ABSTRACT The polarity of oxide surfaces can dramatically impact their surface reactivity, in particular with polar molecules such as water. The surface species that result from this interaction change the oxide electronic structure and chemical reactivity in applications such as

photoelectrochemistry, but are challenging to probe experimentally. Here we report a detailed study of the surface chemistry and electronic structure of the perovskite LaFeO_3 in humid conditions using ambient pressure X-ray photoelectron spectroscopy. Comparing the two possible terminations of the polar (001)-oriented surface, we find that the LaO -terminated surface is more reactive toward water, forming hydroxyl species and adsorbing molecular water at lower relative humidity than its FeO_2 -terminated counterpart. However, the FeO_2 -terminated surface forms more hydroxyl species during water adsorption at higher humidity, suggesting adsorbate-adsorbate interactions may impact reactivity. Our results demonstrate how the termination of a complex oxide can dramatically impact its reactivity, providing insight that can aid in the design of catalyst materials.

TOC GRAPHICS

Perovskite oxides such as LaFeO_3 show great promise as catalysts for energy conversion and storage. Applications such as electrocatalysis,^{1–4} photoelectrochemistry,^{5–7} and gas sensing^{8–10} all take place in an aqueous or humid environment, where the interaction with water plays a key role in determining the functionality of these complex oxides.^{11–13} The formation of surface hydroxyl groups and adsorption of water can impact the surface electronic structure¹⁴ and ultimately the mechanisms and kinetics of surface chemical reactions.^{15,16} Initial studies have considered the reactivity of perovskites with water using ambient pressure X-ray photoelectron spectroscopy

(AP-XPS),^{12,17} enabling study of the surface species present in equilibrium with water vapor. The hydroxylation of these surfaces appeared greater than that of binary transition metal oxides.¹⁸ However, the chemical nature of the hydroxyl site in such systems remained elusive due to the unknown surface termination.

The polar layers of (001)-oriented polar perovskite LaFeO₃ (LFO) have been the subject of numerous recent investigations that consider the dipole formed at the (Nb-doped) SrTiO₃ substrate-film interface^{19–21} and the formation of a 2D metal at this interface²². However, despite the promising photoelectrochemical activity⁵ and sensing capabilities,^{9,10} missing is an experimental understanding of the surface properties for each layer. Density functional theory (DFT) calculations report a lower work function for LaO- versus FeO₂-termination,²³ which is expected to result in notably different chemical reactivity. Of further interest is how the electronic structure of each surface changes as a result of the formation of e.g. hydroxyl species, where surface band bending in aqueous environments²⁴ is the critical component to charge separation at the semiconductor/water interface in photoelectrochemical water splitting.

In the present work, we consider (001)-oriented epitaxial films of LFO distinctly terminated on (LaO)⁺ or (FeO₂)⁻ planes to probe the influence of perovskite surface termination on chemical reactivity using ambient pressure X-ray photoelectron spectroscopy (AP-XPS).^{18,25,26} We find LaO-terminated LFO (LaO-LFO) is more reactive toward water, forming hydroxyl species at lower relative humidities than its FeO₂-terminated (FeO₂-LFO) counterpart, consistent with DFT calculations that indicate a greater stability of hydroxylated LaO-LFO.¹² The LaO surface is also characterized by an additional surface oxygen species in both dry and humid conditions, the formation of which is attributed to the positive charge of a (LaO)⁺ layer and its high surface energy. Core level shifts and changes in the gas-phase water peak indicate a downward band

bending/flattening²⁷ and a decrease in work function,²⁸ respectively, resulting from hydroxylation and water adsorption.

Epitaxial 9 unit cell (u.c.) LFO films were fabricated by oxygen-assisted molecular beam epitaxy (MBE) on Nb-doped SrTiO₃ (001) surfaces at Pacific Northwest National Laboratory (Figure S1). The substrate was prepared with SrO or TiO₂ termination, resulting in LaO-LFO or FeO₂-LFO, respectively (Figure 1). Cross-sectional high-angle annular dark field (STEM-HAADF) images, shown in Figure 1, confirm the excellent quality and epitaxy of the film. We observe differences in the surface termination, although damage resulting from TEM sample preparation makes it difficult to unambiguously identify the surface layer. Instead, the termination of the as-prepared film was confirmed by angle resolved XPS (Table S1) and remained unchanged during AP-XPS experiments (Figure S2).

Figure 1. Colorized cross-sectional STEM-HAADF images and schematics of the 9 unit cell (u.c.) LaFeO₃/Nb:SrTiO₃ films fabricated by oxygen assisted MBE. FeO₂-LFO was grown on a

8
9 Upon introduction to the AP-XPS chamber at the Advanced Light Source, the films were
10 cleaned of ambient carbon contaminants by heating to 300 °C in 100 mTorr oxygen. The
11 resulting O 1s spectra are compared in Figure 2 (top panel) for the LaO- and FeO₂-terminated
12 surface, with the C 1s spectra shown in the inset. For the FeO₂-LFO, one main O 1s peak is
13 present, characteristic of bulk lattice oxygen, with a small shoulder at ~1.1 eV higher binding
14 energy attributed to hydroxyl (OH) species, the location of which was determined from
15 difference spectra during subsequent water dosing (Figure S3). For LaO-LFO, a third peak is
16 present at ~2.3 eV higher binding energy, termed “surf”. Such a surface feature has been often
17 observed for epitaxial perovskite films of unknown termination, as well as perovskite particles,
18 and has been attributed to a host of potential species such as carbonates,^{29,30} adsorbed water,^{31,32}
19 hydroxyls,^{31–33} peroxide species,³⁴ undercoordinated oxygen,^{35,36} and the terminal layer(s) of a
20 polar surface due to a shift in Madelung potential.¹⁷ Considering the AP-XPS spectra collected at
21 300 °C in 100 mTorr oxygen (and similarly at ~24 mTorr oxygen, Figure S4), we rule out the
22 presence of carbonates and adsorbed water, and the lack of such a feature on the FeO₂-terminated
23 surface suggests it does not arise from a change in Madelung potential at the surface. Instead, we
24 propose that the feature at ~2.3 eV above bulk oxygen arises from oxygen species present on the
25 surface with reduced screening, where DFT calculations on MgO surfaces support such a binding
26 energy offset for peroxo groups,³⁴ although a similar offset is also reported for OH groups on
27 MgO.³⁷ The higher surface energy of the LaO- versus FeO₂-terminated surface predicted by
28 DFT¹² supports the model that the (LaO)⁺ surface reconstructs chemically (adsorbing additional
29 oxygen) and/or electronically to compensate its polarity, while the (FeO₂)[–] surface seems stable

with only formation of a few hydroxyl groups (Figure 2B). A similar feature is observed on the SrO-terminated surface of (001)-oriented SrTiO₃, but not for the TiO₂ termination (Figure S5).

We next perform a water isobar to probe the LFO surfaces under different relative humidity (RH). After removing oxygen gas, 100 mTorr H₂O is introduced into the chamber at 300 °C (corresponding to a RH of 10⁻⁴%). The OH feature on LaO-LFO increases notably, while that on FeO₂-LFO increases only slightly (Figure 2 middle panel). The feature at ~2.3 eV on LaO-LFO from undercoordinated oxygen/peroxo species persists in humid environments, which might protonate with minimal shift in binding energy. A peak from gas phase water is present at >5 eV higher binding energy than bulk oxygen. Further cooling leads to the formation of adsorbed water (H₂O_{ads}) at ~3.4 eV above bulk oxygen (Figure 2 bottom panel), the location of which is confirmed by difference spectra upon removal of water (Figure S6). The wider bulk peak at higher temperatures is consistent with thermal (vibrational) broadening. Due to the high propensity of LFO to form carbonate upon interaction with any residual CO₂ in the chamber,³⁸ care was taken to quantify such species in the O 1s spectra from the intensity in the C 1s core level (Experimental methods). All spectra were fit with the species described above with fitting parameters found in Table S2, and depth profiling by changing the incident photon energy confirms that the “surf” peak, OH, CO₃, and H₂O_{ads} are located above that of the bulk (Figure S7).

Figure 2. O 1s spectra and C 1s spectra (inset) for (A) LaO-LFO and (B) FeO₂-LFO at 300 °C in 100 mTorr O₂ (top), 300 °C in 100 mTorr H₂O (middle) and 25 °C in 100 mTorr H₂O (bottom). Raw data are shown as points with fitted components and envelope (black) as lines. O 1s components correspond to the bulk oxide (orange), hydroxide (light blue), carbonate (gray), surface (peach), adsorbed water (medium blue), and gas phase water (dark blue). C 1s components correspond to carbonate (gray), adventitious carbon (purple), and an intermediate carbon oxidation (teal). The binding energy scale is shown relative to the bulk oxide (O 1s) and adventitious carbon (C 1s) to better illustrate relative offsets of species in fitting.

The chemical reactivity of each surface toward water can be assessed by considering the extent of hydroxyl species present as a function of RH. Figure 3A compares the OH and $\text{H}_2\text{O}_{\text{ads}}$ components normalized to the bulk oxygen signal (likely canceling out any thermal broadening effects), with similar trends observed when considering them as a percentage of total oxygen signal (Figure S8) or using a multilayer electron attenuation model¹⁷ to compute coverage (Figure S9, Table S3). Both terminations display similar OH contents in dry conditions (300 °C in 100 mTorr oxygen, yellow band in Figure 3A). In humid conditions, however, LaO-LFO is much more reactive toward water, with notable hydroxyl content at low RH. This is consistent with DFT calculations that report greater stability of hydroxylated LaO- versus FeO_2 -LFO.¹² The amount of hydroxyls on the LaO surface remains roughly constant upon further increase of RH during the isobar, suggesting sites with a high binding strength for hydroxyls saturate at low RH.

The FeO_2 -terminated surface has notably less hydroxyl species at low RH, which remains constant until $\sim 10^{-3}\%$ RH. At this point, $\text{H}_2\text{O}_{\text{ads}}$ begins to form on the surface, and the amount of OH on FeO_2 -LFO increases in parallel. This is in direct contrast to the hydroxyl behavior of LaO-LFO, but similar to that observed on Fe_3O_4 ³⁹ and Fe_2O_3 ⁴⁰ surfaces, where it was attributed to adsorbate-adsorbate interactions. In contrast, LaO-LFO adsorbs more water at a given RH with a lower onset RH; however, this does not significantly impact the formation of OH species.

Figure 3. (A) Area of the OH (light blue, circles) and H₂O_{ads} (medium blue, squares) normalized to that of the bulk oxide as a function of RH probed by changing temperature in a 100 mTorr H₂O isobar. Dry conditions (300 °C in 100 mTorr O₂) are indicated with a yellow bar. LaO-LFO (solid) is more reactive toward water compared to FeO₂-LFO (open). (B) Location of the gas-phase H₂O_{vap} peak relative to the bulk oxygen peak for LaO-LFO (solid) and FeO₂-LFO (open) as a function of RH. The increase in binding energy corresponds to a decrease in sample work function, or formation of a surface dipole aiding photoelectron removal.

The use of AP-XPS also enables assessment of changes in the work function or surface dipole through shifts in the gas phase peak.^{28,41} The H₂O_{gas} peak shifts to higher binding energy with RH, indicating a decrease in sample work function and/or formation of a surface dipole (Figure

3B). For example, adsorption of polar OH^- species have been shown to increase the surface potential of ceria.⁴¹ This ~ 0.5 eV shift is similar to that observed on Fe_3O_4 ,³⁹ where DFT indicated adsorption of OH, H_2O , or co-adsorption of the two would lower the surface work function. For LFO, we highlight that the LaO-terminated surface exhibits a steady increase in gas phase binding energy with RH, while that of the FeO_2 -terminated surface remains constant until $\sim 10^{-3}\%$ RH. This suggests that the decrease in work function is most influenced by the adsorption of polar water molecules, confirmed by its reversal upon decreasing the water pressure and desorbing $\text{H}_2\text{O}_{\text{ads}}$ (Figure S10).

Further insight regarding changes in the electronic structure upon OH and H_2O adsorption can be obtained from the metal core levels and valence band. Aside from changes to the lanthanum-oxygen ionicity reflected in the satellite intensity (Figure S11),⁴² the line shape of the La 4d and Fe 3p are negligibly affected by the formation of OH and $\text{H}_2\text{O}_{\text{ads}}$ groups. However, their absolute binding energies (Figure 4) are affected, with shifts to a higher binding energy reflecting downward band bending. This shift is greatest for LaO-LFO, which also exhibits greater reactivity toward water. The change in spectral intensity at ~ 2.5 eV in FeO_2 -LFO is not fully understood and merits further study.

Figure 4. Noted Fe 3p, La 4d core levels and valence band (VB) for (A-C) LaO-LFO and (D-F) FeO₂-LFO. Solid lines are for 690 eV incident photon energy with a larger information depth than dashed lines for 350 eV. Conditions are 300 °C in 100 mTorr O₂ (black), 300 °C in 100 mTorr H₂O (orange) and 25 °C in 100 mTorr H₂O (blue). The shift to higher binding energies with increasing RH corresponds to downward band bending, and is greater for LaO-LFO.

In conclusion, we have presented a detailed study of the interaction between water and (001)-oriented LaFeO₃ films terminated with either the LaO or FeO₂ plane. Using ambient pressure X-ray photoelectron spectroscopy to probe the surface species present in equilibrium with gas phase water, we find greater hydroxylation of the LaO- versus FeO₂-LFO surface at low humidity, consistent with previous reports using DFT. However, the ultimately larger amount of OH on FeO₂-LFO at high humidity (commensurate with water adsorption) suggests adsorbate-

adsorbate interactions may play an important role in dictating reactivity. An additional surface oxygen species often observed on perovskites is present only on the LaO termination, such as a peroxy group that could protonate in humid conditions. Core level shifts and changes in the gas-phase water peak indicate a downward band bending/flattening and a decrease in work function, respectively, upon interaction with water. This experimental study of the impact of termination in complex oxides on chemical reactivity and the resultant electronic structure brings new insight to applications such as photoelectrocatalysis.

Experimental Methods

Film growth LFO/*n*-STO(001) heterojunctions were prepared using oxygen-assisted MBE. Films were grown at $600 \pm 50^\circ\text{C}$ at a rate of one monolayer (either LaO or FeO₂) every 43 seconds using effusion cells and alternately shuttering the La and Fe beams, with a mixed O/O₂ beam generated by an electron cyclotron resonance source continuously incident on the substrate.⁴³ A pair of 0.05% Nb-doped STO substrates (Crystec) were prepared side-by-side using a boiling deionized water treatment,⁴⁴ followed by an anneal in air at 1000 °C for 30 minutes. The samples were then cleaned in ozone on the bench and loaded into an oxide MBE system (DCA) with an appended x-ray photoelectron spectrometer (VG Scienta R3000 analyzer and monochromatic Al K α x-ray source). The TiO₂ termination was confirmed using angle-resolved XPS measurements (Table S1). A single monolayer of SrO was then deposited using an effusion cell on one of the substrates to achieve the A-site termination, also confirmed by angle-resolved XPS.¹⁹ Increments of three u.c. (1 u.c. = $\sim 3.9\text{\AA}$) of LFO were then grown with a shuttering sequence configured to match the substrate termination (i.e. FeO₂ (LaO) layer deposited first on the SrO- (TiO₂-) terminated substrate) up to a total of 9 u.c.

Ambient pressure X-ray photoelectron Spectroscopy AP-XPS was collected at Beamline 9.3.2 at Lawrence Berkeley National Laboratory's (LBNL) Advanced Light Source (ALS).⁴⁵ LFO films were placed directly onto a ceramic heater and held in place by spring-loaded Inconel tips separated with an Al₂O₃ spacer. The film was grounded through a thermocouple pressed into a gold foil placed directly onto the sample surface for temperature measurements and isolated from the sample holder clip with an Al₂O₃ spacer. Further fitting details are provided in the Supplemental Information.

Figure 1. Colorized cross-sectional STEM-HAADF images and schematics of the 9 unit cell (u.c.) LaFeO₃/Nb:SrTiO₃ films fabricated by oxygen assisted MBE. LaO-LFO was grown on a SrO-terminated substrate (A), and FeO₂-LFO was grown on a TiO₂-terminated one (B). Surface terminations were confirmed by angle resolved XPS (Table S1).¹⁹

Figure 1
76x89mm (300 x 300 DPI)

Figure 2. O 1s spectra and C 1s spectra (inset) for (A) LaO-LFO and (B) FeO₂-LFO at 300 °C in 100 mTorr O₂ (top), 300 °C in 100 mTorr H₂O (middle) and 25 °C in 100 mTorr H₂O (bottom). Raw data are shown as points with fitted components and envelope (black) as lines. O 1s components correspond to the bulk oxide (orange), hydroxide (light blue), carbonate (gray), surface (peach), adsorbed water (medium blue), and gas phase water (dark blue). C 1s components correspond to carbonate (gray), adventitious carbon (purple), and an intermediate carbon oxidation (teal). The binding energy scale is shown relative to the bulk oxide (O 1s) and adventitious carbon (C 1s) to better illustrate relative offsets of species in fitting.

Figure 2

107x125mm (300 x 300 DPI)

Figure 3. (A) Area of the OH (light blue, circles) and H₂O_{ads} (medium blue, squares) normalized to that of the bulk oxide as a function of RH probed by changing temperature in a 100 mTorr H₂O isobar. Dry conditions (300 °C in 100 mTorr O₂) are indicated with a yellow bar. LaO-LFO (solid) is more reactive toward water compared to FeO₂-LFO (open). (B) Location of the gas-phase H₂O_{vap} peak relative to the bulk oxygen peak for LaO-LFO (solid) and FeO₂-LFO (open) as a function of RH. The increase in binding energy corresponds to a decrease in sample work function, or formation of a surface dipole aiding photoelectron removal.

Figure 3
60x107mm (300 x 300 DPI)

Figure 4. Noted Fe 3p, La 4d core levels and valence band (VB) for (A-C) LaO-LFO and (D-F) FeO₂-LFO. Solid lines are for 690 eV incident photon energy with a larger information depth than dashed lines for 350 eV. Conditions are 300 °C in 100 mTorr O₂ (black), 300 °C in 100 mTorr H₂O (orange) and 25 °C in 100 mTorr H₂O (blue). The shift to higher binding energies with increasing RH corresponds to downward band bending, and is greater for LaO-LFO.
