronchoplasty. Endobronchial tumors are extremely rare in children. Their presentations often mimic asthma, which could lead to misdiagnosis and delayed treatment. High index of suspicion in cases with unusual or “atypical” asthma necessitating diagnostic bronchoscopy and biopsy is the key to an early surgical intervention, which generally results in a favorable outcome.

CASE PRESENTATION

A PREVIOUSLY HEALTHY 13-year-old girl presented with a 2-month history of persistent cough and dyspnea on exertion that was unresponsive to asthma therapy. There was no history suggestive of foreign body aspiration. Family history was significant for asthma. Remarkable signs on physical exam were expiratory wheezes and diminished breath sound in the left lung. Plain chest radiographs were essentially normal, without any air trapping. A bronchoscopic exam demonstrated a near complete occlusion of the left main stem bronchus by an intraluminal soft tissue mass (Fig. 1). Tissue biopsy revealed mucoepidermoid carcinoma (Fig. 2). A magnetic resonance image of the chest showed that the mass was well confined in the left main stem bronchial lumen (Fig. 3). The patient underwent a sleeve tumor resection and bronchoplasty.¹ The borders of the resected specimen were free from carcinoma cells. Follow-up bronchoscopic exams and bronchial biopsies at 3, 6, and 12 months post-operatively revealed no recurrence of the tumor.

BRIEF DISCUSSION

Endobronchial tumors are extremely rare in children.^{2–7} Among many different types of tumors are benign (papilloma, hemangioma, leiomyoma), or malignant (mucoepidermoid carcinoma, adenoid cystic carcinoma / cylindroma, carcinoid). Early presenting symptoms often masquerade asthma. If the tumor is left unremoved, compression atelectasis or recurrent pneumonia usually follows.⁸

ENDOBRONCHIAL TUMOR

FIG. 1. A bronchoscopic view of an endobronchial mucoepidermoid carcinoma in the left main stem bronchus of a 13-year-old girl.

Mucoepidermoid carcinoma most commonly affects salivary glands. Its pathological characteristics are intracellular and extracellular accumulation of acid mucopolysaccharides. The origin of this transformation seems to be located within the cells of a glandular duct.⁹ The virulence of its malignancy varies from grade I (least virulent), to grade III (most virulent).¹⁰ Although surgical resection only is required to cure a grade

FIG. 2. Hematoxylin and eosin stain of an endobronchial mass showing mucoepidermoid carcinoma.

FIG. 3. A magnetic resonance image of the chest showing an endobronchial mass in the left main stem bronchus.

I mucoepidermoid carcinoma, optimal treatment for grade II and III tumors continues to be problematic in spite of combined surgery and radiotherapy. Prognosis is much more favorable in children than in adults.

Early diagnosis of endobronchial tumors requires a high index of suspicion in children with atypical respiratory complaints or those who fail to respond to therapy. Further investigation, such as diagnostic bronchoscopy, is of paramount importance in ruling out or establishing anatomical pathology in the conducting airways. The presence of mechanical obstruction, which may be caused by a variety of pathology such as a foreign body, web, granuloma, or in our case, a tumor, may erroneously suggest asthma and lead to delayed diagnosis and care.
