Abstract
Porokeratotic eccrine ostial and dermal duct nevus (PEODDN) is a rare dermatosis initially described as ‘comedo nevus’ and renamed ‘PEODDN’; it has also been referred to as linear eccrine nevus with comedones, porokeratotic eccrine ostial and hair follicle nevus, and porokeratotic adnexal ostial nevus. PEODDN is usually present at birth or develops early in life. Rarely, PEODDN can develop in adults. The treatment of this puzzling condition is not standardized. We report herein a new case of adult-onset PEODDN with dermatoscopic images. Our patient responded favorably to topical tazarotene.

Keywords: porokeratotic eccrine ostial and dermal-duct nevus, porokeratosis, tazarotene

Introduction
Porokeratotic eccrine ostial and dermal duct nevus (PEODDN) is a rare dermatosis initially described in 1979 as 'comedo nevus' [1] and it was renamed 'PEODDN' in 1980 [2]. It has also been referred to as linear eccrine nevus with comedones [3], porokeratotic eccrine ostial and hair follicle nevus [4], and porokeratotic adnexal ostial nevus [5]. Most cases of PEODDN are present at birth or develop during childhood [6]. Rarely, PEODDN can develop in adults.

Case Synopsis
A 38-year-old woman was referred to us for skin lesions that had appeared three years prior on her left upper limb. Physical examination showed an erythematous-pink, slightly hyperkeratotic, rather well-limited elongated plaque on the radial side of her left thumb, extending to the wrist (Figure 1A). Dermatoscopic examination showed an erythematous plaque studded with several distinct whitish pinhead-sized globules (Figure 1B). The patient reported mild occasional pruritus, which was unrelated to her work and showed no clear seasonal variations. She mentioned that similar lesions had appeared previously on the same extremity (forearm and arm) but had regressed spontaneously. The patient was otherwise in good condition, had no other mucocutaneous lesions, and was not taking systemic treatments. She had two healthy children (aged 8 and 10 years) and her family history was unremarkable. Her lesions had been treated by her family physician with topical corticosteroids, which

Figure 1. A) Clinical appearance of the lesion: erythematous-pink, slightly hyperkeratotic, well-limited elongated plaque on the radial side of the thumb, extending to the wrist. B) Dermatoscopic examination shows an erythematous plaque studded with several whitish pinhead-sized globules. C) Clinical improvement after a one-month treatment with 0.1% tazarotene gel.
alleviated pruritus, but had no obvious effect on the appearance of the plaque. Microscopic examination of a punch skin biopsy showed epidermal hyperplasia (hyperkeratosis, acanthosis, papillomatosis) and parakeratotic plugs within dilated, hyperplastic eccrine sweat gland ostia (Figure 2A, B). A lymphocytic infiltrate was present in the dermis, surrounding the superficial part of the excretory eccrine sweat gland ducts and the eccrine sweat gland coil (Figure 2C). These findings were diagnostic of PEODDN. The patient was prescribed treatment with daily applications of tazoretene 0.1% gel. After one month, the lesions had improved, showing less erythema and surface hyperkeratosis (Figure 1C). The treatment was well-tolerated and the patient was advised to continue the treatment for another month.

**Case Discussion**

PEODDN, first described as 'comedo nevus of the palm' [1], is a rare condition of which about 70 cases have been reported in the literature. Most cases are present at birth or develop within the first two decades of life [6]. Seven cases [7-13] had their onset in adulthood, at a mean age of 31 years (range, 18-65). Our patient is therefore the 8th case of adult-onset PEODDN reported in the literature (Table 1).

PEODDN affects almost equally both genders, but the adult onset cases show a slight male predominance (5:3). It presents clinically with unilateral, verrucous or keratotic, pink, brown, or whitish pits with comedo-like plugs or papules, located primarily on the extremities, particularly the palms and soles [7-11, 13-15]. The lesions are more rarely bilateral. They may coalesce into linear plaques [8], sometimes following Blaschko lines [5, 7, 16], and have thereby been considered as a variant of linear porokeratosis by virtue of a similar pathological appearance. The lesions are usually asymptomatic [10, 13, 14] but may be mildly pruritic as in our patient [8, 9]. The clinical differential diagnosis of PEODNN includes dermatoses with linear distribution, such as epidermal nevi, linear psoriasis, linear Darier disease, linear lichen planus, and ichthyotic disorders with a Blaschkoid distribution, such as Conradi-Hünermann-Happle and CHILD syndrome [8, 13]. Dermatoscopic examination may assist the diagnosis by showing whitish pinhead-sized dots (corresponding to the surface of the cornoid lamellae embedded in eccrine ostia) over a slightly erythematous background. The definite diagnosis requires microscopic examination, which shows a variable degree of epidermal hyperplasia (hyperkeratosis, acanthosis, papillomatosis) and the presence of cornoid lamellae (narrow vertical stacks of parakeratotic corneocytes) within eccrine sweat gland ostia. A lymphocytic infiltrate may surround the eccrine gland, as in our case, and highlights the involvement of the eccrine gland in the development of this condition. The presence of cornoid lamellae confined to adnexal ostia differentiates PEODDN from other porokeratosis forms, in which the cornoid lamella is not confined to adnexal ostia [17].

The etiopathogenesis of PEODNN remains poorly known. It has been proposed that the lesions of porokeratosis result from the peripheral expansion of a clone of mutant epidermal keratinocytes located at the base of the cornoid lamella [17]. It can be speculated that the same mechanism could underlie PEODNN if the mutant keratinocytes reside within eccrine glands. Our finding of lymphocytic infiltration around eccrine glands is consistent with
this hypothesis. Heredity may play a role since one familial case has been reported [18]. The distribution of PEODDN lesions along the lines of Blaschko suggests that genetic mosaicism may play a role [19]. More recently, it was found that PEODDN is caused by somatic mutations in the gene \textit{GJB2} encoding for connexin 26 [20], a gap junction protein, which permits intercellular ion and macromolecule flux.

Porokeratotic eccrine ostial and dermal duct nevus, especially when systematized or bilateral, can be associated with various conditions, including hyperthyroidism and sensory polyneuropathy [7], breast hypoplasia [21], deafness, developmental delay [22], alopecia, onychodysplasia [23], psoriasis [24], palmoplantar keratoderma [25], hemiparesis, and scoliosis [26]. Whether or not these associations are fortuitous remains speculative. The association of PEODDN with KID (keratosis, ichthyosis, deafness) syndrome [27] is interesting and seems significant since this complex genetic disease is also related to mutations of the \textit{GJB2} gene. It has been suggested that patients carrying \textit{GJB2} somatic mosaicism are at risk for transmitting systemic disease to their offspring and that all individuals with PEODDN should therefore be counseled regarding the risk of having a child with KID syndrome [20].

The course of PEODDN is chronic. The lesions may remain stable over years [8, 10] or be slightly progressive [12]. Our patient experienced spontaneous regression of part of her lesions on the arm and forearm. The prognosis is as a rule benign; however, transformation of PEODDN into Bowen disease [28] and squamous cell carcinoma [29, 30] has been reported. This fact is consistent with the contention that PEODDN may be a form of linear porokeratosis, known to be at risk for malignant transformation [17].

The treatment of PEODDN is challenging as no standardized option exists. Various treatments have

been used, but none seems to be regularly effective [6]. Topical corticosteroids (methylprednisolone and clobetasol propionate) can achieve temporary relief [31, 32]. Local tretinoin 1% cream, calcipotriene ointment [32], 5-fluorouracil [5], and various keratolytics have been used, including urea ointment or cream [12] and salicylic acid in petrolatum [15], without significant results. Systemic acitretin (50mg/d for two months) was ineffective in one case, although it improved the pruritus [15]. Partial results have been obtained with photodynamic therapy [33]. Carbon dioxide laser [6, 8, 16] alone or combined with erbium [34] have provided good results, especially for large lesions. Topical tazarotene has been tried in three patients, as 0.1% gel or 0.05% or 0.1% cream (Table 2). Two patients showed minimal response [5], but another patient achieved almost complete response within three weeks [28]. We decided to try this treatment in our patient since it can provide good results in various (genetic or acquired) diseases of keratinization and our patient obtained encouraging results. The systemic absorption of tazarotene after local application to small skin areas seems to be limited, nevertheless a pregnancy test is recommended prior to the onset of treatment in women of childbearing potential. The drug is contraindicated in women who are pregnant or desire a pregnancy.

**Conclusion**

Porokeratotic eccrine ostial and dermal duct nevus can rarely appear in adults but should be considered in the differential diagnosis of acral keratotic lesions appearing in adulthood. The diagnosis is usually made by histological examination. Although no regularly effective standard treatment exists our observation suggests that tazarotene 0.1% gel may be a satisfactory treatment option. More cases need to be studied in order to confirm the efficacy of this treatment.
