12 Abstract

13 Radionuclide transport in smectite clay barrier systems used for nuclear waste disposal is controlled by

14 diffusion, with adsorption significantly retarding transport rates. While a relatively minor component of

15 spent nuclear fuel, ^{79}Se is a major driver of the safety case for spent fuel disposal due to its long half-life

16 (3.3×10^5 yr) and its low adsorption to clay ($K_D<10$ L/kg), thus a thorough understanding of Se diffusion

17 through clay is critical for understanding the long-term safety of spent fuel disposal systems. Through-

18 diffusion experiments with tritiated water (HTO, conservative tracer) and Se(VI) were conducted with a

19 well-characterized, purified montmorillonite source clay (SWy-2) under a constant ionic strength (0.1 M)

20 and three different electrolyte compositions: Na^+, Ca^{2+}, and a Na^+-Ca^{2+} mixture at pH 6.5 in order to

21 probe the effects of electrolyte composition and interlayer cation composition on clay microstructure,

22 Se(VI) aqueous speciation, and ultimately diffusion. The results were modeled using a reactive transport

23 modeling approach to determine values of porosity (ε), D_e (effective diffusion coefficient), and K_D

24 (distribution coefficient for adsorption). HTO diffusive flux was higher in Ca-montmorillonite (D_e=1.68 ×

25 10^{-10} m^2 s^{-1}) compared to Na-montmorillonite (D_e=7.83 × 10^{-11} m^2 s^{-1}). This increase in flux is likely due

26 to a greater degree of clay layer stacking in the presence of Ca^{2+} compared to Na^+, which leads to larger

27 inter-particle pores. Overall, the Se(VI) flux was much lower than the HTO flux due to anion exclusion,

28 with Se(VI) flux following the order Ca (D_e=1.03 × 10^{-11} m^2 s^{-1})>Na-Ca (D_e=2.12 × 10^{-12} m^2 s^{-1})>Na

29 (D_e=1.28 × 10^{-12} m^2 s^{-1}). These differences in Se(VI) flux are due to a combination of factors, including

30 (1) larger accessible porosity in Ca-montmorillonite due to clay layer stacking and smaller electrostatic

31 effects compared to Na-montmorillonite, (2) larger accessible porosity for neutral-charge CaSeO4 species

32 which makes up 32% of aqueous Se(VI) in the pure Ca system, and (3) possibly higher Se(VI) adsorption

33 for Ca-montmorillonite. Through a combination of experimental and modeling work, this study highlights

34 the compounding effects that electrolyte and counterion compositions can have on radionuclide transport

35 through clay. Diffusion models that neglect these effects are not transferable from laboratory

36 experimental conditions to *in situ* repository conditions.

1. Introduction

Smectite clays, 2:1 layer-type phyllosilicate minerals, are the primary clay minerals found in bentonite and an important component of engineered barrier systems used for geologic storage of radioactive waste. Long-term nuclear waste disposal repositories must be capable of isolating radioactive waste over the time scales necessary for the decay of long-lived radioactive isotopes ($> 10^6$ years). Smectite clays are good barriers for radioactive waste due to their swelling capacity, ability to seal cracks, low hydraulic conductivity, and their high adsorption capacity for radionuclides. Montmorillonite is a common smectite mineral which has been widely studied. It has a large specific surface area ($\sim$750 m^2/g), cation exchange capacity ($\sim$1 mol$_c$/kg), and strongly-sorbing surface complexation sites on clay edge surfaces.

Natural smectites contain interlayer cations, including primarily Na$^+$, Ca^{2+}, and Mg^{2+}, which balance the negative permanent charge arising from isomorphic substitution in the phyllosilicate structure. The interlayer cation composition of smectite clays, including montmorillonite, affects the hydration and swelling properties of the clays (Bleam, 1990; Honorio et al., 2017; Laird and Shang, 1997; Salles et al., 2013; Subramanian and Nielsen Lammers, 2022; Teich-McGoldrick et al., 2015). For example, the presence of Na$^+$ in the interlayer leads to a higher degree of swelling compared to Ca^{2+} due to differences in the sizes and hydration energies of the cations. Natural smectites can have a wide range of interlayer cation compositions; Missana et al. (2018) studied bentonites currently under investigation for use in nuclear waste repositories and found Na$^+$ comprised <1 to 90% of the interlayer cation composition, with and Ca^{2+} and Mg^{2+} making up the bulk of the remainder. Groundwater intrusion into bentonite barriers can also alter the interlayer cation composition through cation exchange.

In compacted clay, solute transport is controlled by diffusion, and adsorption of solutes to the clay can significantly retard transport. While uranium is the primary constituent of radioactive waste, selenium (^{79}Se) is a major driver of the safety case for nuclear waste disposal due to its long half-life (3.3 × 10^5 yr) and presence as relatively mobile anionic species under a range of chemical conditions (*e.g.*, HSe$^-$, SeO$_3^{2-}$, SeO$_4^{2-}$). Se redox chemistry is complex, with oxidation states ranging from -II to +VI over environmentally relevant conditions. While Se(-II) and Se(0) are relatively immobile due to the formation of low solubility precipitates, Se(IV) and Se(VI) exist as the oxyanions selenite (SeO$_3^{2-}$) and selenate (SeO$_4^{2-}$) and are highly mobile in water due

72 to their high solubility. During deep geologic disposal of nuclear waste, the near field

73 environment is characterized by a relatively short oxic period, followed by anoxic conditions.

74 However, there is significant uncertainty and range in the Eh values expected, which will depend

75 on numerous factors including the host rock type, bentonite composition, and waste canister

76 corrosion. This makes it difficult to predict the speciation of Se in engineered barriers, however

77 selenite and selenate are considered to be the dominant Se aqueous species released during

78 oxidation of spent nuclear fuel (Ma et al, 2019; Chen et al., 1999). Se adsorption to clay minerals

79 is quite low compared to other important radionuclides such as U. K_D values for selenite

80 adsorption to smectite are in the range of 1-10 L/kg (Missana et al., 2009; Montavon et al., 2009)

81 compared to values up to 10^4 for U(VI) (Tournassat et al., 2018). Selenite and selenate

82 adsorption to the clay minerals kaolinite and Ca-montmorillonite were studied by Bar-Yosef and

83 Meek (1987) over the pH range 4-8. Both selenite and selenate adsorption decreased with

84 increasing pH, with very low or negligible adsorption above pH 8. Selenate adsorption to

85 kaolinite was lower than selenite adsorption (Bar-Yosef and Meek, 1987).

86 Selenite diffusion through bentonite has been investigated in several studies (García-Gutiérrez et

87 al., 2001; Idemitsu et al., 2016; Wang et al., 2016; Wu et al., 2017). Idemitsu et al. (2016)

88 measured apparent diffusion coefficient (D_a) values of 2.5×10^{-11} to 1.9×10^{-13} m^2/s over a range

89 of dry bulk densities (0.8-1.6 kg/L), ionic strengths (0.01-1.0 M NaCl), and temperatures (10-

90 55°C) for purified bentonite consisting of 99% montmorillonite. Measured D_a values for bulk

91 bentonite (*i.e.*, with lower smectite content) under similar conditions are 1-2 orders of magnitude

92 higher (Sato et al., 1995; Wu et al., 2014). Due to the lower adsorption of selenate compared to

93 selenite, selenate D_a values are expected to be even higher than observed for selenite, although

94 we could find no studies on selenate diffusion through bentonite in the literature.

95 In this paper, we present experimental and modeling results from tritiated water (HTO) and

96 Se(VI) through-diffusion experiments using a well-characterized, purified montmorillonite

97 source clay (SWy-2) with different interlayer cation compositions (Na^+ and Ca^{2+}). Previous

98 studies have observed higher diffusive flux of HTO (González Sánchez et al., 2008) and ReO_4^-

99 (Wu et al., 2018) through Ca-montmorillonite compared to Na-montmorillonite. Selenate, with a

100 charge of -2 and minimal adsorption, provides an opportunity to further probe anion diffusion

101 (*i.e.*, for divalent species) in Na and Ca-montmorillonite systems and provide direct information

102　on ^{79}Se transport through clay barriers. Experiments were conducted under a single ionic strength

103　(0.1 M) and three different electrolyte compositions representing pure Na$^+$, pure Ca^{2+}, and a Na$^+$-

104　Ca^{2+} mixture in order to probe the effects of electrolyte composition and interlayer cation

105　composition on clay microstructure, Se(VI) aqueous speciation, and ultimately diffusion.

2. Materials and Methods

2.1 Clay Samples

108　Selenium diffusion experiments were conducted using a well-characterized montmorillonite

109　source clay (SWy-2) obtained from the Clay Minerals Society. The montmorillonite was purified

110　in order to remove minor impurities (quartz, feldspars, and calcite). The purification procedure

111　was adapted from Tinnacher et al. (2016). The procedure included the following major steps: (1)

112　dialysis against sodium acetate at pH 5 for carbonate mineral dissolution, (2) dialysis against

113　NaCl to remove acetate and complete Na-saturation, (3) dialysis against water to remove excess

114　salts, and (4) centrifugation to remove quartz and feldspar particles greater than 2 μm.

115　Montmorillonite (50 g) was suspended in 1 L of 1 M sodium acetate solution buffered at pH 5

116　with acetic acid, placed into pre-rinsed dialysis tubing (SpectraPor7, 8 kDa), and dialyzed against

117　acetate buffer for 1 week, changing dialysis solution daily. The acetate buffer dialysis solution

118　was then replaced with 1 M NaCl (dialyzed for 3 days), then with MilliQ water (dialyzed for two

119　weeks), again changing dialysis solution daily. The clay suspensions were then transferred into

120　plastic bottles and diluted and dispersed in MilliQ water to reach a clay concentration of

121　approximately 15 g/L, and centrifuged at 1000 × g for 7 minutes. This centrifugation speed and

122　time was deemed sufficient to remove all particles > 2 μm as calculated from Stoke's Law. The

123　replicate < 2 μm clay fractions were then combined into a glass beaker, dried at 60°C and ground

124　in ball mill with tungsten carbide balls.

125　In order to maintain constant aqueous porewater chemical conditions and interlayer cation

126　composition during the diffusion experiments, purified montmorillonite was pre-equilibrated

127　with the appropriate background electrolyte prior to packing in diffusion cells. 2 g of purified

128　clay was suspended in 100 mL of electrolyte solution and the clay suspension was transferred to

129　pre-rinsed dialysis tubing (SpectrPor7, 8 kDa). Clay samples were dialyzed against 1 L of

130　background electrolyte for 1.5 weeks, changing dialysis solution at least 3 times and manually

131   adjusting pH daily. Once the pH remained between 6.45-6.55 within 24 hours, the background

132   electrolyte solution was replaced with MilliQ water, and dialysis was continued for 5 days,

133   changing the MilliQ water daily. After dialysis was complete, the clay suspension was

134   transferred to 40 mL polycarbonate centrifuge tubes and centrifuged at 39 000 × g for 20

135   minutes. The supernatant was removed and the clay was dried at 60°C and ground in ball mill

136   with tungsten carbide balls and stored at room temperature prior to packing the cells. At the time

137   of packing, a subsample of each clay was dried at 150°C to determine the moisture content.

138   The cation exchange capacity (CEC) and exchangeable cation composition was measured using

139   the hexamine cobalt(III) chloride method (Hadi et al., 2013). Triplicate samples of 50 mg dry

140   clay were weighed into centrifuge tubes and 10 mL of 15 mM hexamine cobalt(III) chloride

141   solution was added. Samples were mixed on an end-over-end sample rotator for 2 hours, then

142   centrifuged at 39,000 x g. Solution samples were analyzed for major cations (Ca, Mg, K, and Na)

143   by ICP-MS and the cation exchange capacity was calculated from the sum of cations released

144   from the hexamine cobalt solution corrected for any soluble salts released during the water

145   extracts. CEC is expressed as mmol$_c$/g (mmol of charge per gram dry clay) and cation

146   composition is expressed as the charge fraction for each cation.

147   2.2 Characterization of Filters

148   In order to accurately model diffusion through clay, the diffusion properties of the filters used in

149   the diffusion cell must be explicitly considered. Therefore, diffusive properties of the filters were

150   measured using custom-built filter diffusion cells based on a modified design of Aldaba et al.

151   (2014). The cells consisted of two polycarbonate reservoirs with a filter connecting the two

152   reservoirs. The filter is held in place with O-rings on each side and the two reservoirs are held

153   together in a base plate. A one-hole silicone stopper was fitted in the top of each reservoir with a

154   conductivity probe inserted through the hole to monitor solute diffusion. In addition, a small

155   needle (22 G) was inserted through each stopper to allow venting and pressure equalization with

156   the atmosphere. Without this venting needle, a small pressure differential can develop between

157   the two cells due to slight differences in stopper insertion, causing water to flow between the two

158   cells. Filters were made of PEEK with a PCTFE ring (IDEX # OC-815). The filters had an

159   overall diameter of 0.95 cm, filter diameter of 0.74 cm, thickness of 0.16 cm, 5 μm pore size, and

160   porosity of 0.26 according to the manufacturer.

161   The diffusion of sodium chloride was measured using this experimental setup in five replicate
162   experiments. The filter was soaked in MilliQ water to remove air bubbles. 45 mL of MilliQ
163   water was then added to each reservoir and allowed to equilibrate for at least 3 h. The low- and
164   high-concentration reservoirs were then spiked with 5 mL MilliQ water or 1 M NaCl,
165   respectively to start the experiment. This resulted in a concentration of 0.1 M NaCl in the high-
166   concentration reservoir. Both reservoirs were stirred constantly throughout the experiment. The
167   electrical conductivity of each reservoir was monitored with a conductivity probe and
168   automatically logged every 30 min. The conductivity probes were calibrated with known
169   concentrations of NaCl. During one experiment, 0.125 mL subsamples from each reservoir were
170   collected and analyzed for Na by ICP-MS in order to verify that the conductivity measurements
171   were accurately representing Na concentration. The measured Na concentrations agreed within
172   3% for the two methods.

173   **2.3 Diffusion coefficient of filters**

174   The cumulative mass (mol) of NaCl in the low-concentration reservoir was plotted over time (s).
175   This results in a pseudo-linear breakthrough curve for the first ~100 h during which the
176   concentration of NaCl in the high-concentration reservoir did not change significantly. The curve
177   was fit with a linear regression and the effective diffusion coefficient (D_e) was determined using
178   the slope (a) from the equation given by

$$D_e = \frac{a\,L}{A\,C_0}$$ Equation 1

179   where L is the thickness of the filter, A is the cross-sectional area of the filter, and C_0 is the initial
180   concentration in the high-concentration reservoir.

181   Effective diffusion coefficients measured for filters depend on the characteristics of both the
182   filter and the solute, according to:

$$D_e = \frac{\varepsilon}{G}\,D_0 = \tau\varepsilon D_0$$ Equation 2

183

184   where D_0 is the bulk diffusion coefficient of a solute in water, while G (or $1/\tau$) is a geometric
185   factor that accounts for the geometry of the filter pore network. τ is often referred to as the

186   tortuosity although it lumps together the true tortuosity and the constrictivity of the material. In

187   this filter diffusion experiment D_0 refers to the co-diffusion of Na^+ and Cl^- (1.61×10^{-9} m^2s^{-1}),

188   which is calculated from the diffusion coefficients of Na^+ and Cl^-, (1.33×10^{-9} and 2.03×10^{-9},

189   respectively at 25°C; Li and Gregory (1974) according to Cussler (2009) (see details in the SI).

190   Diffusion coefficients of aqueous species were calculated using the filter parameters and the

191   known D_0 values for those aqueous species. D_0 values at 25°C for HTO and SeO_4^{2-} were taken at

192   2.30×10^{-9} m^2 s^{-1} and 9.46×10^{-10} m^2 s^{-1} respectively.

2.4 Diffusion Experiments

194   Through-diffusion experiments were conducted with purified, pre-equilibrated montmorillonite

195   at a dry bulk density (ρ_d) of approximately 1.3 kg L^{-1} corresponding to a total porosity (ε) of

196   approximately 0.5 according to:

$$\varepsilon = 1 - \frac{\rho_d}{\rho_g} \qquad\qquad \text{Equation 3}$$

197

198   where ρ_g is the crystal density of clay mineral layers (*i.e.*, grain density). For montmorillonite, ρ_g

199   is approximately 2.84 kg L^{-1} (Bourg et al., 2006; Tournassat and Appelo, 2011). The dry bulk

200   density (ρ_d) is expressed in terms of the 150 °C oven dry weight of clay. There were some small

201   differences in the calculated bulk density and porosity for the three diffusion cells because of

202   differences in the moisture content of the clay at the time of packing (Table 2.).

203   The diffusion cells used for experiments are based on the design of (Van Loon et al., 2003), with

204   dimensions adjusted to accommodate smaller samples (Figure S1). The clay plug inside the

205   diffusion cells had a diameter of 9.5 mm and a length of 5 mm. Cells were machined in-house

206   using PEEK (polyether ether ketone) plastic at Lawrence Berkeley National Laboratory.

207   Experiments were conducted under a single ionic strength (0.1 M) and three different electrolyte

208   compositions: 0.1 M NaCl, 0.033 M $CaCl_2$, and 0.085 M NaCl + 0.005 M $CaCl_2$, representing

209   pure Na^+, pure Ca^{2+}, and a Na^+-Ca^{2+} mixture, respectively. All experiments were performed at

210   room temperature (23°C) at pH 6.5. The pre-equilibrated dry clay samples were weighed into

211   PEEK diffusion cells and compacted using a custom PEEK packing rod.

The diffusion experiments were conducted in three phases: (1) saturation, (2) tritiated water (HTO) diffusion, and (3) Se(VI) diffusion. The clay was saturated by circulating 200 mL of background electrolyte at both ends of the cell at approximately 1 mL/min using a peristaltic pump for 40-42 days. After the saturation period, the HTO through-diffusion phase was started by replacing the background electrolyte solutions with a high HTO reservoir containing background electrolyte spiked with 1110 Bq mL^{-1} HTO (200 mL) at one end and a low HTO reservoir containing only background electrolyte (20 mL) at the other end. The high-concentration reservoir was sampled at the beginning and the end of the HTO diffusion experiment and did not change significantly over that time period. The low HTO reservoir was changed at time intervals of 3-36 h, and the HTO concentration was measured in the low reservoir samples by liquid scintillation counting. An in-house-built autosampler using a 3D printer (Creality Ender 3Pro) as the base was used to change the low reservoir samples at regular time intervals. The HTO concentration in the low reservoir never exceeded 0.5% of the concentration in the high reservoir. The HTO diffusion was continued for 16 days. After this period, the high-concentration reservoir was replaced with a Se(VI)-spiked solution containing 1.0 mM sodium selenate in the background electrolyte with a total volume of 190 mL, marking the start of the Se(VI) diffusion experiment. The low-concentration reservoirs containing only background electrolyte (5-10 mL) were changed at time intervals of 12-48 h for the first 44 days, then 48-170 h for the remaining 33 days, and Se concentrations were measured by ICP-MS. Se concentrations in the low reservoir never exceeded 1% of the concentration in the high reservoir. Subsamples of the high-concentration Se(VI) reservoir were collected at the beginning and end of the experiment and did not change significantly over the experiment.

At the end of the Se(VI) diffusion period, the diffusion cells were disassembled and the clay plug was extruded using the PEEK packing rod and sliced into thin slices. The thickness of the clay slices was measured using a digital caliper with a precision of 0.1 mm. Clay slices ranged in thickness from 0.3 to 0.9 mm. The clay slices were placed into 20 mL glass scintillation vials and dried at 150°C for 24 hours. The dried clay was extracted with 5 mL of 0.5 M trace metal grade hydrochloric acid for 3 days, then centrifuged at 39 000 × g for 20 min and filtered through a 0.45 μm PVDF syringe filter. Selenium concentrations were measured in the acid extracts by ICP-MS. Se concentrations in the clay profiles are expressed in mmol Se per liter of total porosity (C_{Se_pore}), calculated using the following equation:

$$C_{Se\_pore} = \frac{1000 \times C_{Se\_solid} \times \rho_d}{\varepsilon}$$

Equation 4

243

244   Where C_{Se_solid} is the concentration of Se extracted per gram of dry clay (in mmol g^{-1}).

245   **2.5 Analytical Techniques**

246   Samples were analyzed for Se by ICP-MS (Perkin-Elmer Elan DRC II) after acidification and

247   dilution with ultrapure (ultrex grade) 0.15 M nitric acid and internal standard addition. Selenium

248   was measured using oxygen as the cell gas in DRC mode and using Rh as an internal standard.

249   Spike recoveries with known concentrations of Se were run every 5 samples, and recoveries

250   ranged from 0.80-1.25. Independent QC samples were run every 10 samples, with recoveries

251   ranging from 0.9-1.1. HTO samples were analyzed using liquid scintillation counting (Perkin-

252   Elmer Liquid Scintillation Analyzer Tri-Carb 2900TR) by mixing 4 mL of sample with 18 mL of

253   Ultima Gold XR liquid scintillation cocktail and counting until the relative standard deviation

254   was 2% or for a maximum of 90 minutes.

255   **2.6 Modeling Approach**

256   Normalized mass flux (J_N, in m day^{-1}) reaching the low-concentration reservoir is most

257   frequently calculated in the literature using:

$$J_N = \frac{C_{low}V_{low}}{C_{high}A \cdot \Delta t}$$

Equation 5

258   where C_{low} is the concentration in the low-concentration reservoir, C_{high} is the concentration in

259   the high-concentration reservoir, V_{low} is the volume of the low-concentration reservoir (from ~5

260   to ~20 mL depending on the sampling event), A is the cross-sectional area of the diffusion cell

261   (0.709 cm^2), and Δt is the time interval since the previous sampling event. This approximation is

262   applicable for cases in which tracer concentration in the high reservoir does not change

263   significantly over the course of the experiment (i.e., tracer source is considered infinite) and the

264   tracer concentration in the low reservoir remains near zero (Yaroshchuk et al., 2008). However,

265   for modeling purposes, this representation presents some problems (discussed in detail in

266   Tournassat et al. (2023)), which include differences in time-integrated fluxes, J_N, compared to

267   instantaneous fluxes calculated with the analytical solution of the diffusion equations. J_N values

268   may also oscillate with time because of the irregular pattern of sampling events during the

269   experiment. A reactive transport modeling approach makes it possible to consider all

270   experimental features such as the above-mentioned problems, as well as varying boundary

271   conditions, the presence of filters, the presence of an O-ring in the filters, the replacement of the

272   low-concentration reservoir with time, *etc.* (Tournassat et al., 2023). In addition, a reactive

273   transport modeling approach allows comparison of the modeling results directly to the raw

274   experimental data, *i.e.* the tracer concentrations measured in each of the collected vials at all

275   sampling times. For these reasons, all clay sample diffusion experiments were modeled using the

276   reactive transport model CrunchClay (Steefel and Tournassat, 2021; Tournassat and Steefel,

277   2021; Tournassat et al., 2020). The consideration of an O-ring in the filters necessitated carrying

278   out the calculations with a 2D-axisymmetric geometry (Tournassat et al., 2023).

279   CrunchClay was used in combination with the CrunchEase interface (Tournassat et al., 2023) to

280   estimate clay diffusive properties within the framework of a classical $\varepsilon - D_e - K_D$ modeling

281   approach, where ε is the diffusion porosity (-), D_e is the effective diffusion coefficient ($m^2\ s^{-1}$,

282   see Equation 2) and K_D ($L\ kg^{-1}$) is the distribution coefficient that accounts for reversible and

283   linear adsorption processes. We assumed that HTO was present only in solution and that Se was

284   present in solution (with c = aqueous concentration) and on surfaces (with C_{surf} in $mol\ kg_{solid}^{-1}$) so

285   that C_{tot} (in $mol\ m_{medium}^{-3}$) can be expressed as:

$$C_{tot} = c\varepsilon + C_{surf}\rho_d \qquad\qquad \text{Equation 6}$$

286   We assumed that the Se surface concentration C_{surf} was linearly related to the aqueous

287   concentration through $C_{surf} = cK_D$ (with K_D in $m^3_{water}\ kg_{solid}^{-1}$) and that the adsorption process

288   was instantaneous and reversible. Based on this assumption,

$$C_{tot} = c\varepsilon + cK_D\rho_d. \qquad\qquad \text{Equation 7}$$

289   It was further assumed that the media were homogeneous. Hence D_e, ε, ρ_d and K_D are independent

290   of x, and Fick's second law of diffusion reduces to:

$$\frac{\partial c}{\partial t} = \frac{\tau\varepsilon D_0}{\varepsilon + \rho_d K_D}\frac{\partial^2 c}{\partial x^2} = \frac{D_e}{\alpha}\frac{\partial^2 c}{\partial x^2} \qquad\qquad \text{Equation 8}$$

291

292 where α is the rock capacity factor.

293 The dimensions of the diffusion cells are available in the Supporting Information (Figure S1).

294 The exact same dimensions were considered in our reactive transport simulations, which can be

295 reproduced by the readers using the CrunchEase GUI made freely available on Github

296 (https://github.com/Tournassat/CrunchEaseForAll).

297 In the following, the agreement of the model with the experimental data is shown on the raw data

298 (concentration measurements in vials) and the experimental time-averaged flux J_N as a function

299 of experimental conditions is only shown for comparison.

3. Results and Discussion

3.1 Filter Diffusion Properties

302 In order to characterize the baseline performance of the reaction cell, diffusion of NaCl through

303 PEEK filters was measured in five replicate experiments. An example plot of cumulative NaCl

304 mass in the low reservoir over time is shown in Figure S2. There was an initial lag period,

305 followed by a linear increase in NaCl in the low reservoir. This linear portion of the

306 breakthrough curve was used to calculate the effective diffusion coefficient of Na^+ and Cl^-

307 through the filter according to Equation 1, resulting in a measured D_e of $6.1 \times 10^{-11} \pm 0.29 \times 10^{-11}$

308 $m^2\,s^{-1}$.

309 Given the known values for ε and D_0 (Table S1), we calculated G to be 6.82 ± 0.33 ($\tau = 0.147 \pm$

310 0.007). The measured D_e value was lower than for stainless steel filters with a similar pore size

311 ($1.6 \times 10^{-10}\,m^2\,s^{-1}$) (Aldaba et al., 2014). G and ε were slightly lower for the PEEK filters used in

312 this experiment compared to those used by Aldaba et al. (2014), which had a smaller nominal

313 pore size of 1 μm.

3.2 Clay Cation Composition

315 The total cation exchange capacity of the clay after purification was 0.833 ± 0.04 mmol$_c$/g. The

316 cation composition for the Na, Na-Ca, and Ca exchanged clays is shown in Table 1. The cation

317 composition is expressed as a % of charge ($100 \times$mmol$_c$ cation per gram/CEC in mmolc/g). The

318   Na-Ca clay contained 72% (by charge) Ca. A very small amount (1%) of exchangeable Mg was

319   present in all three clays and no K was detected.

320   **Table 1. Exchangeable cation composition of clays expressed as a charge % of the CEC.**

Clay	Na (% charge)	Ca (% charge)	Mg (% charge)
Na	98.3 ± 0.6	0.5 ± 0.6	1.2 ± 0.0
Na-Ca	26.8 ± 0.2	72.2 ± 0.2	1.0 ± 0.0
Ca	1.6 ± 0.3	97.5 ± 0.2	0.9 ± 0.1

321

322

3.3 Tritiated water (HTO) diffusion

324   HTO diffusion reached a steady state after approximately 100 h, with steady-state fluxes

325   increasing in the order Na, Na-Ca, and Ca (Figure 1). A precise estimation of the τ and D_e values

326   of HTO was achieved by modeling the data with the assumption that the total porosity was

327   accessible to HTO (Figure 1 and Table 2). The influence of the variations in sampling time

328   intervals and sample vial volumes during the experiment is almost perfectly captured by our

329   modeling approach (raw data available in the SI), thus giving confidence in the modeled τ and D_e

330   values.

331   The small difference between the Na ($\tau_{HTO} = 0.065$) and Na-Ca ($\tau_{HTO} = 0.070$) cells might be

332   attributed to small differences in cell packing ($\rho_d = 1.35$ vs. $\rho_d = 1.28$ kg L^{-1} for Na and Na-Ca

333   cells respectively). Differences in bulk density will affect not only the total porosity, but also the

334   sample microstructure responsible for the geometrical factor affecting diffusion processes.

335   Archie's law relates the effective diffusion coefficient to the porosity and an empirical

336   cementation factor, m, that captures the change of the geometrical factor as a function of porosity

337   changes:

$$D_e = D_0 \varepsilon^m \qquad\qquad\qquad \text{Equation 9}$$

338   Despite its empirical nature, Archie's law or its extended version (Van Loon and Mibus, 2015) is

339   often able to quantitatively describe the evolution of the effective diffusion coefficient of HTO in

340   clayey materials. The difference between the Na ($\tau_{HTO} = 0.065$) and Na-Ca ($\tau_{HTO} = 0.070$) cells

341   can be described by considering a cementation factor of $m \sim 3$, which is compatible with the

342   cementation factors commonly reported for bentonite samples (Van Loon and Mibus, 2015).

343   However, the difference between the Na-Ca ($\tau_{HTO} = 0.070$) and Ca ($\tau_{HTO} = 0.13$) cells cannot be

344   attributed to the small difference in cell packing only. A cementation factor of $m \sim 10$ would be

345   necessary, which does not fall in the range of values reported for montmorillonite. A reasonable

346   explanation of the observed difference lies in the difference of microstructure of Na- and Ca-

347   exchanged montmorillonite samples: the presence of exchangeable Ca promotes the formation of

348   thicker layer stacks ("tactoids") compared to Na (Segad et al., 2012), which in turn promotes the

349   presence of larger interparticle pores (Holmboe et al., 2012; Ohkubo et al., 2021), hence

350   increasing the diffusivity of the material (Melkior et al., 2009; Tournassat et al., 2011;

351   Tournassat et al., 2016).

352
Figure 1. Left: HTO normalized concentrations in the low-concentration reservoir as a function of time. Right: HTO normalized flux as a function of time. Na, Na-Ca, and Ca refers to the three different salt background and clay conditioning conditions. Circles: experimental data; lines: results of the $\varepsilon - D_e$ models (Table *2.*). Error bars are representative of the analytical error on the HTO measurements (2 standard deviations).

Table 2. Summary of measured diffusion cell parameters, including bulk density (ρ_d), total porosity (ε_{tot}, calculated from Equation 3), along with reference model fitted parameters (τ,

D_e, α_{Se}), assuming $K_D = 0$ L kg^{-1} for both HTO and Se(VI). Note that α_{HTO} is equivalent to ε_{HTO} and ε_{tot}. Uncertainties on the D_e value were estimated from model envelop curves and experimental error bars.

Cell	ρ_d (kg L^{-1})	$\varepsilon_{tot} = \varepsilon_{HTO} = \alpha$ HTO (-)	τ_{HTO} (-)	$D_{e,HTO}$ (10^{-12} m^2 s^{-1})	$\alpha_{Se} = \varepsilon_{Se,max}$ (-)	$\tau_{Se,min}$ (-)	$D_{e,Se}$ (10^{-12} m^2 s^{-1})
Na	1.35	0.524	0.065	78 ± 4	0.0983	0.0138	1.3 ± 0.3
Na-Ca	1.28	0.551	0.070	89 ± 4	0.140	0.0160	2.1 ± 0.5
Ca	1.24	0.562	0.13	168 ± 8	0.450	0.0250	10.6 ± 2.3

3.4 Selenate diffusion

The normalized flux for Se(VI) reached steady state after approximately 300 h, with the Ca-montmorillonite showing the highest normalized flux (Figure 2). The steady-state flux of Se was much lower than that of HTO in all three cells. Total Se concentrations in clay slices also followed the trend Na<Na-Ca<Ca (Figure 3). Se concentrations in the clay slice closest to the high-concentration reservoir (at ~4.5-5.0 mm) were 0.18, 0.25, and 0.77 mM for the Na, Na-Ca, and Ca cells, respectively. The observed variations in Se concentration/flux may result from both differences in effective porosity for Se and from changes in Se adsorption in the presence of increasing Ca concentrations. The profiles in all three cells were linear with depth as expected for steady-state conditions.

Through-diffusion data makes it possible to extract a single set of α, D_e values for each tracer in one experiment (Crank, 1975; Van Loon et al., 2003). However, it does not provide enough constraints to extract a single set of ε, K_D, and τ values and additional data and/or hypotheses are necessary to derive these three quantities independently. In the first attempt, the K_D values for Se(VI) were set to zero. In this condition, the fitted porosity and tortuosity values take their maximum and minimum value respectively ($\varepsilon_{max} = \alpha$ and τ_{min}; Table 2). The corresponding fitted parameters made it possible to almost perfectly reproduce the diffusion data (Figure 2 and Figure 3).

384   In Na-montmorillonite, clay layers are negatively charged and part or all of the porosity is

385   influenced by the presence of an electrical double layer (EDL) that forms at the surface, and in

386   which the solution is not electroneutral (Tournassat and Steefel, 2019). Negatively charged

387   species, including SeO_4^{2-}, are depleted in the EDL-influenced portion of the porosity because of

388   their interaction with the negative electrostatic potential field created by the surfaces of

389   montmorillonite. This process, often called anion-exclusion, is also responsible for a higher

390   geometrical factor, G (or $1/\tau$), for anions compared to neutral tracers such as HTO, because pore

391   throats, which are responsible for the pore network connectivity, may partially or totally exclude

392   anions, thus ascribing longer diffusion pathways to anions compared to neutral species.

393   Consequently, $\tau_{Se} \leq \tau_{HTO}$ and it is possible to define a minimum accessible porosity value for Se

394   corresponding to $D_{e,Se} = \tau_{HTO} \times \varepsilon_{Se,min} \times D_{0,Se}$. This minimum porosity corresponds itself to a

395   maximum K_D value according to $\alpha_{Se} = \varepsilon_{Se,min} + \rho_d K_{D,max}$ (Table 3). We note that the very low

396    $K_{D,max}$ values ($<<1$) in Table 3 are nearly impossible to measure in batch experiments.

397   The calculated minimum value of SeO_4^{2-} accessible porosity ($\varepsilon_{Se,min} = 0.021$) was similar to the

398   values reported for Cl^- in similar compacted Na-montmorillonite materials (Tournassat and

399   Appelo, 2011). Cl^- does not adsorb on clay mineral surfaces, and thus, the difference between

400   total porosity values and Cl^- accessible porosity values reported in the literature are truly

401   representative of the excluded volume for monovalent anions. However, one would expect an

402   increased exclusion for SeO_4^{2-} compared to Cl^- because of their difference in charge. This

403   surprisingly high Se(VI) accessible porosity in the Na-montmorillonite sample may be partly

404   explained by the presence of aqueous and exchanged Mg^{2+} which originates from a limited

405   dissolution of the clay layers (Orucoglu et al., 2018). The formation of $MgSeO_4$ ion pairs, which

406   are neutral and, thus not excluded from the EDL, would then explain the lower value of Se(VI)

407   exclusion than expected. Mg^{2+} was a minor component (1%) of exchangeable cations at the

408   beginning of the experiment (Table 1). However, we did not measure exchangeable cations on

409   the clay at the end of the experiment or aqueous Mg^{2+} during the diffusion experiment, therefore

410   are unable to confirm the formation of $MgSeO_4$ ion pairs. The lowering of Se exclusion from the

411   EDL could also be related to an increased ion pairing in the EDL compared to bulk water

412   conditions (Appelo et al., 2010), which in turn would increase the apparent accessible porosity of

413   Se.

414

Table 3. Summary of constraints on Se diffusion parameters in Na-, Na-Ca-, and Ca-montmorillonite. $K_{D,max}$ values are given in L kg^{-1}.

| Cell	$\varepsilon_{Se,min}$	$K_{D,max}$	$\varepsilon_{Se,min}$ considering CaSeO$_4$ ion pair formation	$K_{D,max}$ considering CaSeO$_4$ ion pair formation
Na	0.021	0.057	-	-
Na-Ca	0.032	0.084	0.036	0.081
Ca	0.086	0.29	0.18	0.22

417

In the Ca-montmorillonite sample, the minimum accessible porosity was found to be 0.086. This higher accessible porosity for Ca-montmorillonite compared to the Na-montmorillonite sample can be explained by a combination of the following effects: the presence of wider interparticular pores, which increases the average anion accessible porosity (Tournassat et al. 2016) and a decrease of the magnitude of the negative electrostatic potential field in the presence of divalent cations (Ca^{2+}). However, the presence of CaSeO$_4$ aqueous complexes which are neutral and thus not repelled from clay mineral surfaces will also affect the minimum accessible porosity, which is not accounted for in the above estimate ($\varepsilon_{Se,min}$ of 0.086 for Ca). Aqueous speciation calculation carried out with the Thermochimie database (Giffaut et al., 2014; https://www.thermochimie-tdb.com/) indicates that 32% of the total Se concentration is present in the form of CaSeO$_4$ in a 0.033 M CaCl$_2$ background solution. Equivalently, at least 32% of the total porosity is accessible to Se in this neutral form, *i.e.* a revised minimum accessible porosity of $0.32 \times 0.56 = 0.18$, giving in turn a revised $K_{D,max}$ value of 0.22 L kg^{-1} (Table 3.). Assuming that the D_0 value for CaSeO$_4$ is similar to that of CaSO$_4$ ($D_0 = 4.71 \ 10^{-10}$ m^2 s^{-1} available from the PHREEQC.dat database), a $\tau_{Se,max}$ value of 0.115 can be deduced.

In the Na-Ca cell, with 0.005 M CaCl$_2$ + 0.085 M NaCl background solution, 6.6% of the total aqueous Se(VI) is in the form of CaSeO$_4$, leading to a minimum accessible porosity of $\varepsilon_{Se,min}$ = $0.066 \times 0.55 = 0.036$. The corresponding $\tau_{Se,max}$ value is 0.123, which is very similar to the value found for the Ca-montmorillonite sample.

437   The above analysis highlights the importance of a good knowledge of the aqueous speciation to

438   understand and predict the diffusion properties of Se and provides realistic constraints for the

439   ranges of ε_{Se}, K_{DSe}, and τ_{Se}.

440

455 **central grid-cells on the symmetry axis). Error bars represent the analytical error (2**

456 **standard deviations). Note that the concentrations at the downstream boundary do not**

457 **tend to zero because of the O-ring and the presence of tubings (i.e., 'dead volumes') in**

458 **which the tracers are accumulating between sampling events.**

459

4. Conclusions

461 An increase of Ca/Na ratio in solution and on clay surfaces is responsible for an increase in HTO

462 and selenate diffusivity in montmorillonite samples. The increase of HTO diffusivity can be

463 explained by a change of microstructure leading to an increase of the τ_{HTO} value. These changes

464 will affect the transport of all radionuclides through clay barriers, including Se. In addition, the

465 aqueous speciation of Se(VI) has a large effect on Se transport. Se(VI) diffusion is limited by

466 anion exclusion due to the formation of the negatively charged species SeO_4^{2-}. However, in the

467 presence of Ca^{2+}, the formation of $CaSeO_4$ neutral ion pairs, which can access a larger portion of

468 the total porosity, increases selenate diffusivity. While additional insights about the exact

469 distribution of the interlayer and interparticle porosities and the influence of the diffuse layer on

470 selenate ion pair formation would be necessary to build a comprehensive mechanistic model for

471 selenate diffusion in montmorillonite samples, we provide constraints on model parameters that

472 can be used to predict a range of Se(VI) transport in engineered barrier systems. Our analysis

473 highlights that Se(VI) diffusion parameters (*e.g.*, effective diffusion coefficients) obtained with

474 simplified laboratory systems cannot be transferred to the simulation of a repository if *in situ*

475 geochemical conditions, especially ionic strength and major element concentrations (*e.g.*, Ca),

476 are different from the laboratory conditions. Furthermore, these results have similarly important

477 implications for the diffusion of other radionuclides which are present as anions or mixed-

478 species in waste repositories, including Se(IV) ($HSeO_3^-$, SeO_3^{2-}), U(VI) (e.g., $UO_2(OH)_3^-$,

479 $UO_2(OH)_4^{2-}$), Mo(VI) (MoO_4^{2-}) and others. Radionuclide aqueous speciation together with the

480 presence of an EDL must be explicitly taken into account in the model in order to accurately

481 predict their transport. The results also emphasize the need to understand the overall chemical

482 evolution of repository conditions as changes in aqueous speciation due to many factors (*e.g.*,

mineral dissolution/precipitation or groundwater penetration) can change the mobility of important species.

Supplementary Material

Supplementary information, including diffusion cell schematics and additional information about measuring diffusive properties of the filters is provided in a separate file and is available free of charge online.

Data Availability

Raw experimental data used in this manuscript is available on Mendeley Data (Fox et al., 2024).
