Human infection by Zika virus (ZIKV) during pregnancy can lead to vertical transmission and fetal aberrations, including microcephaly. Prophylactic administration of antibodies can diminish or prevent ZIKV infection in animal models, but whether passive immunization can protect nonhuman primates and their fetuses during pregnancy has not been determined. 2004 and 2021 are neutralizing monoclonal antibodies to domain III of the envelope (EDIII) of ZIKV. Together the two antibodies protect nonpregnant macaques against infection even after Fc modifications to prevent antibody-dependent enhancement (ADE) in vitro and extend their half-lives. Here we report on prophylactic coadministration of the Fc-modified antibodies to pregnant rhesus macaques challenged three times with ZIKV during first and second trimester. The two antibodies did not entirely eliminate maternal viremia but limited vertical transmission, protecting the fetus from neurologic damage. Thus, maternal passive immunization with two antibodies to EDIII can shield primate fetuses from the harmful effects of ZIKV.

Results

The combination of human IgG1 monoclonal antibodies Z004 and Z021 significantly reduces plasma viral loads and prevents emergence of viral escape mutations in nonpregnant rhesus macaques challenged with a superphysiologic dose of ZIKV i.v. (10^6 plaque-forming units [PFU]) (23). Similar results were obtained when the antibodies were modified to prevent antibody-dependent enhancement (ADE) in vitro by mutations that abrogate Fc-γ receptor engagement (GRLR; refs. 23 and 24).

Significance

Zika virus (ZIKV) infection during pregnancy can cause fetal abnormalities. Vaccines against ZIKV are under development, but because of potential safety concerns due to disease-enhancing antibodies, and the time required by active immunization to induce protective antibodies, there is a need to explore alternative strategies. Recombinant monoclonal antibodies can be modified to prevent enhancement of infection, and thus could be an efficacious and safe alternative to vaccines to confer rapid protection. We show that prophylactic administration of two engineered antibodies, 2004 and 2021, to pregnant macaques partially protects against fetal neurologic damage and limits vertical transmission of ZIKV.

To evaluate the protective effect of these antibodies against what is considered to be a more physiologic dose and route of administration, we administered Z004GRLR + Z021GRLR to macaques 24 h before s.c. inoculation with 10^3 PFU of ZIKV (Fig. L4) (25, 26). In untreated controls, plasma viremia peaked on days 4 to 5 after infection, reaching between 10^5 and 10^7 RNA copies/mL (n = 4; black in Fig. 1B). In contrast, plasma viremia was undetectable in three out of six antibody-treated macaques, and it was lower and delayed in the remaining three animals (green in Fig. 1B–D). Since ZIKV can be detected in macaque tissues even when absent from plasma (13, 27), we measured viral RNA in a panel of 17 tissues (Fig. 2). Viral RNA was evident in multiple tissues in control animals as well as in the three animals that showed low and delayed viremia after infection (Fig. 2 A, Right). In contrast, viral RNA was low or undetectable in tissues from macaques with no detectable plasma viremia (Fig. 2 A, Left and Fig. 2B). Thus, prophylactic administration of Z004GRLR + Z021GRLR prevents or reduces viral accumulation in plasma and tissues upon low-dose ZIKV challenge.

The half-life of Z004 and Z021 can be extended by altering the antibody’s Fc domain (LS mutation; refs. 28 and 29) without altering ZIKV neutralizing activity in vitro or in vivo (23). To determine whether Z004GRLR/LS + Z021GRLR/LS remains efficacious in macaques, we administered the combination before low-dose s.c. challenge with ZIKV. Z004GRLR/LS + Z021GRLR/LS showed extended half-lives and their levels in plasma remained more than 4 logs above the in vitro inhibitory concentration throughout the monitoring period (SI Appendix, Fig. S1). The treatment prevented plasma viremia in two of six macaques; one macaque had a single episode of low-level viremia (less than 10^3 viral RNA copies/mL on day 2 postinfection), and the remaining three had lower and delayed viral loads (orange in Fig. 1 B–D) compared to untreated controls. The macaques that developed plasma viremia after administration of Z004GRLR + Z021GRLR or Z004GRLR/LS + Z021GRLR/LS had viruses with mutations in the envelope domain III (EDEH) region: T309A, T309A/V330L, T309I/V330L, and V330L (Fig. 3 A–C). To determine whether these substitutions confer resistance to the antibodies, we produced reporter virus particles (RVPs; ref. 30) with these mutations and evaluated them for sensitivity to the two antibodies (Fig. 3D). Both antibodies retained potency against RVPs containing the V330L mutation, which was also found in untreated control animals (Fig. 3A). This mutation is located outside the epitope of either antibody (Fig. 3B). Although T309 is in the epitope of both antibodies (Fig. 3B and C), its mutations affected the potency of Z021 alone. Since T309 mutations did not alter ZIKV sensitivity to the combination of antibodies in vitro, they are unlikely to represent virus escape (Fig. 3D). Consistent with these findings, the mutations involved residues other than those altered in the viruses emerging from macaques treated with the individual antibodies (Figs. 3D and S3) with Z004 with Z004, and T335 with Z021; ref. 23 and SI Appendix, Fig. S2). We conclude that Z004GRLR/LS + Z021GRLR/LS prevents emergence of viral escape variants found with monotherapy (ref. 23 and SI Appendix, Fig. S2) and are as efficacious as their GRLR counterparts against ZIKV in macaques.

ZIKV infection of pregnant macaques is associated with fetal demise and neuropathology (11–13). To evaluate the effect of anti-ZIKV antibodies on fetal development and health in pregnant primates, we performed timed breeding experiments and challenged the dams three times with 10^3 PFU of ZIKV s.c. on gestational days (GDs) GD30, GD60, and GD90, which correspond to first and second trimester (normal gestation of rhesus macaques is ∼165 d) (21). Macaques in the treatment group received i.v. infusions of Z004GRLR/LS + Z021GRLR/LS antibodies 24 h before each virus challenge (Fig. 4A). Both dam and fetus were closely monitored; animals were killed near the end of gestation for detailed tissue analysis (SI Appendix, Tables S1 and S2). During this whole observation period, human IgG plasma levels remained 3 logs or higher than the in vitro inhibitory concentration (Materials and Methods and SI Appendix, Fig. S3).

Untreated macaques developed plasma viremia that peaked between days 2 and 5 after the first ZIKV inoculation (Fig. 4B, Left and ref. 21). In contrast, out of the eight antibody-treated dams, three had no detectable viremia, while four other animals had delayed peak viremia on days 7 (n = 1) or 21 (n = 3) after the first inoculation, and a fifth developed peak viremia on GD90, 30
days after the second ZIKV inoculation (Fig. 4 B, Right). In addition, viremia was significantly lower and of shorter duration in antibody-treated dams (Fig. 4 B–F). Fetal death (i.e., no heartbeat on ultrasound) was detected in two control animals (C03 and C07) on GD35 and GD60 (i.e., 5 and 30 d after the first ZIKV inoculation), with detectable viral RNA in placental and fetal tissues (21). Fetal death was observed on GD51 in one of the antibody-treated macaques (AB02). This occurred 1 wk after undergoing routine amniocentesis and was coincident with a sudden spike of maternal viremia (>10⁵ RNA copies/mL; Fig. 4B) and ZIKV in the amniotic fluid (10⁵ RNA copies/mL) and placental-amniotic tissues (>10⁴ RNA copies/g tissue). In the antibody-treated pregnant dams, mutations in the EDIII region of the emerging viruses were similar to the previously observed mutations that did not alter sensitivity to the antibodies in combination and therefore are unlikely to represent escape (Fig. 3 and SI Appendix, Fig. S4). We conclude that the Z004GRLR/LS + Z021GRLR/LS combination prevents or significantly reduces maternal viral loads during pregnancy.

Amniocentesis was performed regularly to monitor potential ZIKV transmission to the placental-fetal compartment. Six control animals (50%) had detectable ZIKV RNA in at least one amniotic fluid sample. In contrast, except for antibody-treated animal AB02 at time of fetal death, none of the other antibody-treated animals had detectable vRNA in amniotic fluid samples (SI Appendix, Fig. S5). Since vertical transmission of ZIKV can cause congenital Zika syndrome (CZS), we examined the fetuses in the pregnancies that reached term. Fetal body, placenta, brain, and other fetal organ weights were indistinguishable between controls and treatment groups (SI Appendix, Fig. S6). In 9 of the
10 control untreated fetuses that made it to the end of gestation, ZIKV RNA was detected in at least 1 of the 17 examined tissues. These include the maternal–fetal interface (MFI), lymphoid, cardiopulmonary, urinary, gastrointestinal, and central nervous systems, and the skin (average of 6 ZIKV RNA positive tissues per fetus; Fig. 5 A). In contrast, viral RNA was undetectable in the same fetal tissues from the seven antibody-treated animals that reached end of gestation (Fig. 5 A). Moreover, fetuses that received antibodies had less brain pathology overall, as only 1 out of 7 fetuses (14%) had a brain pathology score of moderate (score of 3) or above, in contrast to 4/10 (40%) of the control fetuses (ref. 21, Fig. 5 B, and SI Appendix, Fig. S7 and Table S3). Though its dam had no detectable viremia, it is possible that the moderate brain pathology score in one antibody-treated fetus (AB08-F) reflects earlier infection that was cleared by the time the fetus was harvested. Pathology scores of placenta and amnion were not significantly different between groups (SI Appendix, Fig. S7 and Table S3). Finally, there was no correlation between maternal viremia and pathology scores; while aviremic animal AB05 had normal fetus and placenta, macaque AB07 was also aviremic but its fetus and placenta showed mild to moderate pathology scores, respectively; in contrast, the fetus of animal AB06, which had higher than 10^4 RNA copies/mL at peak maternal viremia, had normal brain findings but moderate placental pathology (Fig. 5 B and SI Appendix, Fig. S7). We conclude that maternal administration of Z004GRGR/LS + Z021GRLR/LS limits vertical transmission and fetal brain damage by ZIKV.

Discussion

Recombinant antibodies represent an alternative to vaccines for at-risk populations. Passive immunization reduces or prevents ZIKV infection in nonpregnant rodents and macaques (23, 25, 26, 31, 32). In addition, antibodies diminish ZIKV viral burden in the placenta and fetal organs, and also reduce fetal demise in mouse pregnancy models (33–35). Some of these ZIKV mouse pregnancy models reproduce features of the human disease, including brain
pathology (4–6). However, mice are not natural hosts for ZIKV, and the development of pathology typically requires an impaired immune system. As opposed to immunocompetent rodents, macaques can be infected readily with ZIKV and their pregnancies are anatomically and physiologically far more similar to humans (36). Whether antibodies can prevent fetal disease in macaques had not been determined. Our experiments show that the combination of two ZIKV neutralizing human monoclonal antibodies is sufficient to thwart or significantly reduce maternal viremia, prevent virus accumulation in fetal tissues, and reduce fetal pathology following repeated ZIKV challenge in macaques. The results have many similarities, but also some differences, with results obtained using the ZIKV DNA vaccine VRC5283 that was tested in the same animal model of congenital ZIKV disease (21). VRC5283 is a DNA vaccine that produces subviral particles with premembrane, membrane, and envelope proteins, is immunogenic in a phase 1 clinical trial, and is currently being evaluated in a phase 2/2b (17, 37, 38). In the macaque pregnancy experiment with similar design to the present study, two doses of vaccine prior to ZIKV inoculation significantly reduced maternal viremia when animals were challenged between 4 d to 1 y after the second immunization (21). Viremia was undetectable in 5 of 13 animals (38%), a rate of protection comparable to the current antibody treatment study (37.5%; n = 8). In addition, in the ZIKV DNA vaccine study, the presence or absence of detectable viremia in vaccinated dams correlated with the titer of neutralizing antibody responses at the time of the first ZIKV challenge (i.e., animals with antibody titers above a threshold had no detectable viremia). For vaccinated animals with detectable viremia, the reduced viremia was always early (peak viremia ≤5 d after ZIKV inoculation), and short in duration (≤14 d after the first ZIKV challenge), consistent with the observed rapid augmentation of antiviral antibody and T cell-mediated immune responses in vaccinated animals after challenge (21).
In the passive immunization studies with Z004 and Z021, antibodies failed to prevent viremia when nonpregnant macaques were inoculated i.v. with a high dose of virus (10^5 PFU; ref. 23). In contrast, we achieved an overall 40% protection from detectable viremia in 20 animals infected with a more moderate dose of 10^3 PFU of ZIKV administered s.c. (5 protected out of 12 nonpregnant macaques and 3 protected out of 8 pregnant dams). This dose is still higher than the typical dose received from a mosquito bite, which in laboratory experiments was ~30 PFU for both the ZIKV isolates used in this study (39). This protection was observed irrespective of Fc domain mutations that modify Fc receptor binding. Neutralizing antibody levels on day of challenge were similar between antibody-treated animals with or without detectable viremia and were ≥3 logs higher than the in vitro inhibitory concentration. However, animals showing low levels and even no ZIKV in plasma had detectable viral RNA in tissues. This indicates that in some animals the virus was able to spread despite high levels of the neutralizing antibodies in serum. These results contrast with earlier reports of sterilizing protection by antibodies under similar virus challenge conditions (s.c. inoculation with 10^3 PFU). However, sampling was less frequent and over a shorter time period in those studies and therefore transient or delayed viremia may have gone undetected (25, 26). The delay in viremia in the current study, despite high levels of the two neutralizing antibodies in circulation, suggests that following moderate- to high-dose ZIKV inoculation, virus can still reach tissues and initiate replication, either because in some tissues antibodies did not penetrate sufficiently, or because certain cell types became infected via mechanisms (e.g., via different cell receptors) that are insufficiently captured in the standard in vitro neutralization assays. The delayed peak viremia (7 to 60 d post-inoculation) in the pregnant dams likely reflects burst of virus replication in such reservoirs, which then triggered the development of active immune responses. The observation of early fetal losses in two control fetuses and one antibody-treated dam, with high levels of virus in fetal or placental tissues, and rapid disappearance of plasma viremia following fetectomy, indicates the fetal-placental compartmen as a possible reservoir that is shielded from antiviral immune responses. The observation of delayed viremia also in antibody-treated nonpregnant macaques suggests the existence of additional reservoirs, of which the identification will improve our knowledge of ZIKV pathogenesis and our ability to develop intervention strategies.

For the unimmunized control pregnancy arm, we previously reported a positive association between fetal pathology scores and prolonged maternal viremia (21). In contrast, overall pathology scores were reduced compared to the control arm, some fetuses in the active or passive immunization arms had demonstrable fetal or placental pathology despite having no detectable viral RNA in tissues or circulation. While small group sizes are an inherent limiting factor, several other factors may contribute to this finding. As mentioned earlier, the absence of viral RNA at time of killing does not exclude the possibility of earlier ZIKV replication followed by viral clearance. In addition, independent of ZIKV, the frequent amniocentesis procedures may also be a confounding factor that can directly affect amnioplacental pathology scores and ultimately fetal brain development (reviewed in ref. 40). Finally, although representative specimens were sampled to our best ability, pathological lesions and viral RNA may be localized temporally and spatially, rather than evenly distributed.

Despite these study limitations, and despite differences in the kinetics of viremia, early versus delayed viremia in vaccinated versus antibody-treated pregnant dams, the reduced maternal viremia and associated improved fetal outcomes were similar in the two studies (21). Thus, the VRC5283 vaccine and the Z004GRLR/LS + Z021GRLR/LS antibodies are comparably efficacious vis-à-vis fetal protection, with each strategy having their intrinsic advantages and limitations in terms of speed of induction, potential for enhancement, and durability of protective immunity. Dengue is a flavivirus closely related to ZIKV. Dengue virus reinfection can lead to antibody-enhanced disease by a mechanism that is associated with serologic cross-reactivity between different dengue serotypes and prior dengue infection has been associated with increased risk of Zika microcephaly (41–44). Antibodies to dengue also cross-react with ZIKV and experiments in mice and with human placental explants have shown that ZIKV infection can be enhanced by antibodies in these systems (45–48). Conversely, antibodies to ZIKV that are maternally acquired cause more severe disease in mice infected with dengue (49). Finally, features of the antibodies that increase ZIKV infection in in vitro ADE assays correlate with an
enhanced risk of Zika microcephaly in humans and brain pathology in macaque (22). Thus, the potential for enhancement is a safety concern for ZIKV vaccine development that clinical trials need to address. Since monoclonal antibodies that are Fc modified to prevent ADE can shield against ZIKV infection and fetal damage, they represent a potentially safe and efficacious alternative intervention strategy in the face of a ZIKV outbreak.

Materials and Methods

Cell Lines. Human embryonic kidney (HEK) 293-6E cells were cultured at 37 °C in 8% CO2, shaking at 120 rpm. The other cell lines were cultured at 37 °C in 5% CO2, without shaking: human hepatocyte (Huh)-7.5 cells were grown in Dulbecco’s modified Eagle medium (DMEM) supplemented with 1% non-essential amino acids (NEAAs) and 5% fetal bovine serum (FBS); human Lenti-X 293T cells were grown in DMEM supplemented with 10% FBS.

Antibodies. The human IgG1 antibodies Z004 and Z001 and their Fc variants (GRLR and GRLR/LS) were previously described (23, 30). Z004GRL and Z021GRL were prepared by transient transfection of mammalian HEK 293-6E cells in the presence of PolyJet (PBS). Z004GRLR/LS (TDI-Y-001) and Z021GRLR/LS (TDI-Y-002) were produced by WuXi Biologics and provided by the Tri-Institutional Therapeutics Discovery Institute (TDI). In TDI-Y-002, the 2021 heavy chain variable sequence was modified (C30V).

Macaque Infection Experiments.

Animals and care. All rhesus macaques (Macaca mulatta) in the study were of Indian origin and were born and raised in the conventional (i.e., not specific pathogen free) breeding colony at the California National Primate Research Center (CNPRC) (SI Appendix, Table 54). None of the animals was positive for type D retrovirus, simian immunodeficiency virus (SIV), or simian lymphocyte tropic virus type 1, two animals in the pregnancy control group (CO2 and CO7) were seropositive for West Nile virus due to prior outdoor housing. All animals had additional time points of sedation for blood collection and IV antibiotic administration 1 d before each ZIKV inoculation. EDTA anti-coagulated blood was collected using venipuncture at every time point for complete blood counts (with differential count), and a separate aliquot of blood was centrifuged for serum at 1000  g to be used for virus isolation and prior pregnancy samples.

After collection of amniotic fluid and cord blood, the fetus was killed with an overdose of sodium pentobarbital (120 mg/kg). Fetal and organ weights were measured with a scale, and crown–rump length, biparietal diameter, head height, head length, and femur length, were derived from caliper measurements. A detailed tissue dissection was performed. Except for some animals that had early fetal loss and were maintained several weeks after removal of the fetus, all other mothers were killed shortly after their fetus with an overdose of sodium pentobarbital for tissue collection. Each tissue was grossly evaluated in situ, and then excised, with further dissection with separate forceps and razor blades for each tissue to minimize risks for cross-contamination. Tissues were collected for viral analyses in RNAlater (according to manufacturer’s instructions); extra available samples were snap frozen and stored at −70 °C. Tissues were also preserved in 10% neutral-buffered formalin and routinely paraffin embedded, and slides were created and routinely stained with hematoxylin and eosin (H&E).

Isolation and quantification of viral RNA from fluids and tissues for determination of infection status. ZIKV RNA was isolated from samples and measured in triplicate by qRT-PCR according to methods described previously (27). The carrier temperature was modified to increase the initial volume of sample tested from 140 to 300 μL to further remove cells, and aliquots were immediately frozen at −80 °C.

Ultrasound-guided amniocentesis was conducted starting at day 14 after inoculation (GD44), and at all tissue points listed above with exception of days 32 and 62 after initial infection. The amniocentesis was conducted using sterile techniques by inserting a 22-gauge, 1.5-inch spinal needle into the amniotic sac. The fetal heart rate was obtained before and after amniocentesis. The area of umbilical entry through the amniotic sac was always avoided to prevent damage to the umbilical arteries and vein. Whenever possible, placental tissue was avoided during the collection of amniotic fluid. Amniotic fluid was spun to remove cellular debris, and the supernatant was aliquoted and immediately cryopreserved at −80 °C for viral RNA assays.

Necropsy and tissue collection. All necropsies were performed by a board-certified veterinary pathologist. At pathology dissection, tissues were collected, and the amnion was incised from the amniotic fluid with an incision 1.5 mm from the amnion that had early fetal loss, the procedures described below were performed to the best extent possible based on fetal size. Hysterotomy was performed by a veterinary surgeon on the pregnant macaques under inhalation anesthesia. After collection of amniotic fluid and cord blood, the fetus was killed with an overdose of sodium pentobarbital (≥120 mg/kg). Fetal and organ weights were measured with a scale, and crown–rump length, biparietal diameter, head height, head length, and femur length, were derived from caliper measurements. A detailed tissue dissection was performed. Except for some animals that had early fetal loss and were maintained several weeks after removal of the fetus, all other mothers were killed shortly after their fetus with an overdose of sodium pentobarbital for tissue collection. Each tissue was grossly evaluated in situ, and then excised, with further dissection with separate forceps and razor blades for each tissue to minimize risks for cross-contamination. Tissues were collected for viral analyses in RNAlater (according to manufacturer’s instructions); extra available samples were snap frozen and stored at −70 °C. Tissues were also preserved in 10% neutral-buffered formalin and routinely paraffin embedded, and slides were created and routinely stained with hematoxylin and eosin (H&E).

Isolation and quantification of viral RNA from fluids and tissues for determination of infection status. ZIKV RNA was isolated from samples and measured in triplicate by qRT-PCR according to methods described previously (27). The carrier temperature was modified to increase the initial volume of sample tested from 140 to 300 μL to further remove cells, and aliquots were immediately frozen at −80 °C.
per milliliter of fluid. RNA later preserved tissues were homogenized to a liquid state with glass beads (Fisher Scientific) or a 5-mm steel ball (Qiagen). For tissues, the limit of detection (LOD) varied depending on the weight of tissue sampled with a mean of 3.5 log_{10} RNA copies/g of tissue, determined according to the calculations described in ref. 50.

For maternal plasma, amniotic fluid, fetal cord blood, and fetal cerebrospinal fluid, all samples from both control and vaccine groups that could be collected were tested. For the maternal tissue samples, as maternal infection was not the main focus of this study, a limited selection of lymphoid tissues most likely to contain viral RNA based on prior study was tested (11, 27), with addition of uterus due to proximity to the placenta and fetus. For the analysis of fetal tissue samples for viral RNA, we started our analysis with the control fetuses and tested 26 fetal and MFI tissues, consisting of tissues most likely to contain viral RNA based on our prior study (11). Next we generated a heatmap and selected a list of 17 tissues consisting of those most likely to be infected and diagnosed with CZS in the control fetuses, with addition of brain regions most likely to have histological lesions in the current study (such as hippocampus), or found to be infected in human fetuses affected by CZS (51).

The criteria to define infection were used systematically for both control and antibody-treated group fetuses: a fetus was considered ZIKV infected if at least one tissue had a consistent qRT-PCR signal (3/3 replicates positive for viral RNA); this situation applied to 11 of the 12 control fetuses. In a rare case, when a fetus had a sample with inconsistent qRT-PCR signal (1 out of 3 replicates positive) while all other tissues were negative, retesting was performed, generally on a different aliquot. If the retest result was negative (3/3 replicates), the sample was considered not to contain detectable ZIKV RNA; if this occurred for all tissues from a fetus, the fetus was considered not infected. One control fetus (CD7-F) and one antibody-group fetus (AB05-F) met these criteria and were therefore considered uninfected.

Histopathology. Sections of fixed and embedded fetal tissues were stained with H&E and evaluated by a board-certified anatomic pathologist. Scoring of critical fetal tissues was done according to criteria outlined in SI Appendix, Table S3.

Virus Sequencing. For the detection of virus mutations at the EDIII region, ZIKV RNA was extracted at peak plasma viremia and QIagen One-Step RT-PCR was performed using either of two primer sets targeting sequences surrounding the ZIKV EDIII region, as previously detailed (23). Due to low levels of viremia in some samples, reliable EDIII sequence information was not always obtained in samples with amounts below 10^3 RNA copies/ml plasma. Mutations reported are based on changes in the majority nucleotide in sequencing chromatograms; concordant sequences in both directions were used to identify mutations.

Reporter Virus Particles. Luciferase encoding RVPs bearing the wild-type or mutant ZIKV E proteins of interest were produced by cotransfection of LentiX-293T cells with plasmid pWNVII-Rep-REN-1B (WNV replicon expression construct; ref. 52) in combination with plasmids expressing flavivirus CprME (1 μg of pWNVII-Rep-REN-1B and 3 μg of the CprME plasmid) as previously detailed (30). The plasmids for expression of wild-type ZIKV CprME with E protein sequence corresponding to Puerto Rican ZIKV (strain PRVABC59) that was used in this study was generated from plasmid pZIKV/HFF/PcprME*E* (30) by replacing a BspHI/SacII fragment with sequences corresponding to the PRVABC59 strain that were generated by PCR using oligos RU-O-24379 and RU-O-24380 and PRVABC59-derived cDNA as template. The resulting sequence was designated pZIKV/HFF/PcprME*PRVABC59E*. Assembly PCR-based site-directed mutagenesis was then used to introduce in pZIKV/HFF/PcprME*PRVABC59E* the V330L, T309A, V330L/T309A, and V330L/T309I mutations that resulted in plasmids pZIKV/HFF/PcprME*PRVABC59E* (330L), pZIKV/HFF/PcprME*PRVABC59E* (330L/309A), pZIKV/HFF/PcprME*PRVABC59E* (V330L/T309A), and pZIKV/HFF/PcprME*PRVABC59E* (V330L/T309I). Similarly, the ZIKV RVPs encoding for the T335 mutations (SI Appendix, Fig. S2) were generated by modifying plasmid pZIKV/HFF/CprME*E* (30) to introduce the T335A and T335I modifications resulting in pZIKV/HFF/CprME*E*T335A and pZIKV/HFF/CprME*E*T335I, respectively. The primers used for assembly PCR and mutagenesis are listed in SI Appendix, Table S5. All PCR-derived plasmid regions were verified by sequencing.

In Vitro Neutralization Assay. RVP neutralization of luciferase-encoding RVPs by antibodies was performed with HuH-7 S cells in 96-well plates, in triplicate, as previously detailed (30), and the luciferase activity was read using a FLUOstar Omega luminometer (BMG LabTech). The neutralization capability of the antibodies against wild-type or mutant RVPs was determined by the percentage of luciferase activity obtained relative to RVPs incubated with isotype control antibody 10-1074 (53). Representatives of at least two independent experiments are shown.

Measurements of Human IgG in Macaque Plasma. ELISA was used for the detection of human IgG as previously detailed (30). Briefly, the biotinylated anti-human IgG capture antibody was added to neutralin-coated 96-well plates. Upon washes, the plates were blocked with 2% bovine serum albumin (BSA), blotted, and then serial dilutions of the macaque plasma were added to the wells (5 steps of 1:4 dilutions in PBS-T, starting with 1:10). Each plate included serial dilutions of the standard, in duplicates (2004 IgG, 11 steps of 1:3 dilutions in PBS-T, starting with 10 μg/mL). Plates were incubated for 1 h at room temperature and washed prior to adding the detection agent anti-human IgG-horseradish peroxidase (HRP). After washes, the reaction was developed with 2,2'-azino-bis-(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) substrate (Life Technologies).

Measurements of Human IgG in Mouse Serum. ELISA was used for the detection of human IgG as previously detailed (30). Briefly, FcNhFcR-humanized mice were injected i.v. with 100 μg of 2004 or 2021 Fc variants. High-binding 96-well plates were coated overnight (Nunc) with antibodies for 1 h. All sequential steps were performed at room temperature. Plates were blocked for 1 h with PBS/2% BSA and incubated with biotinylated goat anti-human IgG antibodies for 1 h (5 μg/mL; catalog 109-066-170, Jackson Immunoresearch). Serum samples were serially diluted and incubated for 1 h, followed by incubation with HRP-conjugated anti-human IgG. After washes, the reaction was developed with the 3,3',5,5'-tetramethyl benzidine (TMB) peroxidase substrate system (KPL) and stopped with 2 M phosphoric acid. Absorbance at 450 nm was immediately recorded using a SpectraMax Plus spectrophotometer ( Molecular Devices), background absorbance from negative control samples was subtracted, and duplicate wells were averaged.

Statistical Analyses. Statistical analyses were performed with Prism 8 (GraphPad).

Data Availability. All data are available in SI Appendix.

ACKNOWLEDGMENTS. We thank Kai-Hui Yao and Daniel Yost at Rockefeller University, as well as A. Gibbons, M. Allen, V. Bakula, M. Christensen, L. Crabtree, H. Von Mory, J. Wang, I. B. Wang, and other veterinary staff, and the staffs of Colony Management and Research Services and the Clinical Laboratory at the California National Primate Center for expert assistance. We also thank Mohsan Saeed (Boston University) for construction of plasmid pZIKV/HFF/PcprME*PRVABC9E. This work was supported by awards from NIH, U19AI11825, P01AI13893, and ULTR001866 (to D.F.R.), R01AI037526, U1MA1100663, U19AI111825, P01AI138938, and ULTR001866 (to M.C.N.); funding from Lyda Hill Philanthropies (to M.C.N.); grants R01AI124690 and U19A057229 (CCHI pilot project); The Rockefeller University Development Office, and anonymous donors (to C.M.R. and M.R.M.); the Office of Research Infrastructure Programs/OD (grant P51OD011107); start-up funds from the Pathology, Microbiology, and Immunology Department (to L.C.C.); and grant R21AI129479-S (to K.K.A.V.R.). Support was also provided by the Robertson Therapeutic Development Fund (to D.F.R. and M.C.N.) and a scholarship from the Studienstiftung des Deutschen Volkes (to T.K.). S.R.E. is supported by NIH National Research Service Award Fellowship F30AI147579 and NIH National Institute of General Medical Sciences Training grant T32-GM008004 through the University of California, Los Angeles-Caltech Medical Technical Training Program. M.C.N. is a Howard Hughes Medical Institute Investigator.
