In a recent paper dealing with ceramic compounds formed by heating vanadium at low air pressures, Edington and Smallman⁽¹⁾ report experimental data which are almost identical to those reported by us for ordered tantalum-carbon alloys.^(2,3) Consequently we believe that the reported transformation⁽¹⁾ is actually that of interstitial ordering viz. the spatial arrangement of the matrix V atoms remains virtually undisturbed, but the interstitial atoms occupy definite crystallographic positions, producing a body centered tetragonal structure as described in ref. 3. Thus, the so called vanadium compound⁽¹⁾ is actually an ordered phase identical to that of $Ta_{64}C$ and the structure should be as shown in fig. 1 where the squares represent vanadium unit cells and the circles interstitial atoms in $\langle 0, \frac{1}{2}, 0 \rangle$ octahedral positions. Both the diffraction patterns and micrographs of ref. 1 can be successfully interpreted in terms of such ordered structures. For example, the diffraction patterns of Edington and Smallman are actually superlattice patterns and are in complete agreement with those predicted from the structure of fig. 1. Their sketches of figs. 3a, 4b also satisfy this structure. However the remainder of their diagrams are incompatible with their diffraction patterns (fig. 2a, 7b). If the diffraction patterns are indexed relative to superlattice diffraction spots there are no systematic absences and this is in accord with the space group of the $Ta_{64}C$ structure viz. $I4/mmm$.

In figs. 3b,c,d and 5b the authors indicate missing diffraction spots in the higher layers of the reciprocal lattice but in the reported diffraction data and some of their sketches these absences are not observed. We conclude therefore that if the authors' diagrams were all consistent with their diffraction data, systematic absences cannot exist. The non observance of superlattice diffraction patterns in apparently ordered areas can be explained if one considers the high degree of order necessary to produce a superlattice diffraction pattern. This is because in certain regions the superlattice pattern is not reinforced due to the different diffracting conditions from domain to domain.

The reciprocal lattice of the ordered structure can be physically described as two interpenetrating, coincident, face centered tetragonal reciprocal lattices. The complete analysis of such structures has been described elsewhere.³

The formation of these ordered structures does not take place at high temperatures, but rather on cooling from high temperatures. This can be explained when one considers that the interstitial must be present in a given volume of the specimen in the right proportion to cause the ordering reaction (about 1.5% at .% interstitial). In the case of a thin foil the ordering reaction will first occur in the thinnest regions of the foil.

The micrographs of Edington and Smallman are typical of those expected from ordered alloys containing domain boundaries.⁽³⁻⁵⁾ Both foils and bulk specimens exhibit domain contrast. The images of fig. 6, ref. 1 are consistent with those expected from overlapping domain boundaries³ the exact nature of which can be determined by dark field work. The domains in figs. 7a,c are both high and low angle domain boundaries.³ Fig. 8 shows high angle domain boundaries (viz. the domains are parallel to the electron beam) on (011). The domain boundaries can take up any orientation, and a single domain can

lie on more than one plane.³ It is apparent when domain configurations are considered, that the {110} is the most stable and habit plane determinations confirm this.

The formation of these domain boundaries is a growth process rather than a dislocation process as suggested by the authors.⁽¹⁾ Actually to form coherent domain boundaries ({110} twins) the matrix material, vanadium, is only slightly distorted while the interstitial atoms require the greatest shifts. We believe this to be more compatible with a growth phenomenon.

It is interesting to note the similarities between the Ta-C and V-O systems. Beshers⁽⁶⁾ has suggested on the basis of geometric and energetic arguments that in the group V-A metals the interstitials should occupy tetrahedral sites except for oxygen in vanadium and carbon in tantalum. Since the space group for the Ta-C and V-O superlattices are identical viz. $I4/mmm$, and on the basis of our structure factor work and c/a ratio determinations and the striking similarity between Ta-C and V-O, we conclude that the interstitials must occupy octahedral sites in the structure. A recent detailed analysis of the Nb-O ordering reaction⁽⁷⁾ suggests that the ordered structure is Nb_2O in which oxygen atoms are most likely located in tetrahedral sites[†]. This limited evidence supports Beshers' conclusions.

This work was supported by the United States Atomic Energy Commission.
