OT-RSH for molecules using the ionization potential theorem (IPT) and more recently extended to solid-state systems, based on an *ansatz* Inverse chain length that generalizes the IPT to the removal of charge from a localized

of increasing size, from the monomer limit to the infinite polymer limit using this approach. By comparing our results with other localization-based methods and where available with experiment, we demonstrate that Wannier-localization-based optimal tuning is highly accurate in predicting ionization potentials for any chain length, including the nanoscale regime.

I. INTRODUCTION

Accurate prediction of the electronic properties of molecular and solid-state systems is of crucial importance in electronics and optoelectronics. In particular, the ionization potential (IP), electron affinity (EA), and therefore the fundamental gap, defined as the difference between the IP and EA, are key quantities in understanding materials and device properties. Ab initio many-body perturbation theory, typically within the *GW* approximation, $1-\frac{7}{7}$ $1-\frac{7}{7}$ $1-\frac{7}{7}$ can be a highly accurate method for predicting these quantities. But owing to its relatively high computational cost, there is an ongoing interest in developing accurate enough approximations within density functional theory (DFT) (see, e.g., refs $4,8-14$ $4,8-14$ $4,8-14$), that can serve as an inexpensive yet potentially still accurate alternative for computing these important properties.

method for predicting ionization potentials. This was first achieved

Wannier function. Here, we study one-dimensional molecular chains

Within the framework of DFT, we focus on optimal tuning $(OT)^{15}$ of (screened)^{[16](#page-6-0)} range-separated hybrid ((S)RSH) functionals, where screening is included for the case of bulk solids. OT-(S)RSH has been shown to be a highly accurate, nonempirical method for predicting electron removal/addition energies and therefore fundamental gaps for a variety of molecular systems (see, e.g., refs [15,17](#page-6-0)−[24](#page-6-0)) and molecular solids (see, e.g., refs [16,25](#page-6-0)−[30\)](#page-6-0). Generally, RSH functionals allow for a different combination of exchange and correlation approximations at different ranges of electron−electron interactions and therefore offer flexibility in choosing
appropriate functional parameters.^{[31](#page-6-0)–[34](#page-6-0)} OT-(S)RSH allows one to choose such parameters nonempirically by enforcing

two conditions: the correct asymptotic behavior of long-range interactions^{[35](#page-6-0)−[37](#page-6-0)} and the ionization potential theorem (IPT).[35,36,38](#page-6-0),[39](#page-6-0) The latter has been shown to be particularly crucial not only for IP predictions, but also for accurate EA and therefore gap predictions.⁴⁰

▼ WOT-RSH

Unfortunately, optimal tuning based on straightforward application of the IPT fails in the solid-state limit. This is because, owing to the natural delocalization of electronic orbitals in this limit, the IPT is trivially satisfied for any choice of functional parameters, regardless of the accuracy (or lack thereof) of the obtained electronic structure.^{[41](#page-6-0)−[44](#page-7-0)} To overcome this significant limitation, a Wannier-localization-based optimal tuning of SRSH (WOT-SRSH) has been proposed.⁴⁵ This approach enforces a generalized IPT *ansatz*, [46](#page-7-0) based on a constrained removal of charge from a localized Wannier function.[47](#page-7-0) WOT-SRSH has recently been shown to be highly successful in predicting band gaps and optical spectra of solids, both alone^{[45,48,49](#page-7-0)} and as an optimal starting point to GW calculations, $49,50$ $49,50$ $49,50$ without any empiricism.

Figure 1. Ionization potential as a function of *n*, the number of repeating units (top axis), and the inverse of *n* (bottom axis), for (a) alkanes, (b) *trans*-oligoacetylenes (tOAs), and (c) oligothiophenes (OLTs). Computed results are given by the negative of the HOMO energy based on OT-RSH (red circles), WOT-RSH (green triangles), KIPZ (magenta squares, from ref [59\)](#page-7-0), and LOSC (cyan plus signs, from ref [13\)](#page-6-0). Experimental results (black stars) are taken from the following sources: For alkanes: $n = 0.5$: ref [73,](#page-7-0) $n = 1$: ref [74,](#page-7-0) $n = 1.5$, 2, 2.5: ref [75,](#page-7-0) $n \rightarrow \infty$: refs [76](#page-7-0)–[78](#page-7-0). For tOAs: $n = 1,2$: ref [75](#page-7-0), $n = 3$: ref [79](#page-7-0), $n = 4$: ref [80](#page-7-0), $n \to \infty$: ref [81.](#page-7-0) For OLTs: refs [51,82.](#page-7-0) Inset: schematic view of the repeating unit of each chain, showing carbon atoms in black, hydrogen atoms in gray, and sulfur atoms in yellow.

The success of OT-RSH in the molecular limit and WOT-SRSH in the solid-state limit immediately raises important questions as to the utilization of (W)OT approaches for intermediate-size systems. Specifically, for systems of increasing size, at which point does localization become necessary for optimal tuning? How do OT and WOT calculations compare with one another and how well do they predict the evolution of electronic properties with system size, compared to experiment and/or other benchmark calculations?

A class of systems where such questions arise naturally and can be examined systematically is that of linear oligomers, i.e., linear molecular chains composed of a variable number of repeating units of a given monomer. Indeed, such systems have been previously used to test the accuracy of various approaches within DFT.^{[13,17,](#page-6-0)[51](#page-7-0)-[57](#page-7-0)}

Here, we use these benchmark systems to answer the above questions by employing OT- and WOT-RSH to compute the IPs of three different one-dimensional molecular chains of increasing length, from the monomer limit to the infinite polymer limit. By comparing our results to other methods and to experiment where available, we show that OT- and WOT-RSH yield essentially identical results for shorter chains, but deviate from each other for larger chains, with WOT-RSH yielding a correct convergence to the infinite polymer limit and providing consistently more accurate results than OT-RSH, as compared to reference theoretical results.

Figure 2. HOMO (top row) and highest expectation energy Wannier function (bottom row) for selected alkanes: (a) ethane (*n* = 1), (b) propane $(n = 1.5)$, (c) butane $(n = 2)$, and (d) polyethylene $(n \rightarrow \infty)$. Carbon and hydrogen atoms are shown in black and gray, respectively. The wave function isosurface is shown in light blue and yellow for a value of 2.0.

II. METHODS

II.I. Benchmark Systems. We study three types of onedimensional molecular chains: Linear alkanes, *trans*-oligoacetylenes (tOAs), and oligothiophenes (OLTs), the chemical formulas of which are $C_{2n}H_{4n+2}$, $C_{2n}H_{2n+2}$, and $C_{8n}H_{4n+2}S_{2n}$ respectively (see inset of [Figure](#page-2-0) 1). Half-integer *n* values correspond to an odd number of carbon atoms for the alkanes and tOAs and an odd number of sulfur atoms for the OLTs. For clarity, throughout we use the term "polymer" to refer only to the limit of $n \rightarrow \infty$, namely polyethylene, *trans*polyacetylene and polythiophene, respectively. Molecular geometry was optimized using molecular mechanics, without further optimization at the DFT level (to which spectral properties are sensitive⁵⁸), so that the effect of orbital delocalization is due to chain length increase alone. This follows a similar practice in refs [55,59.](#page-7-0) See the [Supporting](https://pubs.acs.org/doi/suppl/10.1021/acs.jctc.4c00847/suppl_file/ct4c00847_si_001.pdf) [Information](https://pubs.acs.org/doi/suppl/10.1021/acs.jctc.4c00847/suppl_file/ct4c00847_si_001.pdf) $(SI)^{60}$ $(SI)^{60}$ $(SI)^{60}$ for more details.

II.II. Range-Separated Hybrid Functionals. In RSH functionals, $61,62$ $61,62$ the Coulomb operator is partitioned into two terms, typically by exploiting the error function, erf, in the form

$$
\frac{1}{r} = \frac{\alpha + \beta \text{erf}(\gamma r)}{r} + \frac{1 - [\alpha + \beta \text{erf}(\gamma r)]}{r}
$$
\n
$$
\frac{r}{\text{SLx}}
$$
\n(1)

where *r* is the interelectronic distance and α , β , γ are free parameters. While eq 1 represents a trivial identity, this split of the Coulomb repulsion allows for use of different approximations for the electron exchange associated with each term. For the first term, we use Fock (exact) exchange (xx), whereas for the second we use semilocal exchange (SLx). This leads to two limiting-case fractions of exact exchange: *α* for short-range (SR) interactions $(r \to 0)$ and $\alpha + \beta$ for long-range (LR) interactions $(r \rightarrow \infty)$. These two limits are interpolated smoothly via the error function, with the transition governed by the range-separation parameter, *γ*. Accordingly, the exchange energy of RSH is expressed as

$$
E_{\rm x}^{\rm RSH} = \alpha E_{\rm xx}^{\rm SR} + (1 - \alpha) E_{\rm SLx}^{\rm SR} + (\alpha + \beta) E_{\rm xx}^{\rm LR}
$$

$$
+ (1 - \alpha - \beta) E_{\rm SLx}^{\rm LR}
$$
(2)

In this work, we choose α as 0.25 throughout, as in global and short-range hybrid functionals,^{[63](#page-7-0)-[65](#page-7-0)} in order to retain a useful balance between exchange and correlation in the short-range.^{[66](#page-7-0)} The correct asymptotic limit of the potential is attained by setting $\alpha + \beta = 1/\varepsilon$, where ε is the scalar dielectric constant.^{[25](#page-6-0)} In this work we set $\varepsilon = 1$, the appropriate choice for an isolated molecule in vacuum,^{[35](#page-6-0)–[37](#page-6-0)} which is correct also for the polymers, where asymptotic screening vanishes owing to the low dimensionality (see, e.g., refs [67](#page-7-0)−[69](#page-7-0), for two dimensions). We use the range-separated version^{70,[71](#page-7-0)} of the Perdew−Burke−Ernzerhof (PBE) exchange functional^{[72](#page-7-0)} to treat the semilocal exchange components in the RSH, along with full PBE semilocal correlation. Nonempirical methods employed to select *γ* are discussed below.

Once the three parameters are selected, one can compute any property of interest. In this work, we focus on the eigenvalue corresponding to the highest occupied molecular orbital (HOMO), the negative of which provides a prediction for the IP in an optimally tuned functional.

II.III. Optimal Tuning of RSH. As mentioned in the introduction, in the OT-RSH approach *γ* is selected to enforce the IPT, which is an exact physical condition in DFT. Here, we enforce the IPT for the neutral system, namely we seek *γ* such that

$$
\Delta J^{\gamma} \equiv E^{\gamma}(N-1) - E^{\gamma}(N) + \epsilon_{\text{H}}^{\gamma} = 0 \tag{3}
$$

where $E'(N)$ and $E'(N-1)$ are the total ground-state energies for the neutral system with *N* electrons and the singly ionized cation, respectively, and ϵ_H^{γ} is the HOMO eigenvalue for the N -electron system. See the SI^{60} SI^{60} SI^{60} SI^{60} for more computational details.

II.IV. Wannier-Localization-Based Optimal Tuning of RSH. As mentioned above, in the bulk limit the IPT is trivially satisfied for any choice of γ , which precludes the predictive

selection of a unique range-separation value based on [eq](#page-3-0) 3. Many authors have explored localized orbitals as a means of circumventing this limitation of the IPT, in the context of different approaches within DFT.[11](#page-6-0),[13](#page-6-0),[45,46](#page-7-0),[56](#page-7-0),[59](#page-7-0)[,83](#page-8-0)−[95](#page-8-0) In the context of SRSH functionals, Wing et al.^{[45](#page-7-0)} adopted an *ansatz*^{[46](#page-7-0)} that generalizes the IPT to the removal of an electron from a state that corresponds to a localized Wannier function, namely

$$
\Delta I^{\gamma} \equiv E^{\gamma}[\phi](N-1) - E^{\gamma}(N) + \langle \phi | \hat{H}_{N}^{\gamma} | \phi \rangle = 0 \tag{4}
$$

where ϕ is the maximally localized Wannier function^{[47](#page-7-0)} for which the expectation energy with respect to the DFT Hamiltonian of the *N*-electron system, $\langle \phi | \hat{H}_{N}^{\prime} | \phi \rangle$, is the largest. $E^{\gamma}[\phi](N-1)$ is the total energy of the constrained $(N-1)$ electron system, which differs from the ground-state $(N - 1)$ electron system in that an electron has been removed from the Wannier function.^{[45](#page-7-0)} This constraint is imposed via a Lagrange multiplier that controls the occupancy of the Wannier function, which is constructed of the occupied-orbital manifold using the PBE functional. We emphasize that for finite systems, maximally localized Wannier functions reduce to Foster-Boys orbitals, $96-99$ $96-99$ $96-99$ and can be viewed as their solid-state equivalent.[47](#page-7-0) We use the term Wannier functions throughout, because it applies in both the molecular and solid-state limits and because the localized orbitals that we use are generated with the WANNIER90 code.^{[100](#page-8-0)} Additional computational details are given in the [SI.](https://pubs.acs.org/doi/suppl/10.1021/acs.jctc.4c00847/suppl_file/ct4c00847_si_001.pdf) [60](#page-7-0)

III. RESULTS AND DISCUSSION

[Figure](#page-2-0) 1 shows the computed IP, based on the negative of both the OT-RSH and WOT-RSH HOMO energy, as a function of the inverse of *n*, the number of repeating units, for each of the three systems studied in this work. These results are compared with those obtained from two other localization-based methods: the integer Koopmans plus Perdew−Zunger (KIPZ) correction method for the alkanes, taken from ref [59](#page-7-0), and the localized orbital scaling correction (LOSC) approach for the tOAs, taken from ref [13.](#page-6-0) The computational results are further compared with experiment where available.

First, we compare the OT-RSH and WOT-RSH results. We observe two trends that are common to all three systems. First, the two methods predict essentially identical IPs for the shorter chains, where the HOMOs are "naturally" localized owing to the small system size. This is a significant observation, because it demonstrates the validity and generality of the IPT *ansatz* used in WOT-RSH, even in a realm for which it was not designed and in which it is not strictly necessary. Second, the deviation between the two methods increases with chain length and becomes as large as ∼0.8 eV for the case of alkanes with *n* = 7. We attribute this to the delocalization of the HOMO in the longer chains, shown in [Figure](#page-3-0) 2 for selected alkanes and in the [SI](https://pubs.acs.org/doi/suppl/10.1021/acs.jctc.4c00847/suppl_file/ct4c00847_si_001.pdf) for selected tOAs and OLTs. This delocalization ultimately prevents the use of OT-RSH altogether for large enough chains, as the IPT is approaching the point where it is trivially obeyed and a numerically stable determination of the range-separation parameter is no longer possible. In contrast, the WOT-RSH relies on a Wannier function that is localized by construction and changes little with *n*, as also shown in [Figure](#page-3-0) 2 for selected alkanes and in the [SI](https://pubs.acs.org/doi/suppl/10.1021/acs.jctc.4c00847/suppl_file/ct4c00847_si_001.pdf) for selected tOAs and OLTs. As a result, the WOT-RSH procedure is numerically stable and physically meaningful for any *n*, including $n \to \infty$, i.e., the polymer limit.

Interestingly, while the trend of OT- and WOT-RSH results deviating from one another is common to the three systems, it appears to be more abrupt for the alkanes, where the deviation starts already at relatively short chains, but more gradual and at larger *n* for the two other systems. We note that the abrupt deviation in the alkanes occurs between *n* = 1.5 and *n* = 2. This can be associated with an abrupt change in the symmetry of the HOMO, owing to orbital reordering, between these two chains, as demonstrated in [Figure](#page-3-0) $2(b,c)$. The same symmetry as in $n = 2$ is then maintained for all $n > 2$. The symmetry of the HOMO for the tOAs and OLTs, on the other hand, is unchanged for all *n*, as demonstrated in the [SI](https://pubs.acs.org/doi/suppl/10.1021/acs.jctc.4c00847/suppl_file/ct4c00847_si_001.pdf).

Next, we compare our results to benchmark computational data. As shown in [Figure](#page-2-0) 1, the general trend of the IP saturating with increasing chain length, up to the polymer limit, is clearly captured. This trend is less observed in the tOAs, in agreement with the results of ref [55](#page-7-0), which showed that the saturation occurs in longer chain lengths that are outside the range studied in this work. Furthermore, the WOT-RSH results agree very well quantitatively with previous localization-based schemes�to ∼0.1 eV with KIPZ results and ∼0.2 eV with LOSC, on average. Conversely, and as expected based on the above discussion, the OT-RSH results do not extrapolate to the correct polymer limit.

Finally, we compare the computed results to experimental ones. For alkanes, the experimental results agree well with all theoretical methods for $n = 0.5$ and $n = 1$. For $n = 1.5$, all theoretical methods appear to agree, but predict a value larger than experiment by \sim 0.5 eV. For $n = 2$ and $n = 2.5$, WOT-RSH and KIPZ overestimate experiment by a similar amount, while OT-RSH is in better agreement with it. This, however, may be accidental, given the fact that the *n* = 1.5 result of OT-RSH overestimates experiment. The IP for $n \to \infty$, polyethylene, agrees well with several experimental estimations.^{[76](#page-7-0)−[78](#page-7-0)}

For the tOAs, agreement with existing experimental values for finite chains is consistently good for all theoretical methods. The experimental value for *trans*-polyacetylene is taken from solid-state measurements, where the IP can be smaller by hundreds of meV from the gas-phase IP_{ℓ}^{81} IP_{ℓ}^{81} IP_{ℓ}^{81} possibly explaining the deviation from the WOT-RSH prediction. For the OLTs, with the exception of the $n = 0.5$ monomer, our results underestimate experimental ones by more than 0.3 eV. Whether this discrepancy is related to structural differences, thermal effects, experimental uncertainties, or theoretical limitations is at present unknown. Even so, the WOT-RSH results agree qualitatively and semiquantitatively with the experimental ones, whereas the OT-RSH results do not. Overall, then, the WOT-RSH results provide good agreement with experimental trends, where available, throughout.

In order to obtain a deeper understanding of the similarities and differences between OT-RSH and WOT-RSH, we further analyze quantities that are central to the optimal tuning procedure. [Figure](#page-5-0) 3(a) shows the spatial spread, *R*, which is the square root of the second moment of the position operator, 47 and therefore a measure of the degree of localization (see the [SI](https://pubs.acs.org/doi/suppl/10.1021/acs.jctc.4c00847/suppl_file/ct4c00847_si_001.pdf) for additional details). It is shown for all systems studied in this work, as a function of effective chain length, for both the HOMO used in the OT approach ([eq](#page-3-0) 3) and for the Wannier function used in the WOT approach (eq 4). [Figure](#page-5-0) $3(b)$ similarly shows the optimal tuning length, namely the inverse of the optimally tuned range-separation parameter *γ**. Here, the effective chain length is defined via $c_0 + nc_1$, where c_0 and c_1 have been determined through a linear fit of *R* of the HOMO

Figure 3. (a) Spatial spread, *R*, and (b) optimal tuning length, 1/*γ**, as a function of effective chain length (see text for details), for the three systems studied in this work. Blue curves correspond to highestoccupied molecular orbitals and the OT approach, red curves correspond to Wannier functions and the WOT approach.

to *n*. This means that the effective chain length is simply the linear fit of *R*, based on the (justified) assumption that the HOMO is delocalized across the entire chain.

The first observation of note is that the HOMOs and Wannier functions exhibit different spreads already for short chains. Nonetheless, for the same shorter chains *γ** values are nearly identical in OT and WOT. We further tested this result by applying the same methodology to benzene. This yielded spreads of 1.7 and 1.1 Å for the HOMO and Wannier function, respectively, but similar *γ** values of 0.42 and 0.39 Å[−]¹ from OT and WOT, respectively. This indicates that the energy differences caused by the different densities used in the OT and WOT procedures are compensated for, consistently, by the different tuning criteria of the two approaches. Thus, using WOT over OT for small molecules is not strictly necessary but is useful for consistency along the evolution of system size.

The second observation of note is that the spread of the HOMO continues to increase as chain length increases, reflecting the increased delocalization observed in [Figure](#page-3-0) 2, with a concomitant increase in the optimal tuning length. In fact, there is an almost perfectly linear relation between orbital spread and optimal tuning length for the longer chains in all three molecule types. This validates, by providing a more quantitative framework, the conceptual argument regarding the failure of OT for increasingly larger systems due to a uniform removal of an electron from the entire system.

A third observation of note is that despite the spread of the Wannier functions attaining its $n \to \infty$ limit already for very short chains (manifested as near constant red plots in Figure $3(a)$), the optimal tuning length continues to vary more significantly as the chain length increases. This can be rationalized by considering that the WOT procedure represents the removal of a localized electron, but that electron is still effectively removed from the entire molecule. This shows that the WOT procedure is indeed capable of capturing features of the "true" potential, including those on a larger scale than the orbital itself. Taken together, the above observations explain the utility of the WOT approach throughout the evolution of the chain length.

IV. CONCLUSIONS

We have compared two optimal tuning methods of RSH, namely OT-RSH and WOT-RSH, for the computation of the IP of one-dimensional molecular chains of increasing length. We have demonstrated the known failure of OT-RSH for long chains, owing to orbital delocalization. We found, however, that WOT-RSH is successful in predicting accurate IPs throughout the evolution of the chain length, not only in the polymer limit for which it was originally designed, but throughout the entire range of oligomers, from monomer to polymer. Specifically, WOT-RSH results agree with both experimental trends and past localization-based computational schemes. This provides a first step in the application of optimal tuning to nanosized objects where neither the molecular nor the bulk limits apply.
