### Abstract

**Objectives**—We hypothesized that a screening and treatment intervention for early cryptococcal infection would improve survival among HIV-infected individuals with low CD4 cell counts.

**Methods**—Newly enrolled patients at Family AIDS Care and Education Services (FACES) in Kenya with CD4 100 cells/μl were tested for serum Cryptococcal antigen (sCrAg). Individuals with sCrAg titer 1:2 were treated with high-dose fluconazole. Cox proportional hazard models of Kaplan-Meier curves were used to compare survival among individuals with CD4 100 cells/μl in the intervention and historical control groups.

**Results**—The median age was 34 years [IQR: 29,41], 54% were female, and median CD4 was 43 cells/μl [IQR: 18,71]. Follow-up time was 1224 person-years. In the intervention group 66% (514/782) were tested for sCrAg; of whom 11% (59/514) were sCrAg positive. Mortality was 25% (196/782) in the intervention group and 25% (191/771) in the control group. There was no significant difference between the intervention and control group in overall survival [Hazard Ratio(HR): 1.1 (95% CI:0.9,1.3)] or three-month survival [HR: 1.0 (95% CI:0.8,1.3)]. Within the

intervention group, sCrAg positive individuals had borderline lower survival rates than sCrAg negative individuals [HR:1.8 (95%CI: 1.0, 3.0)].

**Conclusions**—A screening and treatment intervention to identify sCrAg positive individuals and treat them with high-dose fluconazole did not significantly improve overall survival among HIV-infected individuals with CD4 counts  $\geq 100$  cells/ $\mu$ l as compared to a historical control. Potential explanations include intervention uptake rates or poor efficacy of high-dose oral fluconazole. Future studies to identify the best treatments for early cryptococcal infection and improve uptake of the intervention are critical.

Cryptococcus; screening; prevention; Africa; outcomes; cryptococcal meningitis

### Introduction

In sub-Saharan Africa and southeast Asia, invasive cryptococcal disease is the second most common life-threatening HIV-associated opportunistic infection after tuberculosis and is responsible for up to 20% of deaths(1-4). A recent study estimates that cryptococcal meningitis may even be surpassing tuberculosis as the leading cause of death among individuals with HIV infection in sub-Saharan Africa(5). This may be because case fatality(6, 7) and prevalence rates(2-4, 8) for invasive cryptococcal disease are higher in resource-limited settings.

Several developments have led to a growing interest in creating new approaches for the early treatment of invasive cryptococcal disease in resource-limited settings(9, 10). First, diagnostic testing and treatments for cryptococcal disease are now more available even in resource-limited settings. Both antiretroviral therapy (ART) and fluconazole are increasingly available in sub-Saharan Africa(11, 12). In addition, serum cryptococcal antigen (sCrAg) is a well-established and highly sensitive and specific assay for invasive cryptococcal disease(13). A novel point-of care cryptococcal antigen test which can be used on serum, plasma, or urine has also been recently evaluated(14, 15).

Furthermore, cryptococcal antigenemia, or asymptomatic cryptococcal infection, is both a prevalent and highly morbid condition among HIV-infected individuals in Africa and Southeast Asia. Four observational cohort studies from Uganda, South Africa, and Thailand were recently published; these studies revealed that 6-13% of individuals entering HIV outpatient care with a CD4 cell count  $\geq 100$  cells/ $\mu$ l have asymptomatic cryptococcal infection(16-20). Retrospective studies conducted in sub-Saharan Africa provide data on the clinical implications of untreated asymptomatic cryptococcal infection in HIV-infected individuals with CD4 cell counts  $\geq 100$  cells/ $\mu$ l. One study demonstrated that asymptomatic cryptococcal infection was 100% sensitive for the development of cryptococcal meningitis during the first year of ART(20). A second study reported a population attributable risk for mortality of 18% among individuals initiating ART, comparable to that associated with active tuberculosis(18). Thus, despite treatment with ART, asymptomatic cryptococcal infection in individuals with low CD4 cell counts is predictive of cryptococcal meningitis and death.

Only a few small studies describe the outcomes of treatment with both anti-fungal medications and ART; mortality due to asymptomatic cryptococcal infection after treatment with ART and low-dose fluconazole is unacceptably high(16, 19). There are no published studies of high-dose fluconazole for asymptomatic cryptococcal infection, though this has been studied for cryptococcal meningitis(21, 22).

In summary, screening asymptomatic HIV-infected individuals with advanced immunosuppression for sCrAg clearly identifies a population at high risk of cryptococcal meningitis and death. Furthermore, routine sCrAg testing is feasible in resource-limited settings. While the mainstay of anti-cryptococcal therapy in resource-limited settings is oral fluconazole, preliminary evidence suggests that low-dose fluconazole is not an effective treatment.

In response to these findings, Family AIDS Care and Education Services (FACES), a decentralized outpatient HIV care and treatment program in Kenya, initiated an intervention to screen HIV-infected individuals with advanced immunosuppression for early cryptococcal infection and treat those with cryptococcal infection with ART and high-dose fluconazole. The goal of this evaluation was to determine whether this intervention would improve survival among all adults with CD4 counts  $\leq 100$  cells/ $\mu$ l as compared to a historical control. To our knowledge, there are no published reports of the outcomes of cryptococcal antigen screening in an outpatient HIV care setting, though there is one recent study from Tanzania reporting outcomes from screening HIV-infected individuals in an inpatient medical ward(23).

## Methods

A screening and treatment intervention for early cryptococcal infection in HIV-infected adults with low CD4+ T-cell counts was initiated at FACES in November of 2009. Founded in 2004, FACES has pioneered a family-centered model of HIV care, prevention and treatment and supports 83 HIV care and treatment sites across 5 districts in Nyanza Province, Kenya. As of July 2011, FACES had cumulatively enrolled 101,617 individuals and has 40,546 individuals on ART.

The screening and treatment intervention consisted of several components. FACES protocols require all HIV-infected adults who are newly enrolling in clinical care to have a CD4+ T-cell count and rapid plasma reagin (RPR) test. Laboratory tests are conducted centrally at five district laboratories. Laboratory protocols were developed so that all adults who had CD4+ T-cell count  $\leq 100$  cells/ $\mu$ l and had a serum sample (drawn for RPR) were automatically tested for the presence of sCrAg (Immuno-Mycologics, Norman, OK). If the RPR sample was not present and CD4+ T-cell count was  $\leq 100$  cells/ $\mu$ l, a request was sent back to the clinic site for a serum sample. If a sCrAg test was positive (defined as titer  $\geq 1:2$ ) then a treatment protocol was sent back to the health facility along with the test results.

Our treatment protocol for all patients with a positive sCrAg test recommended high-dose fluconazole for intensive and consolidation therapy (1200mg per day for 2 weeks followed by 800mg per day for 8 weeks). This was followed by maintenance fluconazole (200mg per day). Fluconazole dose adjustments were recommended for individuals with renal failure or concurrent rifampicin treatment. If signs or symptoms of clinical meningitis were absent, the protocol recommended that ART be started at 2 weeks after initiating fluconazole treatment. If signs or symptoms of meningitis were present, ART was started at 6 weeks. Signs and symptoms of meningitis included: headache, stiff neck, photophobia, altered mental status, seizures, or focal neurological deficits.

Our treatment protocol did not differentiate between asymptomatic and minimally symptomatic patients though individuals with frank clinical meningitis as described above were not included in the intervention. Instead, we grouped asymptomatic and minimally symptomatic individuals together and defined this group as “early cryptococcal infection.” Thus, individuals with early cryptococcal infection had a positive sCrAg test (titer  $\geq 1:2$ ) and may have had minimal symptoms of meningitis, but were well enough to be seeking

medical care in an outpatient setting. We did not recommend different treatments for asymptomatic and minimally symptomatic patients because in our setting, even cryptococcal meningitis is treated primarily with fluconazole monotherapy(24). Furthermore, in our setting, patients must pay for inpatient charges while outpatient care and oral fluconazole are free. In addition, amphotericin is only intermittently available, and only at central district hospitals. Flucytosine is not licensed in Kenya. Our experience was that patients would be reluctant to be admitted unless moribund, and even once admitted, would likely not receive anything more than oral fluconazole. Thus, we included minimally symptomatic patients in our outpatient treatment protocol.

Although the intervention was implemented across all FACES-supported clinical sites, because of the challenges of gathering the evaluation data, we selected one rural and one semi-urban district for this evaluation (Rongo and Kisumu districts, respectively). Inclusion criteria for both the control and intervention groups were adults  $\geq 15$  years of age, CD4+ T-cell count  $\geq 100$  cells/ $\mu$ l, enrolled in HIV care and treatment in one of the 18 clinics in Rongo or Kisumu districts. The intervention group was comprised of individuals enrolled in HIV care and treatment between November 1, 2009 through May 31, 2010, and the historical control group was comprised of individuals enrolled between April 1, 2009 through Oct 31, 2009. The primary endpoint was all-cause mortality.

Retrospective review of charts and home visits were performed between January 2010 and December 2011. Lists of newly enrolled patients during the study period were generated from an electronic medical record (when available) or from a review of paper records of new enrollees. The paper or online medical records were reviewed to determine age and CD4+ T-cell count. A standardized chart review was performed by trained abstractors for all cases that met inclusion criteria. Home visits were performed for all individuals who had not attended a clinic appointment within 3 months of the date of chart abstraction.

First we calculated the percent uptake of the intervention using the following formula:  $100 * (\text{No. sCrAg positive individuals who received fluconazole during the intervention}) / (\text{expected number of sCrAg positive individuals in the intervention group with perfect implementation})$ . The expected number of sCrAg positive individuals in the intervention group was calculated as follows:  $(\text{total number of individuals who met inclusion criteria during the intervention period}) * (\text{proportion of individuals with CD4 T-cell count } \geq 100 \text{ cells}/\mu\text{l}) * (\text{proportion of individuals who were sCrAg positive})$ . The latter two proportions were calculated using data from the intervention group but excluding those who were not tested from the denominator.

Descriptive statistics for the intervention and control groups were compared using Wilcoxon rank-sum tests for continuous variables and Fisher's exact tests for categorical variables. Demographic and clinical variables included: age, gender, Body Mass Index (BMI), CD4+ T-cell count, receipt of ART, time between enrollment and initiation of ART, receipt of anti-tuberculosis medication during follow up period, serum cryptococcal antigen test results, and whether an individual was hospitalized for cryptococcal infection.

We compared survival among all HIV-infected adults with CD4+ T-cell count  $\geq 100$  cells/ $\mu$ l (regardless of sCrAg test results) before and after implementation of the intervention. Our primary endpoints were all-cause mortality at 3 months and at the end of the follow-up period. We were not able to ascertain cause of death but date of death was either reported in the chart or given by a relative upon home visit. Survival was defined as time from enrollment until date of death or censoring. Individuals were censored at the date of the last clinic visit. We defined lost-to-follow-up as individuals who had not attended a clinic visit within 3 months of the date of chart abstraction. Individuals who were lost-to-follow-up and

upon home visit were found to be alive were censored at the date of the home visit. Kaplan-Meier curves were generated for the intervention and historical control groups. Cox proportional hazard models were used to compare survival between the two groups.

We conducted sensitivity analyses to account for (1) incomplete uptake of the intervention, and (2) potential early initiation of the intervention. First we excluded individuals who were not tested for sCrAg in the intervention group (n=268). Then we additionally excluded individuals who were sCrAg positive but did not have documentation of fluconazole therapy (n=6). Finally, we excluded individuals in the control group who were tested for sCrAg but did not have documented signs or symptoms of meningitis (n=96).

We also compared descriptive statistics and survival between individuals with and without early cryptococcal infection in the intervention group. Statistical analyses were performed with STATA/SE 11.2 (StataCorp, College Station, TX). A significance level of  $p < .05$  was used.

### Power Calculation

We estimated approximately 10% overall mortality in HIV-infected individuals with CD4+ T-cell counts  $< 100$  cell/ $\mu$ l within one year of enrolling in care (an average between similar cohorts reporting 16.8%(20) and 6.4%(18). Mortality in sCrAg positive individuals with CD4+ T-cell counts  $< 100$  cell/ $\mu$ l starting ART was estimated at 22% and 5.3% mortality among sCrAg negative individuals(18). We assumed a 10% sCrAg positive rate in the FACES population. Assuming the maximum benefit of our intervention would be to decrease the mortality among sCrAg positive individuals to the mortality rate of sCrAg negative individuals, we estimated that the post-intervention mortality would be approximately 5.3%. The sample size needed to detect this difference, equivalent to a hazard ratio of 0.51 was 562 (assuming an alpha of 0.05, power of 0.8, 10% withdrawal rate and 1:1 ratio of cases to controls). After we had the actual sample size and mortality rate in our population, we additionally performed a post-hoc power calculation assuming a sample size of 770 in each group, 75% probability of survival in the control group at the end of the follow-up period, and alpha of .05. This calculation suggests that we are 80% powered to detect a hazard ratio of 0.74. This is roughly equivalent to a 26% reduction in mortality, or using our sample size, a reduction from 192 deaths (25% mortality) to 142 deaths, a difference of 50 deaths. However, our observed mortality rate in sCrAg negative individuals was substantially higher than those reported in prior studies (24% as compared to 5.3%(18) and 14%(20)) while our mortality rate of 39% in sCrAg positive individuals was higher than previously reported rates of 37%(20) or 22%(18). Furthermore, our intervention only reduces mortality in those who are sCrAg positive, which in our sample was 59 individuals. At best, if we reduced the mortality in the sCrAg positive group from 39% to 24%, we would only reduce the number of deaths from 23 to 14, a reduction of 9 deaths. Thus, because of the higher baseline mortality, in this programmatic evaluation we are underpowered to detect an impact on overall mortality.

### Ethics

This non-research protocol using routinely collected FACES program data for evaluation purposes was approved by the University of California San Francisco Committee on Human Research, the Kenya Medical Research Institute Ethical Review Committee, and the Centers for Disease Control and Prevention.

## Results

Of 12,211 individuals enrolling in HIV care and treatment at FACES supported sites in Kisumu and Rongo districts, Nyanza Province, Kenya, there were 1601 adults with CD4+ T-cell counts  $\geq 100$  cells/ $\mu\text{l}$  of whom charts were available for 1553 (97%) (Figure 1). The rate of loss-to-follow-up was 23% [95% Confidence Interval (CI): 21, 25] (360/1553) (Figure 1). Home visits were attempted for all individuals lost-to-follow up and vital status was determined for all but 8% [95%CI: 6, 9] (118/1553). Among the 118 individuals with unknown vital status, 86% [95%CI: 79, 92] (101/118) had given false directions to their home.

Overall, there were 1224 person-years of follow up time; 691 person-years in the control group and 532 person-years in the intervention group. The median follow-up period in the control was 331 days [Range: 1-981] and in the intervention group was 237.5 days [Range: 1-736]. Overall mortality during the follow-up period in both the control and intervention groups was 25%, and mortality within the first 3 months after enrollment into HIV care and treatment was 16% in the control group and 17% in the intervention groups. Median survival time among individuals who died in the control group was 52 days [95%CI: 44, 70] and was 57 days [95%CI: 45, 65] in the intervention group.

Overall uptake of the intervention was 52% [95%CI: 42, 62] (51/98). In the intervention group, 4757 adults were enrolled, of whom 92% [95%CI: 91, 92] (4354/4757) had a CD4 T-cell count performed. Of the 782 adults with a CD4 T-cell count  $\geq 100$  cells/ $\mu\text{l}$ , 66% [95%CI: 62, 69] (514/782) had sCrAg tests performed, of whom 11% [95%CI: 9, 15] (59/514) were positive, defined as early cryptococcal infection. Of the individuals with early cryptococcal infection, 86% (51/59) [95%CI: 75, 94] received fluconazole.

The intervention and control groups were not significantly different with regard to mortality rates, age, gender, BMI, CD4+ T-cell count, proportion started on ART during the follow-up period, or the time between enrollment and initiation of ART (Table 1). Individuals in the intervention group were significantly more likely to have sCrAg test checked ( $p < .001$ ), and have lower rates of sCrAg positive tests ( $p < .001$ ) (Table 1). Importantly, the median time between enrollment and having sCrAg tested was less than one week for the intervention group, and was 12 weeks for the control group ( $p < .001$ ). These findings reflect the change in clinical practice from ordering sCrAg tests only for individuals with suspected meningitis to a routine screening test.

Kaplan-Meier curves were generated for the intervention and control groups (Figure 2). There were no significant differences between the intervention and control groups with regard to overall survival [HR: 1.1; 95%CI: 0.9,1.3] or survival at three months [HR: 1.0; 95%CI: 0.8, 1.3]. Sensitivity analyses were conducted to account for potential early implementation of the intervention by excluding individuals in the control group who were tested for sCrAg but did not have documentation of signs or symptoms of meningitis. In addition, sensitivity analyses to account for incomplete uptake of the intervention by excluding (1) individuals in the intervention group who were not tested for sCrAg, and (2) individuals in the intervention group who were sCrAg positive but did not have documentation of fluconazole therapy. Even after exclusion of these groups, no significant differences in survival were demonstrated between the intervention and control groups (Table 2).

Within the intervention group, individuals with positive sCrAg had significantly higher overall mortality and mortality at three months (Table 3). There were few significant differences in key demographic or clinical characteristics between individuals with positive sCrAg, negative sCrAg or those who were not tested. However, individuals with positive

sCrAg had significantly lower CD4+ T-cell counts, significantly higher rates of hospitalization for cryptococcal infection, and were more likely to be treated with anti-tuberculosis medications.

Kaplan-Meier curves were generated for the 508 individuals in the intervention group who had sCrAg tests performed (Figure 3). In the intervention group, individuals with early cryptococcal infection had significantly lower overall survival [HR: 1.8 (95%CI: 1.2, 2.9); p=.009]. There were no significant differences in survival at three months between individuals with or without early cryptococcal infection [HR: 1.8 (95%CI: 1.0, 3.0); p=.03]. Similar results were obtained if individuals who had early cryptococcal infection but did not have documentation of fluconazole therapy were excluded for overall survival [HR: 1.8 (95%CI: 1.1, 2.9); p=.01] and survival at three months [HR: 1.8 (95%CI: 0.9, 3.1); p=.05].

## Discussion

An intervention to screen HIV-infected individuals with CD4+ T-cell count  $\geq 100$  cells/ $\mu$ l for early cryptococcal infection and treat with high-dose fluconazole did not demonstrate significant differences in overall or three-month survival. Potential explanations for why this intervention was not effective include limited uptake of the intervention, inclusion of individuals with minimal signs or symptoms of meningitis, inadequate power, or poor efficacy of high-dose oral fluconazole. Sensitivity analyses to account for uptake of the intervention or possible early implementation of the intervention in the control group did not alter the results. However, our study was not likely powered to detect differences in overall survival in a programmatic setting. The mortality rates in our control population were substantially higher than those observed in prior studies, thus, a post-hoc power calculation suggests that we are underpowered to detect a reduction in the overall risk of mortality due to the effect of this intervention.

Our study demonstrated significantly lower survival among individuals with early cryptococcal infection as compared to those without early cryptococcal infection even when excluding those who did not receive high-dose fluconazole. However, the magnitude of the survival difference is substantially below that reported in prior research of individuals with **untreated** asymptomatic cryptococcal infection. A study from Uganda noted a relative risk of death of 6.6 [95%CI: 1.86, 23.61](18) and a study from South Africa noted a hazard ratio of 4.75 [95%CI: 2.6, 8.8], and an adjusted hazard ratio of 3.2 [95% CI: 1.5, 6.6] for individuals with asymptomatic cryptococcal infection(20). Lower survival among sCrAg positive individuals may have been due to significantly lower CD4+ T-cell counts or possibly due to significantly higher rates of concurrent tuberculous infection. Nonetheless, since we included individuals with minimal signs and symptoms of cryptococcal meningitis, we would expect larger hazard ratios than those reported in studies of individuals with asymptomatic cryptococcal infection if fluconazole treatment was not effective. Thus, our findings suggest that treatment with high-dose fluconazole may have some benefit. Further study of high-dose fluconazole in a controlled research setting is essential to determine its efficacy.

In addition, sCrAg positive individuals were documented to have higher rates of hospitalization for cryptococcal infection. However, it is difficult to know how to interpret this because of the way data was acquired. As part of the intervention, clinicians caring for sCrAg positive individuals received a special form with treatment information as well as a request for information such as whether the individual was referred for hospitalization and whether the individual had signs and symptoms of meningitis. Individuals who were sCrAg negative did not receive this form so it is unclear whether the higher hospitalization rate is real or due to improved documentation of hospitalizations for sCrAg positive individuals.

Nonetheless, mortality rates among HIV-infected individuals with advanced immunosuppression remain unacceptably high both in our sample of HIV-infected individuals and similar cohorts in sub-Saharan Africa(1, 12). Thus, interventions to identify HIV-infected individuals earlier in the course of their disease, initiate ART, and improve health outcomes among this vulnerable population remains of critical importance.

There are several key limitations of this program evaluation. The uptake of 52% likely reduced the effect of the intervention on mortality. Second, because of the study design, our outcome measure was mortality among all individuals with CD4+ T-cell count  $< 100$  cells/ $\mu$ l (including individuals with and without early cryptococcal infection). This likely diluted the effects of the intervention as most of the individuals in the intervention group were sCrAg negative. For ethical reasons, we could not use a control group of individuals with early cryptococcal infection who did not receive fluconazole treatment. In addition, since we used a historical control, there may have been other unmeasured differences between the groups that led to confounding, though analysis of key clinical and demographic characteristics demonstrated that the groups were similar. Also, providing the same treatment to individuals with and without minimal signs or symptoms of meningitis may have diluted the effects of the intervention as we would expect individuals with cryptococcal meningitis to have poorer outcomes from monotherapy with fluconazole than those with positive sCrAg but no cryptococcal meningitis(19). However, determining whether individuals who had minimal signs and symptoms had cryptococcal meningitis was not possible for this analysis.

In addition, because this was a program evaluation using available clinical records some information was missing due to missing enrollment information [0.1% (18/12,211)] or missing files at clinic sites [4% (395/9513)]. Finally, documentation of fluconazole treatment was poor. We had documentation of at least some fluconazole treatment in 86% of individuals with early cryptococcal infection; however, clear documentation of fluconazole dose, duration, and adherence was not available.

A program evaluation of a screening and treatment intervention for early cryptococcal infection does not demonstrate significant improvement in overall survival among HIV-infected individuals with advanced immunosuppression as compared to a historical control group. Potential explanations include inadequate power, low uptake the intervention, inclusion of individuals regardless of mild signs or symptoms of meningitis, or poor efficacy of high-dose oral fluconazole for the treatment of early cryptococcal infection. However, based on this evaluation, it cannot be concluded that systematic pre-emptive fluconazole therapy for asymptomatic and minimally symptomatic patients does not reduce cryptococcal-specific mortality or overall mortality in an adequately powered study. Furthermore, the lower hazards of death observed in this evaluation among individuals with early cryptococcal infection as compared to studies of untreated individuals suggests that there is some benefit to this intervention. Future controlled studies in research settings are critical to identify efficacious treatments for early cryptococcal infection. Further, identifying ways to improve uptake of similar interventions and improve access to inpatient treatment for individuals with signs and symptoms of meningitis are crucial to improve outcomes for this high-risk population in decentralized HIV care and treatment programs.

## Acknowledgments

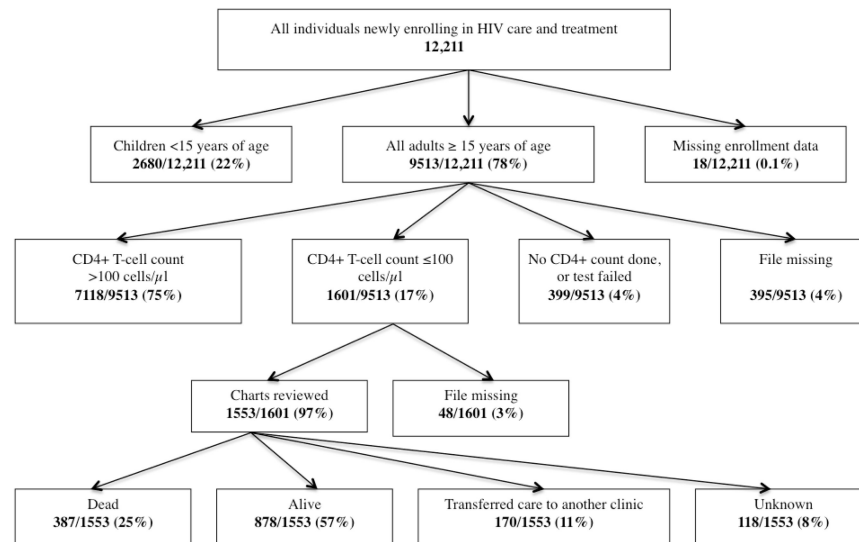

We would especially like to thank the Family AIDS Care and Education Services (FACES) Social Science Department clinic/community health assistants for their assistance with data collection. We would like to thank the medical officers, clinical officers, nurses, staff and patients at FACES for their participation. In addition, we would like to thank the Ministry of Public Health and Sanitation and the Ministry of Medical Services, Nyanza Province for their support. Finally, we would like to thank the Director of the Centre for Microbiological Research and the Director of Kenya Medical Research Institute (KEMRI) for their support.

**Sources of Support:** This work was supported by the President's Emergency Plan for AIDS Relief [U62/CCU924511 to CRC and EAB] the American Academy of Neurology Foundation Practice Research Training Fellowship [to ALM], the Hellman Family Foundation [to ALM], and the Fogarty International Clinical Research Fellowship [5 R24 TW00798; 3 R24 TW00798-02S1 to ALM] from the National Institutes of Health, Fogarty International Center through Vanderbilt University, the National Cancer Institute (NCI), the National Institute on Drug Abuse (NIDA), Office of the Director, National Institutes of Health and the National Institute of Mental Health (NIMH). The Centers for Disease Control & Prevention had a role in editing the final manuscript and approved the manuscript for publication. This manuscript is submitted with permission to publish from the Director KEMRI.

**Figure 1.** Flow chart describing eligibility and outcomes of HIV infected individuals newly enrolling in care and treatment at Family AIDS Care and Education Services in Kenya in 2009-2010.

**Figure 2.** Kaplan-Meier survival curves for overall survival in the control and intervention groups in an evaluation of a screening and treatment intervention for early cryptococcal infection in Kenya in 2009-2010.

**Figure 3.** Kaplan-Meier survival curves for overall survival in serum cryptococcal antigen (sCrAg) positive and negative individuals identified as part of a screening and treatment intervention for early cryptococcal infection in Kenya in 2009-2010

**Table 1**

Comparison of key baseline clinical and demographic variables between the control and intervention groups in an evaluation of a screening and treatment intervention for early cryptococcal infection in HIV-infected individuals in Kenya in 2009-2010.

	Intervention n=782	Control n=771	p
Overall mortality	25% (196) [22, 28]	25% (191) [22, 28]	0.91
Three-month mortality	17% (131) [14, 19]	16% (122) [13, 18]	.63
Age (years)	35 [29, 41]	34 [29, 42]	.96
Female	55% (414) [49, 56]	55% (424) [51, 59]	.44
Body Mass Index (kg/m <sup>2</sup> ) <sup>*</sup>	18.8 [17.0, 20.9]	18.6 [16.8, 20.7]	.43
CD4+ T-cell Count (cells/ $\mu$ l)	41 [18, 70]	45 [18, 72]	.35
Started on ART during follow-up period	77% (601) [74, 80]	76% (586) [73, 79]	.72
Time between enrollment and initiation of ART (weeks) <sup>†</sup>	4 [2,7]	4 [2,6]	.10
Received anti-tuberculous medication	23% (183) [20, 26]	27% (209) [24, 30]	.10
Hospitalized for cryptococcal infection	0.3% (2) [-0.1, 0.6]	1% (8) [0.3, 1.8]	.06
<i>sCrAg testing:</i>			
Tested for sCrAg	66% (514) [62, 69]	15% (114) [12, 17]	<.001
Positive sCrAg test (titer 1:2) <sup>‡</sup>	11% (59) [9, 14]	28% (32) [20, 36]	<.001
Time between enrollment and sCrAg test (weeks) <sup>**</sup>	0 [0, 2]	12 [2, 25]	<.001

Note: Data are % (n) [95% confidence interval] of patients or median [interquartile range] unless otherwise indicated. Two-sided Fisher's exact test was used for categorical variables and Wilcoxon rank-sum tests were used to compare continuous variables.

Abbreviations: ART: anti-retroviral therapy, sCrAg: serum cryptococcal antigen

\* n=1499, control n=741, intervention n=758

† n=1133, control=557, intervention=576

‡ n=628, control=114, intervention=514

\*\* n=627, control=113, intervention=514

**Table 2**

Comparison of overall and three month survival between the control and intervention groups in an evaluation of a screening and treatment intervention for early cryptococcal infection in HIV-infected individuals in Kenya in 2009-2010.

		<b>Overall survival Hazard Ratio [95% CI]</b>	<b>Three-month survival Hazard ratio [95% CI]</b>
Overall Sample (n=1553)		1.1 [0.9, 1.3]	1.0 [0.8, 1.3]
<b>Sensitivity analysis excluding:</b>			
Poor Uptake	Individuals in the intervention group who were not tested for sCrAg (n=1285)	1.1 [0.8, 1.3]	1.0 [0.8, 1.4]
	AND Individuals in the intervention group who were sCrAg positive but did not have documentation of fluconazole therapy (n=1277)	1.0 [0.8, 1.3]	1.0 [0.8, 1.3]
Early Implementation	AND Individuals in the control group who were tested for sCrAg but did not have documentation of signs or symptoms of meningitis (n=1181)	0.99 [0.8, 1.2]	0.99 [0.7, 1.3]

Abbreviations: sCrAg: serum cryptococcal antigen

**Table 3**

Comparison of outcomes, clinical and demographic variables among individuals who had sCrAg testing performed in the intervention group in an evaluation of a screening and treatment intervention for early cryptococcal infection in HIV-infected individuals in Kenya in 2009-2010.

	sCrAg positive (titer 1:2) n=59	sCrAg negative n=455	p
Overall mortality	39% (23) [26, 52]	24% (107) [20, 27]	.02
Mortality within 3 months of enrollment	27% (16) [16, 39]	16% (71) [12, 19]	.04
Age (years)	36 [29, 42]	35 [28, 42]	.64
Female	54% (32) [41, 67]	50% (228) [46, 55]	.58
Body Mass Index(kg/m <sup>2</sup> )*	18.9 [16.3, 19.9]	18.7 [16.9, 20.8]	.22
CD4+ T-cell Count (cells/ $\mu$ l)	23 [9, 56]	41 [19, 70]	.002
Started on ART during follow-up period	68% (40) [56, 80]	78% (355) [74, 82]	.06
Time between enrollment and initiation of ART (weeks) <sup>†</sup>	4.5 [2.5, 8]	4 [2, 7]	.29
On anti-TB medication during follow up period	37% (22) [25, 50]	24% (109) [20, 28]	.04
Hospitalized for cryptococcal infection	4% (2) [-1, 8]	0% (0) --	.01

Abbreviations: ART: anti-retroviral therapy; sCrAg: serum Cryptococcal antigen; ND: Not done; sCrAg: serum cryptococcal antigen; TB: tuberculosis.

Note: Data are % (n) [95% confidence interval] of patients or median [interquartile range] unless otherwise indicated. Two-sided Fisher's exact test was used for categorical variables and Wilcoxon rank-sum tests were used to compare continuous variables.

\* sCrAg+n=57, sCrAg- n=442.

<sup>†</sup> sCrAg+n=40, sCrAg- n=34
