6 ABSTRACT

7 To fully utilize the results of laboratory-based studies of the chemistry of model atmospheric
8 aerosol reactions, it is important to understand how to relate them to the conditions found in
9 nature. In this study, we have taken a validated reaction-diffusion mechanism for oxidation of
10 $C_{30}H_{62}$ aerosol by OH under flow tube conditions and examined its predictions for another
11 experimental regime (continuous flow stirred tank reactor) and for the atmosphere, spanning
12 alkane aerosol viscosities from liquid to semi-solid. The results show that under OH-
13 concentration-limited and aerosol-mixing-limited conditions, it should be possible to select
14 laboratory experimental conditions where many aspects of the particle phase and volatile product
15 chemistry under atmospheric conditions can be revealed. If the OH collision and organic
16 diffusion rates are comparable, however, reactivity is highly sensitive to the details of both OH
17 concentration and internal mixing. The characteristics of the transition between limiting

18conditions provide key insights into which parts of the reaction mechanism dominate in the
19various kinetic regimes.

20Introduction

21

22 Laboratory studies are central for interpreting field observations and parameterizing
23models to understand and ultimately predict chemical transformations in the atmosphere.¹ Gas-
24phase rate coefficients, yields and formation mechanisms of secondary organic aerosol, and
25multiphase transformation mechanisms and rates provide quantitative parameters needed to
26improve the fidelity of regional and climate models. A key challenge, noted by many, is
27developing reliable methods to mimic or reliably extrapolate the chemistry conducted in the
28laboratory-scale reactors to the real atmosphere.²⁻⁷ Central to this challenge is the difficulty of
29matching laboratory and atmospheric concentrations and timescales that often differ by orders of
30magnitude.

31 To determine the oxidation lifetime of many trace gas species, rate coefficients can be
32easily quantified under laboratory conditions and directly applied to atmospheric conditions.
33Here the experimental challenge centers on understanding complex reaction networks and
34accurately providing oxidation conditions and trace gas levels to reproduce the competition
35between bimolecular and unimolecular pathways in polluted and pristine regions of the
36atmosphere. This is nicely illustrated by the recent discovery of the importance of unimolecular
37autoxidation pathways^{8, 9} of gas-phase peroxy radicals (RO_2) when bimolecular reactions of NO
38are suppressed (e.g. a source of aerosol in the pristine regions of the atmosphere¹⁰⁻¹²). Another
39example is the formation and chain propagation of aerosol-phase alkoxy radicals when reaction

40 conditions are designed to favor $\text{RO}_2 + \text{NO}$ or SO_2 (i.e., the urban atmosphere) rather than typical
41 laboratory oxidation conditions that naturally favor $\text{RO}_2 + \text{RO}_2$ pathways.^{13, 14}

42 It is not so straightforward, however, to examine the coupling of gas-aerosol interactions
43 with oxidative ageing of aerosols. Direct extrapolation of laboratory observations to the
44 atmosphere becomes more tenuous due to the emergence of additional timescales (i.e., particle-
45 phase diffusion, uptake, evaporation) within the aerosol particles that can govern the kinetics.
46 For example, heterogeneous oxidation lifetimes (involving OH or O_3) and oxidized product
47 distributions of organic species in aerosol are not determined solely by intrinsic reactivity but are
48 often complex, time-dependent functions of internal aerosol mixing timescales.¹⁵⁻²² This is
49 because when internal mixing is slow (e.g., a semisolid), reactions are localized at the aerosol
50 surface, while rapid mixing in liquids results in uniform composition changes and scaling of
51 overall reactivity with particle volume. Whether a reaction is localized to a surface or scales
52 with volume does not depend on aerosol viscosity alone, but is an emergent property¹⁸ that
53 depends upon oxidant concentration in the gas phase and particle diameter. What is most
54 important is the time between oxidant collisions with the particle surface relative to the mixing
55 time within the aerosol. Thus, in the laboratory, reactions using semisolid aerosol at high [OH]
56 and short reaction times may not replicate the heterogeneous chemistry occurring over the long
57 time, low oxidant field of the atmosphere. A semisolid aerosol in the laboratory may in fact
58 appear well-mixed in the atmosphere since aerosol constituents have ample time to sample the
59 entire particle volume between reactive events. New approaches are needed to better understand
60 when the results of existing laboratory experiments can be extrapolated to other conditions, and

61to guide the design of experiments that more faithfully replicate the coupling of diffusive and
62reactive timescales of the atmosphere.

63 In the present work, we report results of a comprehensive computational study that
64provides a means to connect laboratory data to atmospheric aerosol chemistry using a single
65reaction-diffusion mechanism that has been validated for liquid and semisolid alkane aerosol
66oxidation.^{22, 23} It builds on an initial investigation in which we predicted the compositions of 200
67nm diameter aerosol particles with a range of viscosities intermediate between liquid and solid
68for an OH partial pressure typical of laboratory flow tube conditions ($[\text{OH}] = 5.04 \times 10^{10}$
69molec./cm³).¹⁹ We introduced a reaction-diffusion index (I_{RD}) to provide a quantitative link
70between particle viscosity and reactivity, enabling identification of the specific parts of the free
71radical chain reaction mechanism that dominate aerosol composition when the relative extent of
72mixing is varied. Here, we use the same reaction scheme to predict both aerosol and volatile
73product compositions as well as aerosol size and mass under OH densities typical of flow tube
74(FT, $[\text{OH}] = 5.04 \times 10^{10}$ molec./cm³) and continuous flow stirred tank²⁴ (CFSTR, $[\text{OH}] = 5.04 \times$
75 10^8 molec./cm³) reactors and the atmosphere ($[\text{OH}] = 5.04 \times 10^6$ molec./cm³). The results are
76analyzed in terms of I_{RD} , allowing identification of regimes where atmospheric reactivity of
77alkanes is readily predictable from laboratory experiments, and where it is not. The simulations
78provide insights to how product distributions, regimes, and factors that control the kinetics are
79connected.

80Simulations

81

82 The free radical oxidation scheme used in this work was developed and validated for
83 reaction between OH and C₃₀H₆₂ in liquid (squalene) and semisolid (triacontane) under laboratory
84 flow tube conditions.^{22, 23} The chain reaction is launched by H abstraction from the alkane,
85 forming alkyl radicals that rapidly condense with available O₂ to form peroxy radicals. O₂ is
86 assumed to be instantly replenished from the surrounding gas due to its fast diffusion through
87 liquids and solid organics.^{25, 26} The peroxy radicals disproportionate and fragment through
88 subsequent chain reactions, forming a variety of condensed and gas - phase products. A summary
89 of the reaction scheme is presented in the Supporting Information (SI), Section 1. Since known
90 or calculated rate constants are used for the elementary reaction steps involved, rather than
91 adjustable parameters, and the mechanism spans initial abstraction to fully oxidized CO₂, the
92 simulations are predictive for a broad range of reaction conditions even outside of those used to
93 establish the reaction scheme.

94 In the description we have developed for the free radical reactions involved in alkane
95 oxidation,²³ the individual product molecules formed by free radical functionalization and
96 fragmentation reactions are not explicitly included. Rather, molecules are represented as a set of
97 functionalities and carbon backbone lengths to allow the essential characteristics of the chemical
98 system to be captured, while minimizing the extreme complexity of tracking all the kinds of
99 molecules that can be generated by a free radical chain spanning H abstraction from pure
100 hydrocarbon to formation and evaporation of CO₂. The initial C₃₀H₆₂ molecule is taken to be a
101 straight chain with primary and secondary alkyl groups for all aerosol viscosities, thus neglecting
102 the branching that adds tertiary carbon reactions²³ and reduces viscosity.²⁷ The free radical
103 groups generated during the reaction are alkyl, peroxy, alkoxy, acyl, acyl peroxy and acyloxy,

located at primary or secondary positions. The radicals react further to form ketone, aldehyde, carboxylic acid and alcohol functionalities, accompanied by C_{30} chain fragmentation. Stochastic reaction-diffusion simulation methods²³ have been used to perform simulations using this scheme to generate spatially resolved concentration vs time curves that include the effect of variable volume on instantaneous rates. The software package is Kinetiscope.²⁸ The 200-nm-diameter aerosol is represented by an array of 200 $13.17\text{ nm} \times 13.17\text{ nm} \times 0.5\text{ nm}$ compartments located along the particle radius when full reaction-diffusion simulations are performed, or by a single compartment when the diffusion coefficient is fast enough for the particle to be well-mixed at all times.

In our initial study assuming FT conditions,¹⁹ the $C_{30}H_{62}$ diffusion coefficients were varied from 1×10^{-11} (liquid) to $8.39 \times 10^{-19}\text{ cm}^2/\text{s}$ (semi-solid using the diffusion coefficient of triacontane derived from viscosity measurements²⁹) in increments of factors of 10, and all product species in the simulation were assumed to diffuse with the same coefficient as the initial alkane throughout the system, neglecting possible decreases in viscosity as the particle composition changes. This range is typical of self-diffusion in semisolid α -pinene SOA.³⁰ In this paper, we use this scheme to predict both gas and condensed phase products for the same viscosity range over a broad OH concentration range, representing FT, CFSTR and atmospheric conditions. Table 1 lists the OH densities studied, with reaction times selected to reach a constant total OH exposure of $3.024 \times 10^{12}\text{ molecules cm}^{-3}\text{ s}$. The largest diffusion coefficients used for fully spatially resolved FT, CFSTR, and atmospheric reaction-diffusion simulations are 10^{-11} , 10^{-13} , and $10^{-15}\text{ cm}^2/\text{s}$, respectively. Above these values, the aerosol is well-mixed and the calculations become very expensive. Instead, we can represent the system accurately by single

126 compartment simulations with instantaneous mixing as shown in Houle et al.¹⁸ and Wiegel et
 127 al.^{22, 23}

128

129 **Table 1.** Simulation conditions for OH + C₃₀H₆₂

Conditions	OH concentration molec/cm ³	Reaction time (s)	Self-diffusion coefficients (cm ² /s)	OH Exposure (molec. cm ⁻³ s)
Laboratory flow tube (FT) ^a	5.04×10^{10} (31, 32)	60	instantaneous, $10^{-11} - 8.39 \times 10^{-19}$	3.024×10^{12}
Continuous flow stirred tank (CFSTR)	5.04×10^8 (24,13, 14)	6000	instantaneous, $10^{-13} - 8.39 \times 10^{-19}$	3.024×10^{12}
Atmosphere, daytime	5×10^6 (33,34)	604800 (1 week)	instantaneous, $10^{-15} - 8.39 \times 10^{-19}$	3.024×10^{12}

130 a. Simulation results for FT conditions are taken from Houle et al.¹⁹

131Results

132

133 The simulations provide complete data sets for volume, mass, carbon chain lengths and
134 functionality concentrations in the particle and gas phases as a function of time. Spatial
135 distributions of all particle-phase species are generated when a multicompartment scheme is
136 used. These results are analyzed to compare the outcomes of the oxidation reaction over a broad
137 range of conditions, providing new information on how reactivity varies with OH concentration
138 and aerosol viscosity. Details of the simulated data are presented in the SI, Section 2.

139

140I. Trends in consumption of C₃₀H₆₂ by OH reactions

141 A striking result of the simulations is the emergence of distinctive patterns in several
142 particle properties as viscosity and OH concentration are varied. For example, nearly identical
143 C₃₀H₆₂ decay curves (Figure S1) and spatial distributions (Figure S2) as a function of time are
144 found for FT, CFSTR and atmospheric OH densities when diffusion coefficients are offset by
145 about 2 orders of magnitude. These self-similarity trends are surprising but can be rationalized
146 by considering the relative rates of reaction and internal mixing via self-diffusion, which controls
147 the concentration of abstractable hydrogen near the aerosol surface where most reactions with
148 OH take place.^{18, 35} As described previously,¹⁹ a reaction-diffusion index, I_{RD} can be defined as:

149
$$I_{RD} = \frac{k_{rxn} [\text{OH}(\text{g})] d_p^2}{4 \pi^2 D} (1)$$

150 where k_{rxn} is the rate constant for reaction between OH and species in the particle, d_p is the
151 particle diameter, $[\text{OH}(\text{g})]$ is the concentration of OH in the gas phase and D is the self-diffusion

coefficient of organic molecules in the particle. When important characteristics of the reactions such as initial uptake

Figure 1. Initial uptake coefficients for $C_{30}H_{62}$ reacting with all three OH concentrations as a function of I_{RD} . The IRD ranges corresponding to the limiting kinetic regimes are labeled.

coefficients and ratios of products as a function of OH concentration and D are plotted as a function of I_{RD} , trends are captured in a way that allows these characteristics to be compared self-consistently. As shown in Figure 1, initial uptake coefficients calculated from the decay curves in Figure S1 are nearly coincident, indicating that at the very early stages of oxidation, the kinetic factors that control $C_{30}H_{62}$ consumption are essentially unchanged over a 10^4 variation in OH concentration. Table S1 lists the values for I_{RD} for each combination of diffusion coefficient and OH concentration used in Figure 1.

The definition of I_{RD} is closely related to the definition of the uptake coefficient, γ , through the reacto-diffusion length, L .¹⁸ If the aerosol is well-mixed, $2L$ is equal to the diameter of the particle. If it is not, $d_p > 2L$, and the more general expression for γ is

$$\gamma = \frac{2k_{rxn}\rho_0 N_A}{3cM d_p^2} [d_p^3 - (d_p - 2L)^3] \quad (2)$$

where ρ_0 is the aerosol density, c is the velocity of the OH molecules, M is the molecular weight of the aerosol material, and N_A is Avogadro's number. Specifically,¹⁸

$$L = \left(\frac{2k_{rxn}}{I_{RD} \pi^3 c \sigma} \right)^{1/2} \quad (3)$$

where σ is the probability that a colliding OH will stick to the aerosol surface long enough to react.

As I_{RD} increases due to decreasing D (increasing viscosity) and/or increasing OH gas concentration, both L and γ decrease. This trend is evident in Figure 1, where all three γ vs I_{RD} datasets fall on a single curve, with 3 distinct regimes. When $I_{RD} < 10^{-2}$, γ is essentially constant at a value similar to that for OH reaction with liquid squalane under FT conditions,³⁶ and reflects reactivity controlled only by OH reactions at the aerosol surface. When $I_{RD} > 10^2$, γ is similarly constant, but with a value lower than reported in previous work.^{13, 37} However, a quantitative comparison of the predicted and experimental values for γ is complicated by the fact that the decay curves used to calculate γ are not exponential and the experimental particle geometry is not well-defined. The OH concentration- and organic-mixing-limited cases are separated by a transition region where γ decreases rapidly.

II. Trends in physical properties

188 Although the uptake coefficients follow a regular pattern, other characteristics do not.
 189 Aerosol final diameters and masses are compared in Figure 2, and masses as a function of time
 190 for the 3 OH densities are shown in Figure S3. The variation in final diameter with I_{RD} is not
 191 monotonic: it passes through a minimum around $I_{RD}=10$ -100, which coincides with the uptake
 192 coefficient transition regime shown in Figure 1. The final particle mass, on the other hand,
 193 decreases as I_{RD} increases. Under well-mixed conditions when $I_{RD} < 10^{-2}$, there is a net mass

194
 195 **Figure 2.** Aerosol diameter and mass characteristics after OH exposure. The mass is relative to
 196 the initial mass of unreacted $C_{30}H_{62}$.

197

198increase relative to the pure alkane due to oxygen incorporation. The mass increase competes
 199with mass loss due to fragmentation and volatilization as the diffusion coefficient decreases and
 200the chemistry becomes self-diffusion limited. The extent of mass loss increases with decreasing
 201gas - phase OH concentration, and is most pronounced under atmospheric conditions, where OH
 202concentration is lowest. This result indicates that there are significant differences in reactivity as
 203OH concentration and particle viscosity are varied even though the reaction mechanism is the
 204same.

205

206**Figure 3.** Total functional groups present (a) in the aerosol particle and (b) in the gas phase
 207(including CO_2) after OH exposure, normalized to the total amount of $C_{30}H_{62}$ reacted, for the
 208three OH densities.

209

210**III Trends in particle and gas - phase oxidation products**

211 The simulations track the functionalities formed during oxidation in both the condensed
212 and gas phases. Figure 3 shows the total accumulated oxygen-containing functionalities in the
213 particle and gas phases per $C_{30}H_{62}$ reacted, which reflects the extent of reaction over the range of
214 OH densities and viscosities. Figure 3a shows that functionality accumulation in the particle is
215 similar for all OH densities when mixing is fast, increases significantly in the I_{RD} transition
216 region, then decreases as the reaction becomes mixing limited. Figure 3b shows that this trend is
217 accompanied by very low fragmentation and volatilization to form oxidized gas products when
218 mixing is fast transitioning to abundant gas product formation as I_{RD} increases into the mixing-
219 limited regime.

220 Plots of the total amounts of each stable functionality as a function of time – ketones,
221 alcohols, aldehydes, carboxylic acids and CO_2 – normalized to the instantaneous amount of
222 unreacted $C_{30}H_{62}$ are presented in Figures S4-S12, organized according to I_{RD} . The data show
223 that while the functionality compositions of the aerosol particles are similar for each I_{RD} across
224 the full range of OH densities, those of the volatilized gases are not. Figures 4 and 5 summarize
225 these results for the transition regime, showing the final functionality distributions
226 corresponding to the totals in Figure 3 for particles and gas phase, respectively.

227

228

229 **Figure 4.** Composition of aerosol particles after exposure to OH in the transition kinetic regime
 230 between [OH] limited and self-diffusion limited.

231

232

233

234 **Figure 5.** Composition of the gas phase surrounding the aerosol particles after exposure to OH in
 235 the transition kinetic regime between [OH] limited and self-diffusion limited. (a) gas products
 236 that originate from minority functionality components in the aerosol; (b) gas products that
 237 originate from majority functionality components in the aerosol.

238 The simulation results in Figure 4 show that there is a dramatic change in composition as
 239 a function of I_{RD} in the transition regime, with FT, CFSTR and atmospheric OH densities having
 240 the same chemistry although the extents of oxidation are quite different (Figure 3). Ketones
 241 become the dominant functional group, accompanied by a modest increase in carboxylic acids.
 242 The ketones are relatively unreactive to OH and accumulate as the reaction becomes self-
 243 diffusion-limited, unlike the alcohols which undergo a significant decrease in concentration. The

244aldehydes, present in small amounts, also decrease with increasing I_{RD} . Carboxylic acids,
245although minor products, accumulate as the reaction becomes mixing limited.

246 The gaseous product distribution is qualitatively different from the particle phase
247composition, as shown in Figure 5. Although ketones and alcohols are the major particle phase
248components of the aerosol, aldehydes and CO_2 are the major volatile products. The OH
249concentration conditions affect the gas composition for two of the products: FT conditions,
250which have the highest OH-aerosol collision frequency, favor CO_2 volatilization, while
251atmospheric conditions favor ketone volatilization.

252 Inspection of the molecular chain lengths (carbon numbers) at $I_{RD} = 10$ for the three OH
253regimes (Figure S13) shows that although the aerosol particle functionality distributions are very
254similar for the three OH concentration cases in the transition regime (Figure 4), the carbon
255numbers are not. As the OH concentration decreases from FT to atmosphere, the average carbon
256number at the end of OH exposure increases. Figure 2 shows that the particle mass decreases,
257however, with mass loss being greatest for the lowest OH concentration when $I_{RD} = 10$. These
258results together with the data in Figures 3a, 5 and S7 show that under atmospheric
259concentrations, volatilization of oxidized functionalities is favored relative to FT conditions.

260Discussion

261 Using a detailed reaction-diffusion mechanism developed and validated for the reaction
262of OH + semisolid and liquid $\text{C}_{30}\text{H}_{62}$ under FT conditions,^{19, 23, 29} we have performed a
263computational study to predict oxidative aging chemistry for the much lower OH partial
264pressures typical of laboratory CFSTR and atmospheric conditions over a broad range of alkane

viscosities. Strong patterns in chemical and physical properties are evident as OH concentration and alkane self-diffusion coefficients are varied over ranges of 4 and 7 orders of magnitude, respectively. These patterns are rationalized in terms of the reaction-diffusion index I_{RD} , which is a measure of the balance between the availability of OH from the gas phase for H abstraction reactions and the extent of mixing by self-diffusion in the aerosol, for each combination of OH concentration and particle viscosity.

The results in Figures 4, and S4-S6 suggest that laboratory measurements of alkane aerosol particle compositions during reactions with OH under both FT and CFSTR conditions may be predictive of compositions under atmospheric conditions when the chemistry is strongly limited by arrival of OH at the aerosol surface ($I_{RD} < 10$). When $I_{RD} > 10$, the aerosol compositions are qualitatively similar, but not identical (Figures 4 and S7-S8). These trends continue into the higher I_{RD} range. The results in Figures 5 and S4-S12 show clearly that laboratory measurements will only be qualitatively predictive for the limiting cases and not predictive at all in the transition regime. Experimental tests of these findings will be very valuable for model validation and improvement, particularly measurements of particle size in the transition regime, and of the ratio of ketones to alcohols in the particle phase across the I_{RD} range.

To understand these trends, we examine the free radical oxidation chemistry involved in the three kinetic regimes, which is sketched in Figure 6. When the oxidation kinetics are in the OH concentration-limited range, the aerosol is relatively C-H rich. Abstraction events generate peroxy radicals, which form ketones and alcohols as the primary oxidation products for the OH exposure times studied. This simple picture only applies when internal mixing is fast and oxidized moieties are dilute. As the rates of OH reaction and self-diffusion become competitive,

the *sec*-peroxy radical concentration increases from near-zero to significant amounts and the reaction becomes confined to the near-surface region of the aerosol, as shown in Figures S2, S14 and S15.

Figure 6. Abstraction, propagation, and product formation steps for the heterogeneous reaction of OH with alkanes. The blue arrows mark steps that are second order in peroxy radical concentration. Acyloxy and alkoxy radicals undergo unimolecular decomposition reactions and generate additional peroxy radicals. Under reaction-limited conditions (dashed line box), ketone and alcohol formation dominate. Under mixing limited conditions, the entire free radical chain is active.

The other radicals, which are more reactive, are present in negligible quantities. Under these conditions, disproportionation of peroxy radicals to form alkoxy radicals and O_2 , which is quite slow when the aerosol is well-mixed,¹⁸ becomes kinetically significant. Alkoxy radicals

302 fragment to form aldehydes and primary alkyl radicals that react and dissociate to form mixture
303 of alkyl, peroxy, acyl, acyloxy and acylperoxy radicals. This intensely reacting environment
304 rapidly consumes available C-H and O-H bonds, and the steady state population of peroxy
305 radicals decreases to near-zero. These conditions favor acyl radical formation and fragmentation
306 to form CO₂.

307 The chemical trends for alkane oxidation shown in Figure 6 connect the reaction
308 mechanism to the product functionality distributions shown in Figures S4-S12. When $I_{RD} < 1$,
309 particle phase ketones and alcohols dominate for all OH densities, with very little fragmentation
310 to form volatiles, indicating that the chemistry does not go deeply into the free radical chain.
311 This I_{RD} range corresponds to $D > 10^{-12}$ cm²/s for FT conditions, $D > 10^{-14}$ cm²/s for CFSTR
312 conditions, and $D > 10^{-16}$ cm²/s for atmospheric conditions for this particle size (200 nm initially).
313 This suggests that FT measurements with liquid phase aerosol can be informative for
314 atmospheric conditions even when the target atmospheric material is quite viscous. When $I_{RD} >$
315 10^2 , the product distribution is also simple, dominated by ketones in the particle phase and CO₂
316 in the gas phase, consistent with formation of terminal products. The self-diffusion coefficient
317 range for this regime is in the highly viscous fluid to semisolid range: $D > 10^{-14}$ cm²/s for FT
318 conditions, $D > 10^{-16}$ cm²/s for CFSTR conditions, and $D > 10^{-18}$ cm²/s for atmospheric conditions
319 for 200 nm particles. Given the challenges of generating well-controlled solid aerosol
320 nanoparticles, laboratory investigations of the oxidation of highly viscous liquids may be a
321 reasonable proxy to learn about reactivity in the atmosphere. The correlation by I_{RD} allows
322 development of similar useful experimental strategies for other particle diameters.

While the initial uptake coefficients and condensed phase functionality distributions are independent of OH concentration in the transition region, the gas product distribution, extent of fragmentation, particle mass and particle diameter are not, and it is not possible to extrapolate between the OH concentration ranges without use of explicit reaction-diffusion models. Moreover, some features appear only in this range. For example, as shown in Figure 3, there is a dramatic increase in formation of oxygen-containing functionalities in the particle and mass loss relative to the OH concentration and self-diffusion limited regimes, as well as an increase in peroxy radical densities. Examination of Figures S4-S12 reveals that the primary chemical signature of the transition region is the OH concentration-dependence of the relative amounts of gaseous products, specifically CO₂ relative to aldehydes. In addition, Figure S15 shows that peroxy radicals have a lower steady state concentration above $I_{RD} = 1$ for CFSTR conditions relative to FT and atmosphere. This pattern reveals that the delicate balance between mixing and reaction mainly affects the formation and subsequent reactions of alkoxy radicals. Since aldehydes are formed via H abstraction from alcohols and subsequent fragmentation to form aldehydes and new peroxy radicals, this suggests that the peroxy radical disproportionation chemistry dominates under CFSTR conditions, reducing the peroxy radical population relative to higher and lower OH densities and generating volatile aldehydes. FT and atmospheric OH densities, on the other hand, favor acyl radical formation and fragmentation. Although OH concentration is lowest under atmospheric conditions, the extent of erosion of the aerosol is greatest in the transition region, leading to a change of about 20% in particle diameter. This indicates that fragmentation to form volatiles is favored when free radical chain initiation events are relatively rare, consistent with carbon numbers in Figure S13.

345 Previous investigations have also sought to develop predictive correlations for
346 heterogeneous aerosol reactions using reaction- and diffusion-limited kinetic regimes.¹⁵ In
347 particular, low diffusion rates in semisolids have been proposed to lead to extended lifetimes for
348 organics in the troposphere.³⁸⁻⁴⁰ It has been suggested that aerosol becomes more viscous during
349 aging, and hence less prone to degradation.⁴¹ The broad trends investigated here for an alkane
350 model system indicate that extrapolations across a range of [OH] and viscosity conditions may
351 not be possible in any simple way depending on the details of the chemistry, reacting
352 environment and particle sizes involved.

353 The combinations of chemical and physical factors that control lifetimes at various stages
354 of aging remain to be fully identified, but are likely to involve the following elements. Important
355 reactions introduced by the presence of alkenes include oligomerization and efficient free radical
356 cycling via hydroxyalkyl chemistry.⁴² While the presence of NO₂ can be neglected if the aerosol
357 is relatively dry, heterogeneous NO reactions can accelerate the oxidation process. NO promotes
358 free radical cycling and fragmentation by increasing the extent of formation of alkoxy radicals
359 even under well-mixed conditions.¹³ Uptake of gaseous water becomes important as the particle
360 becomes more hydrophilic. Particle-phase water adds acid-base chemical pathways that can
361 promote fragmentation⁴³ and can decrease viscosity as can chain fragmentation under dry
362 conditions. Inclusion of all of these elements, which are very important to be able to describe
363 aerosol aging correctly, can be done in a straightforward way by modifying the basic mechanistic
364 framework used here, if sufficient experimental data are available to validate the calculations.
365 We can anticipate some of the effects. As viscosities decrease, they will cause a decrease in the
366 relevant I_{RD} (Eq 1), and may cause the system to enter a kinetic regime that is more gas-collision-

367controlled. However, the effect of such a change on particle composition and properties would
368likely not be pronounced unless the change is from the mixing-limited to the transition regime or
369from the transition regime to the OH limited regime. While we compare 200 nm particles in all
370cases, the I_{RD} analysis allows experimental data obtained on one size of particle to be used to
371predict oxidation on a different size if there are no changes in the chemistry or viscosity.
372Extensions of the present work to include additional reactions and composition-dependent
373viscosities will be valuable for development of new generalizations of chemical transformations
374for atmospheric chemistry models.

384

385ACKNOWLEDGMENT

386The early development of the reaction mechanism and simulation runs was supported by the
387Laboratory Directed Research and Development program at Lawrence Berkeley National

388Laboratory under U.S. Department of Energy Office of Science, Office of Basic Energy Sciences
389under Contract No. DE-AC02-05CH11231. Later analysis of the simulations results was
390supported by the Department of Energy, Office of Science, Office of Basic Energy Sciences,
391Chemical Sciences, Geosciences, and Biosciences Division, in the Gas Phase Chemical
392Physics Program under Contract No. DE-AC02-05CH11231. We are grateful to Dr. William D.
393Hinsberg (Columbia Hill Technical Consulting) for helpful discussions on simulation
394approaches during the course of this work.
