1 ABSTRACT

2 **Purpose.** Despite a growing body of literature on the physiological responses to ultramarathon, there is a paucity of data in females. This study assessed the female physiological response to ultramarathon and 3 4 compared the frequency of perturbations to a group of race- and time-matched males. Methods. Data were 5 collected from 53 contestants of an ultramarathon trail race at 2018/19 Ultra Trail du Mont-Blanc 6 (UTMB[®]). Before and within 2-h of the finish, participants underwent physiological assessments including 7 blood sampling for biomarkers (creatine kinase-MB isoenzyme, CK-MB; cardiac troponin I, cTnI; brain 8 natriuretic peptide, BNP, creatinine, Cr); pulmonary function testing (spirometry, exhaled NO, diffusing 9 capacities, mouth pressures); and transthoracic ultrasound (lung comet tails, cardiac function). Data from eight female finishers (age=36.6±6.9 y; finish time=30:57±11:36 hh:mm) were compared to a group of 10 eight time-matched males (age=40.3±8.3 y; finish time=30:46±10:32 hh:mm). Results. Females exhibited 11 12 significant pre- to post-race increases in BNP (25.8±14.6 vs. 140.9±102.7 pg/mL; p=0.007) and CK-MB 13 $(3.3\pm2.4 \text{ vs. } 74.6\pm49.6 \text{ IU/L}; p=0.005)$, whereas males exhibited significant pre- to post-race increases in BNP (26.6±17.5 vs. 96.4±51.9 pg/mL; p=0.002), CK-MB (7.2±3.9 vs. 108.8±37.4 IU/L; p=0.002), and Cr 14 15 $(1.06\pm0.19 \text{ vs. } 1.23\pm0.24 \text{ mg/dL}; p=0.028)$. Lung function declined in both groups, but males exhibited additional reductions in lung diffusing capacities (DL_{CO}= 34.4 ± 5.7 vs. 29.2 ± 6.9 mL/min/mmHg, p=0.004; 16 17 $DL_{NO}=179.1\pm26.2$ vs. 152.8 ±33.4 mL/min/mmHg, p=0.002) and pulmonary capillary blood volumes $(77.4\pm16.7 \text{ vs. } 57.3\pm16.1 \text{ mL}; p=0.002)$. Males, but not females, exhibited evidence of mild post-race 18 19 pulmonary edema. Pooled effect sizes for within-group pre- to post-race changes, for all variables, were generally larger in males versus females (d = 0.86 vs. 0.63). Conclusions. Ultramarathon negatively 20 21 impacts a range of physiological functions but generally evokes more frequent perturbations, with larger effect sizes, in males compared to females with similar race performances. 22

25 INTRODUCTION

26 Ultramarathons are footraces that typically range from ~30 miles (~50 km) to ~150 miles (~240 km) in a single stage and considerably further in multi-stage events. Participation evokes extreme physiological 27 strain on multiple body systems (1), particularly the cardiovascular and respiratory systems (2). For 28 29 instance, studies show decreased left ventricular function and increased cardiac biomarkers following 30 ultramarathon (3, 4), in addition to lung function derangements of 10–15% with or without evidence of 31 airway obstruction (5). Moreover, while most physiological perturbations are transient and generally 32 recover to baseline within a week, there is the potential for long-term maladaptations and associated health 33 issues (6). For these reasons, there is now a greater emphasis on understanding the acute and chronic physiological and pathophysiological responses to ultramarathon running (1, 2, 6, 7). 34

Despite the growing body of work, there is a paucity of data in female athletes. A recent review on 35 36 pulmonary responses to marathon and ultramarathon running collated 15 studies with a cumulative 232 37 participants of which only 19 (8%) were female (5). This number is considerably below the estimated $\sim 20\%$ 38 of female ultramarathon contestants (8-10) and supports the notion that females may be underrepresented 39 in exercise science research (11). Potential explanations may be a researcher bias that favours males as 40 recruitment participants (12), but also a possible volunteer bias which has males more willing to participate 41 in exercise-related research (13). Nevertheless, anatomical and physiological differences between males and females can influence the exercise response (14-17), and failure to consider these differences may limit 42 43 the specificity of training programs and negatively impact efforts at promoting competitive longevity.

The issue of sex-based physiological predisposition to ultramarathon has also been a topic of recent discussion (10). Indeed, a number of exceptional, record-breaking performances by female athletes in ultramarathon in recent years has roused speculation that they might be predisposed to success in such events. The male-to-female performance gap in regular endurance sports like marathon is ~10% (18), but studies have calculated the performance gap in ultramarathon to be as low as 4% (19). In some instances, female performances may surpass those of their male counterparts (20). Additionally, in ultramarathon, there are distinct performance predictors for males (e.g., age, BMI, years of running) and females (e.g., weekly running mileage and half-marathon record) (9). Thus, while the question of whether females are physiologically predisposed to ultramarathon has not been directly explored, an ability to better tolerate the physiological stress of racing is likely ergogenic in ultramarathon and may also lead to better long-term health management.

Accordingly, there were two aims of this exploratory study. The first was to provide novel data on the physiological responses of females to an ultramarathon trail race, with specific emphasis on respiratory and cardiopulmonary function. The second was to explore sex differences in the frequency of pre- to postrace physiological perturbations in males and females matched for ultramarathon finish time.

59

60 METHODS

61 **Race Characteristics**

Data were collected from runners competing in one-of-two races at the annual Ultra Trail du Mont-Blanc (UTMB®) trail running series in 2018 or 2019. The UTMB® (106 miles/171 km, ~10,000 m ascent) and the CCC® (63 miles/101 km, ~6,000 m ascent) are single-stage, mountainous trail races commencing in Chamonix, France and Courmayeur, Italy, respectively. Both races require intermittent bouts of traversal at altitudes \geq 2,500 m (Fig. 1) and, in the years during which data collection took place, temperature and humidity ranged from -6 to 28°C/35 to 75% (2018) and 6 to 29°C/35 to 70% (2019). Temperature extremes were mediated largely by altitude.

69

70 Ethical Approval and Participants

Ethical approval was granted first by the Mayo Clinic Institutional Review Board (IRB# 17-003843) and then by the Comité de Protection des Personnes Sud-Ouest et Outre-Mer 2 (IRB# 2-18-43-2). Thereafter, runners were contacted by the UTMB® organizers who distributed details of the study via electronic recruitment posters. After providing written, informed consent, data were collected from 53 runners of which 10 (19%) were female. One female runner retired early from the race, and another did not return for post-race assessments; thus, eight female finishers remained (CCC®, n=4; UTMB®, n=4;). A subgroup of eight male runners from the same races (CCC®, n=4; UTMB®, n=4;), whose finish times most closely
matched the female group mean, were selected as a comparison (Table 1). Runners completed a medical
questionnaire and declared that they were free from known cardiorespiratory illnesses. All testing was
conducted in accordance with the declaration of Helsinki.

81

82 Study Design

83 Participants attended the laboratory (based near the start/finish line at 1,035 m) in the week preceding the 84 race to complete baseline testing which was organized into three phases (Fig. 2). Initial measures included 85 vital signs (heart rate, systolic and diastolic blood pressure [SBP/DBP], electrocardiogram [ECG]), basic anthropometry (stature and mass), and venous blood sampling for electrolytes, biomarkers, haemoglobin 86 concentration, and haematocrit. Next, participants completed pulmonary function tests (PFTs) including 87 88 spirometry, forced oscillation, and exhaled nitric oxide, followed by an assessment of respiratory muscle 89 strength. Lastly, resting lung diffusing capacity was assessed followed by transthoracic ultrasound for cardiac morphology and lung comet tails. All physiological measures were repeated as soon as possible 90 91 following race completion (mean \pm SD, 1 h 41 min \pm 54 min).

92

93 Blood sampling

Venous blood samples (~8 mL) were collected via venepuncture and analysed using a commercially
available, hand-held immunoassay device and cartridges (i-STAT Corporation, New Jersey, USA).
Measures included haemoglobin (Hb), haematocrit (Hct), electrolytes (sodium, Na²⁺; potassium, K⁺;
chloride, Cl⁻), and biochemical markers relating to cardiac (troponin I, cTnI; brain natriuretic peptide, BNP),
renal (creatinine, Cr), and skeletal muscle function (creatine kinase-MB, CK-MB). Plasma volume was
calculated from Hct and Hb using the Dill and Costill equation (21).

100

101 **Pulmonary and respiratory muscle function**

102 Pulmonary volumes (forced expiratory volume in 1-second, FEV₁; forced inspiratory volume in 1-second, FIV₁), capacities (forced vital capacity, FVC; inspiratory capacity, IC), and flows (peak expiratory flow, 103 104 PEF; forced expiratory flow between 25 and 75% of FVC, FEF₂₅₋₇₅) were assessed using a portable 105 spirometer (Breeze Suite 8.5 and CPFS/D USBTM, Medgraphics Corporation, Minnesota, USA) during a 106 minimum of three and a maximum of eight forced expiratory manoeuvres (22). Airway resistance at 5 and 107 19 Hz (R₅ and R₁₉) were assessed via forced oscillometry (Resmon Pro V3; MGC Diagnostics, Minnesota, 108 USA) during which participants were seated, had the nose occluded, and were asked to maintain tidal 109 breathing while their cheeks were held firmly by an investigator (23). As a marker of airway inflammation, 110 fractional exhaled nitric oxide (Fe_{NO}) was measured using a handheld device (Aerocrine Nixo Vero®) 510(k), Solna, Sweden, used in 2018; NObreath; Bedfont, Rochester, UK, used in 2019) (24). Lung 111 diffusing capacity for carbon monoxide (DL_{CO}) and nitric oxide (DL_{NO}) were assessed simultaneously via 112 113 the single-breath technique using a 4-s breath-hold (Hyp'air Compact system with Exp'air software, version 114 1.31.05, Medisoft, Dinant, Belgium). Each resting measure was separated by 4 min and performed in 115 duplicate (25). Moreover, DL_{CO} was expressed in absolute terms, expressed relative to alveolar volume (DL_{CO}/VA), and corrected to reference hemoglobin concentrations (DL_{CO,HbCorr}) according to the Cotes et 116 al. equation (25, 26). Following the assessment of DL_{CO} and DL_{NO} , alveolar-capillary membrane 117 118 conductance (DM_{CO}) and pulmonary capillary blood volume (V_C) were calculated using equations 119 described by Pavelescu et al. (27). Finally, maximum static inspiratory pressure (P_{IMAX}) from residual 120 volume and maximum static expiratory pressure (P_{FMAX}) from total lung capacity (28) were measured using 121 a handheld device (MicroRPM, CareFusion, San Diego, USA). All pulmonary and respiratory muscle 122 function tests were performed in accordance with recommended standards (22–25, 27, 28).

123

124 Transthoracic ultrasound

Comet tails. As a measure of extravascular lung water (pulmonary oedema), the number of
ultrasound lung comets was determined via transthoracic sonography (Philips CX50 and S5-1 transducer,
Philips Healthcare, Netherlands), as previously described (29, 30). Briefly, participants lay supine while

128 the sonographer sequentially examined 28 intercostal lung fields located at the parasternal, midclavicular, 129 anterior axillary and mid-axillary lines from the second to the fourth intercostal space (left side) and from the second to the fifth intercostal space (right side). A comet was defined as an echogenic, coherent, wedge-130 shaped signal that originated from the hyperechoic pleural line and extended to the edge of the screen. The 131 132 presence of an ultrasound lung comet was simultaneously verified by two trained operators. In accordance 133 with Picano et al. (31), we employed a semi-quantitative classification for the presence of extravascular 134 lung water, whereby a total lung comet tail count of < 5 was considered "normal"; 5 - 15 was mild 135 extravascular lung water accumulation; 15 - 30 was moderate extravascular lung water accumulation; and 136 > 30 was severe extravascular lung water accumulation (31).

137 *Echocardiography.* All images were acquired while the participant was supine and orientated in the left-lateral decubitus position following 10-min rest. Two-dimensional (2-D) and pulsed-wave tissue 138 139 Doppler echocardiography were performed using ultrasound (Philips CX50 and S5-1 transducer, Philips 140 Healthcare, Netherlands). Images were acquired by an experienced cardiac sonographer in accordance with the guidelines published by the American Society of Echocardiography (32). Echocardiograph data were 141 analysed offline by the same assessor using commercially available software (Q-Lab 13, Philips Healthcare, 142 Netherlands). Measures included cardiac frequency (f_c), stroke volume (SV) determined via the Doppler 143 144 velocity time integral (DVTI) method, and cardiac output (\dot{Q}) determined by the product of $f_{\rm C}$ and SV (32).

145

146 Statistics

Statistical analyses were performed using IBM SPSS Statistics v24 (IBM; Illinois, USA). Normality of distribution was assessed using the Shapiro Wilk test, and data that were not normally distributed were log transformed. Independent samples *t*-tests were used to assess for sex differences in age, race time, velocity, and physiological variables at baseline, with the Welch statistic applied in cases when homogeneity of variance (Levine's test) was violated. Paired samples *t*-tests were used to assess the female (within-group, n=8) pre- to post-race response, the male (within-group, n=8) pre- to post-race response, and the overall pre- to post-race response (n=16). For differences testing, the Benjamini-Hochberg method was used to adjust the *p*-value for the false discovery rate associated with multiple comparisons. The magnitude of the difference between group means was assessed using Cohen's d (0.2 = small; 0.5 = medium; 0.8 = large; (33)). Alpha level was 0.05, and descriptive values are reported as mean \pm SD (unless stated).

157

158 **RESULTS**

Baseline variables

Participant demographics and race data are shown in Table 1. There was no difference in age between females and males (p = 0.361), but males were taller (p = 0.003) and heavier (p = 0.004). Per study design, there were no between-group differences in average finish time (p = 0.975) or running velocity (p = 0.762). Baseline physiological variables are shown in Table 2. Males exhibited greater baseline values for SBP, Na²⁺, Hct, PV, Cr, CK-MB, FVC, FEV₁, PEF, FIV₁, DL_{CO}, DL_{CO,HbCorr}, DL_{NO}, V_C, P_{IMAX}, and P_{Emax}. There were no baseline between-group differences in f_C , DBP, K⁺, Cl⁻, Hb, cTnI, BNP, FEV₁/FVC, FEF₂₅₋₇₅, IC, R₅, R₅-R₁₉, Fe_{NO}, DL_{CO}/VA, DM_{CO}, frequency of lung comet tails, SV, or Q.

167

168 Physiological responses to ultramarathon

Participants returned for post-race assessments 1 h 41 min \pm 54 min after finishing the event, with no difference between the sexes (1 h 44 min \pm 54 min vs. 1 h 38 min \pm 57 min, p = 0.846, d = 0.11). All withingroup pre- to post-race data (means, standard deviations, *p*-values, and effect sizes) are shown in the supplementary table.

173 *Vital signs (f_c, SBP, and DBP).* Paired-samples *t*-tests revealed a significant overall effect of 174 ultramarathon on $f_{\rm C}$ (p = 0.004, d = 1.26) and SBP (p = 0.010, d = 0.88). There was no overall effect on 175 DBP (p = 0.290, d = 0.45). The within-group analysis showed that females exhibited significant pre- to 176 post-race increases in $f_{\rm C}$, while males exhibited significant pre- to post-race decreases in SBP 177 (supplementary table).

178 Blood sampling. Paired-samples *t*-tests revealed a significant overall effect of ultramarathon on Hb 179 (p = 0.032, p = 0.77), Hct (p = 0.036, d = 0.76), PV (p = 0.020, d = 0.82), cTn1 (p = 0.016, d = 1.11), BNP 180 (p = 0.004, d = 1.57), Cr (p = 0.028, d = 0.39), and CK-MB (p = 0.004, d = 2.65). There was no overall 181 effect on Na²⁺ (p = 0.566, d = 0.31) - with no evidence of hyponatremia in any athlete - and no overall effect 182 on K⁺ (p = 0.236, d = 0.77) or Cl⁻ (p = 0.282, d = 0.40). The within-group analysis showed that females 183 exhibited significant pre- to post-race increases in BNP and CK-MB, while males exhibited significant pre-184 to post-race increases in BNP, CK-MB, Cr, and PV (Fig. 3; supplementary table).

185 Pulmonary and respiratory muscle function. Paired-samples t-tests revealed a significant overall 186 effect of ultramarathon on FVC (p = 0.044, d = 0.36), FEV₁ (p = 0.027, d = 0.36), PEF (p = 0.016, d = 0.0160.37), IC (p = 0.004, d = 0.95), Fe_{NO} (p = 0.004, d = 0.72), DL_{CO} (p = 0.005, d = 0.51), DL_{NO} (p = 0.004, d = 0.95), Fe_{NO} (p = 0.004, d = 0.95), DL_{NO} (p = 0.004, d = 0.95), DL 187 188 = 0.52), V_C (p = 0.004, d = 0.88), and P_{IMAX} (p = 0.010, d = 0.56). There was no overall effect on FEV₁/FVC $(p = 1.000, d = 0.11), \text{FEF}_{25.75}$ $(p = 0.412, d = 0.32), \text{FIV}_1$ $(p = 0.264, d = 0.38), \text{R}_5$ (p = 0.472, d = 0.27), (p = 0189 R_5-R_{19} (p = 0.182, d = 0.45), $DL_{CO,HbCorr}$ (p = 0.061, d = 0.32), DL_{CO}/VA (p = 1.000, d = 0.08), DM_{CO} (p = 0.061), d = 0.08), DM_{CO} (p = 0190 191 0.825, d = 0.22), or P_{EMAX} (p = 0.096, d = 0.38). The within-group analysis showed that females exhibited 192 significant pre- to post-race decreases in FVC, PEF, IC, Fe_{NO}, and P_{IMAX}, while males exhibited significant 193 pre- to post-race decreases in PEF, IC, Fe_{NO}, DL_{CO} , DL_{NO} , and V_C (Fig. 4; supplementary table).

194 *Transthoracic ultrasound.* Paired-samples *t*-tests revealed a significant overall effect of 195 ultramarathon on lung comet tails (p = 0.004, d = 1.31) and \dot{Q} (p = 0.020, d = 0.75). There was no overall 196 effect on SV (p = 0.234, d = 0.36). The within-group analysis showed that females exhibited significant 197 pre- to post-race increases in lung comet tails and \dot{Q} , while males exhibited significant pre- to post-race 198 increases in lung comet tails (supplementary table).

199

200 DISCUSSION

The aims of this study were to provide novel data on the physiological responses of females to an ultramarathon trail race, and to explore sex differences in the frequency of pre- to post-race physiological perturbations in groups matched for ultramarathon finish time. The main findings were: i) ultramarathon evoked significant increases in skeletal muscle, cardiac, and renal biomarkers, and significant decreases in various aspects of respiratory and cardiopulmonary function; ii) both males and females exhibited biomarker disturbances but with a greater number of perturbations in males; and iii) ultramarathon reduced lung function and increased comet tails in both groups, with additional reductions in diffusing capacities and pulmonary capillary volumes in males. Our data show that ultramarathon negatively impacts a range of physiological functions but generally evokes more frequent perturbations, with larger effect sizes (pooled effect size for all variables, d = 0.86 vs. 0.63) in males compared to females matched for finish time.

211 In accordance with existing literature (5), ultramarathon resulted in a significant decrease in 212 spirometric indices of lung function; specifically, forced vital capacity (FVC), forced expiratory volume in 213 1 second (FEV₁), and peak expiratory flow (PEF) (Fig. 4). The overall decreases in FVC and FEV₁ were 214 driven primarily by females. Wuthrich et al. published respiratory data from 23 runners (8 female) who contested the UTMB® in 2012 (35). Congruent with our findings, they also reported significant post-race 215 216 decreases in FEV_1 and PEF. Airflow during spirometry is a product of the driving pressure of the thoracic 217 muscles offset against the airway resistance (36). Given that we observed no evidence of small airway 218 obstruction post-race, in either group (i.e., no change in FEF_{25-75} , R_5 , or R_5 - R_{19}), the most likely explanation 219 for the decreases in expiratory flows is a diminished thoracic driving pressure. This may have been attributable to a mild degree of expiratory muscle fatigue, as proposed by Wuthrich et al. (35), and/or a 220 221 failure to start the FVC manoeuvre from a "true" total lung capacity, as reported by Tiller et al. (37). The 222 latter scenario is especially likely given the significantly diminished post-race IC exhibited by both groups. 223 Females generally have smaller lungs and narrower conducting airways than males (16, 38) and 224 are more likely to exhibit expiratory flow limitation during exercise (39). As such, the larger magnitude of

reduction in peak flows in the female athletes was not unexpected. Nevertheless, despite statistically significant decreases in pulmonary function in both groups, follow-up analyses using regression equations from the Global Lung Function Initiative (40) showed that all post-race values of FVC and FEV_1 (with the exception of one male participant, see below) remained within normal limits and were unlikely to pose an acute clinical concern.

The male cohort exhibited a large and significant pre- to post-race decrease in lung diffusing capacities ($DL_{CO} = -16\%$; $DL_{CO,HbCorr} = -12\%$, $DL_{NO} = -16\%$), whereas post-race values in the female group 232 were not significantly different from baseline (Fig. 4). The decreases in DL_{CO} and DL_{NO} , which reflect a 233 reduced capacity for gas transfer from alveoli to the bloodstream, may result from a fall in pulmonary capillary blood volume (V_c) in males, especially given that there was no post-race change in DM_{CO}. There 234 are reports of diminished DL_{CO} and DM_{CO} at altitude without changes in V_{C} in healthy participants (41). 235 236 Acute high-intensity exercise has also been shown to reduce DL_{CO} and V_{C} (42) despite being compensated 237 for, in some cases, by increases in DM_{CO} (43). It is unclear if the reduced capacity for gas transfer in males 238 resulted from ultra-endurance exercise, the intermittent altitude, or a combined effect of both stimuli resulting in a mild post-race pulmonary vascular de-recruitment and an overall null effect on DM_{CO} in 239 240 males. Further study in a larger cohort is required to explore this finding and establish whether a pulmonary 241 vascular phenotype in female runners precludes a decline in DL_{CO} and V_{C} following ultramarathon.

242 There was an overall increase in lung comet tails following the race, and values were significantly 243 elevated in both females and males. Nevertheless, the male group exhibited considerably larger effect sizes 244 (2.41 vs. 0.96), and all males increased comet tails by >1 versus only 4/8 females. As per Picano *et al.*, (31), post-race comet tails in the range of 5 - 15 indicate "mild" extravascular lung water accumulation, and this 245 246 threshold was met only by males. By contrast, values in females remained in the "normal" range (i.e., < 5). Although our data somewhat contradict earlier studies showing greater prevalence of interstitial lung 247 248 oedema in females following marathon (44), there is evidence of pulmonary oedema triggered by both maximal and submaximal (prolonged) exercise, independent of sex and the level of hypoxia (45). As such, 249 250 there is no reason to think that the present increases in lung comet tails were mediated exclusively by the 251 intermittent altitude experienced during the race. Instead, capillary haemorrhage, increased capillary 252 permeability, and/or pulmonary oedema may result from increased cardiac output and pulmonary vascular 253 pressure during exercise (46). It is worthy of note that the individual male and female athletes who exhibited 254 the greatest increases in lung comet tails also exhibited the largest post-race declines in pulmonary function. 255 In fact, the male individual was the only participant in the cohort to exhibit post-race values for FEV_1 that 256 fell below the lower limit of normal. Although our data confirm earlier observations that there is little relation between the change in oedema score and the change in DM_{CO} or FVC (47), there may yet be an 257

interaction among ultra-endurance exercise, intermittent altitude, and pulmonary oedema which warrantsfurther study.

Relative to baseline, we observed significant overall increases in both BNP and cTnI following the 260 race (Fig. 3). The absolute values were modest and remained within normal limits, as was generally 261 262 observed in studies of cardiac biomarkers following the Badwater ultramarathon (216 km; (3)) and the 263 Western States Endurance Run (160 km; (4)). Increased cardiac biomarkers are considered to be a common 264 response to endurance exercise and were reported as elevated in endurance athletes without any 265 accompanying signs of persistent cardiac damage (48). Nonetheless, a recent review highlighted the 266 potential for long-term cardiovascular maladaptations with ultra-endurance running (6) such that the prognostic importance of periodic acute increases in biomarkers (particularly cardiac biomarkers) should 267 268 not be dismissed. Specifically, more research is needed to elucidate the clinical importance of biomarkers 269 that may be repeatedly elevated as a result of frequent ultra-endurance competition.

270 The observation of smaller and less frequent biomarker disturbances in the female group was 271 unexpected. In fact, only BNP and CK-MB were significantly elevated above baseline in females, whereas 272 males exhibited significant post-race disturbances in BNP, CK-MB, and Cr. Pre-race cTnI assessments 273 were negative (≤ 0.01 ng/mL) in all participants except one male (0.02 ng/mL), and an increase of > 0.01274 ng/mL was observed in 5/8 females and 6/8 males, with larger effect sizes in males (0.99 vs 1.18). In 275 marathon runners, Neilan et al. (49) reported that the greatest increase in post-race cardiac biomarkers 276 occurred in those athletes training less than 35 miles/wk. Although this would indicate that higher training 277 volumes and better physical condition could be protective in the release of cardiac troponins during and 278 following exercise, George et al. found no such relationship in a diverse group of recreational runners (50). Accordingly, the clinical relevance of these modest post-race changes is unclear. 279

Pre- to post-race SV was 73.0 to 65.2 mL in males (-11.4%; p = 0.084, d = 0.74) and 63.2 to 61.5 mL in females (-1.4%; p = 0.744, d = 0.11). Although BNP and cTnI were generally elevated following the race, studies have refuted the notion that these biomarkers reflect cardiomyocyte damage (51). Interestingly, the magnitude of the SV reduction in males was similar to that observed by Scott *et al.* (4) following a 160 km ultramarathon (77 to 64 mL). There are several proposed causes of such post-race decreases, including
low-frequency fatigue, the downregulation of cardiac beta-receptors, and decreases in plasma volume (2),
although our data exclude this latter mechanism. We can also speculate that the relative post-exercise
hypotension observed in males may have influenced cardiac afterload and/or preload.

288 Following the race, CK-MB concentrations were elevated above normal in both males and females 289 (Fig. 3) and this is considered an indirect marker of muscle damage. Indeed, several ultramarathon studies 290 report significant post-race increases in total creatine kinase (CK) concentrations with values increasing 291 congruent with race distance (52, 53). Some authors consider the muscle damage and metabolic stress 292 associated with ultramarathons to represent a danger to human health (54), causing possible hepatic damage 293 (55), and it may be that there are protective effects of smaller and less frequent CK isoenzyme perturbations 294 following ultra-endurance exercise. We initially speculated that CK-MB concentrations may be associated 295 with peripheral muscle fatigue during ultramarathon; however, previous studies reporting sex differences 296 in peripheral muscle fatigability following short (<60 km) and long (>100 km) distance ultramarathons also 297 showed show no sex differences in post-race CK isoenzyme concentrations when males and females were 298 matched by percent of winning time by sex (56, 57). Accordingly, any sex differences in peripheral muscle 299 fatigability (14) are likely independent of skeletal muscle damage and/or biomarker levels.

300 Changes in haematocrit and haemoglobin were used to calculate relative changes in plasma volume. There was a large and significant post-race increase in plasma volume in the male group (21%; p = 0.043, 301 302 d = 1.36), whereas the post-race change in females was not significant (7%; p = 0.143, d = 0.61). The 303 magnitude of the change was almost identical (21 vs. 20%) to that observed by Robach et al. in 22 male 304 runners following the UTMB® (58). In that study, the authors speculated that the increase in PV may have 305 resulted from inflammation and an associated interlukin-6-mediated effect on plasma volume expansion. 306 Sex differences in inflammation following ultramarathon have not been comprehensively assessed, but our 307 findings provide some interesting preliminary data that warrant exploration.

308

309 Methodological and physiological considerations

310 The female and male runners in this study were matched for ultramarathon finish time and running velocity 311 (Table 1) because it was deemed that matching the duration of exercise exposure and absolute work rate would be important for comparing the frequency of physiological perturbations. As a result, other aspects 312 of physiological function were unable to be standardized. For example, there will be inherent differences 313 314 in cardiorespiratory fitness between time-matched females and males, discrepancies that we were unable to quantify. During the race, this may have resulted in the two groups operating at different relative exercise 315 316 intensities. Other studies comparing physiological functions between male and female ultramarathon 317 runners opted to match groups by relative performance to the first male and the first female of their specific 318 race (57). While this approach has the advantage that male and female participants would be matched for relative running *ability*, it does not overcome the problem of participants operating at different relative 319 320 exercise intensities and/or metabolic rates. Physiological profiling athletes in future studies would provide 321 clarity in this respect, aid in the interpretation of data, and improve our understanding of the respective male 322 and female ultramarathon performance predictors.

323 Another consideration is that the remote location of the race necessitated that our extensive 324 laboratory measures were limited to those that could be made using portable/point-of-care devices. More 325 detailed measures of physiological responses (e.g., inflammation, body composition, etc.) would require 326 expensive and fragile equipment to be transported into the field, and this is often impractical. The execution 327 of simulated, lab-based ultramarathon research may be one way of deriving more mechanistic insights in 328 the future. The nature of 'field testing' also made it difficult to perform post-race measurements in a timely 329 fashion because, for instance, the measuring devices could not be situated at the finish line. This required 330 athletes to travel a short distance for their post-race assessments and is a common problem with such studies. Presently, we aimed to retrieve participants for their post-race assessments as soon as possible, with the 331 332 actual time being 1 h 41 min \pm 54 min after finishing the race. Although radiographic findings of mild 333 interstitial oedema have been observed to persist for at least 98 min after endurance exercise (marathon 334 running) (44), comet tails and several of our other measures, including aspects of pulmonary and respiratory 335 muscle function, will have started to recover within a few hours (5). As such, it is possible that there may have been an underestimation of the number and/or magnitude of pre- to post-race physiological changes.
Nonetheless, the time in which females and males returned for post-race assessments was similar, thereby
not invalidating a direct comparison of the frequency of between-group perturbations.

339 Finally, in the present study, we examined sex-specific physiological responses to ultramarathon 340 by comparing the *frequency* of physiological perturbations between males and females. However, although 341 our original data set represents one of the larger samples of its kind among the literature, comprising all 342 female participants from an initial mixed-sex cohort of 53 athletes who contested the event over two years, 343 the relatively small sample size (and the large within-group variance) precluded any direct male-to-female 344 comparisons on the *magnitude* of the response. Based on the data reported herein, a power analysis was performed (G*Power version 3.1.9.6) to determine the sample size that would be required to observe a 345 346 statistically significant between-group interaction (should one exist) in future studies using a repeated-347 measures design. Based on an alpha level of 0.05 and a statistical power of 0.8, a total of 32 participants 348 (16 per group) would likely be required where moderate between-group effect sizes are observed (e.g., most 349 biomarker comparisons), although slightly smaller samples sizes would likely be acceptable in the case of 350 larger between-group effects (e.g., diffusing capacity and comet tails). We hope this will inform future 351 research on sex differences in physiological variables in response to ultramarathon.

352

353 Conclusions

Ultramarathon evokes considerable physical stress on multiple body systems, as evidenced by significant pre- to post-race disturbances in numerous aspects of physiological function. In males and females matched for ultramarathon finish time, it was male athletes who exhibited more frequent perturbations, and with larger effect sizes, most notably in lung diffusing capacities and in biomarkers of skeletal muscle, cardiac, and renal function. These data may inform training prescription and future research on long-term health and injury management in ultramarathon.

360

361 Acknowledgments

362 The authors would like to thank the athletes who volunteered their time while contesting one of the world's 363 most arduous footraces. Individual thanks are reserved for Catherine Poletti and Michel Poletti of UTMB®, Patrick Basset and Volker Scheer of the Ultra Sports Science Foundation, and Loïc Chabridon for clinical 364 expertise he provided during data collection. Thanks are also extended to personnel at Grenoble University 365 366 Hospital for their help preparing the ethics application in France, and The institute Ecole Nationale des 367 Sports de Montagne for hosting the research team throughout data collection. This research was funded by 368 a grant that the Mayo Clinic received from Biomobie Regenerative Medicine Co. (Shanghai, China). 369 Finally, the authors would like to thank MGC Diagnostics Corporation (Minnesota, USA), Medisoft (Sorinnes, Belgium), and Philips Healthcare (Eindhoven, Netherlands) for equipment and technical support. 370

371

372 Conflict of Interest

The authors declare no conflict of interest. The results of the present study do not constitute endorsement by ACSM. The results of the study are presented clearly, honestly, and without fabrication, falsification, or inappropriate data manipulation. NBT is supported by a postdoctoral fellowship from the Tobacco-Related Disease Research Program (TRDRP; award no. T31FT1692). GMS is supported by the American Heart Association (AHA#19POST34450022) and a Career Development Award in Cardiovascular Disease Research Honouring Dr. Earl H. Wood from Mayo Clinic.

 Table 2. Baseline physiological comparisons.

Mean ± SD. $f_{\rm C}$ = cardiac frequency (heart rate); SBP = systolic blood pressure; DBP = diastolic blood pressure; Na²⁺ = sodium concentration; K⁺ = potassium concentration; Cl⁻ = chloride concentration; Hb = haemoglobin concentration; Hct = haematocrit; PV = plasma volume; cTnI = cardiac troponin-1; BNP = brain natriuretic peptide; Cr = creatinine; CK-MB = creatine kinase; FVC = forced vital capacity; FEV₁ = forced expiratory volume in 1-second; PEF = peak expiratory flow; FEF₂₅₋₇₅ = forced expiratory flow between 25 and 75% of FVC; IC = inspiratory capacity; FIV₁ = forced inspiratory volume in 1-second; R₅ = airway resistance at 5 Hz; R₅-R₁₉ = airway resistance at 5 Hz minus resistance at 19 Hz (small airways); Fe_{N0} = exhaled nitric oxide; DL_{C0} = diffusing capacity of the lung for carbon monoxide; DL_{C0}HbCorr = diffusing capacity of the lung for carbon monoxide relative to alveolar volume; DL_{N0} = diffusing capacity of the lung for nitric oxide; DM_{c0} = diffusing capacity of the pulmonary membrane for carbon monoxide; V_c = pulmonary capillary blood volume; P_{IMAX} = maximum inspiratory pressure; P_{EMAX} = maximum expiratory pressure; SV = stroke volume; Q = cardiac output. *p* = *p*-value from independent-samples *t*-test; *d* = Cohen's *d* effect size; *statistically significant between-group difference (Benjamini-Hochberg-adjusted *p*-value).
