26 **ABSTRACT**

27 Ground deformation, commonly observed in storage projects, carries useful information about
28 processes occurring in the injection formation. The Krechba gas field at In Salah (Algeria) is one
29 of the best-known sites for studying ground surface deformation during geological carbon
30 storage. At this first industrial-scale on-shore CO₂ demonstration project, satellite-based ground-
31 deformation monitoring data of high quality are available and used to study the large-scale
32 hydrological and geomechanical response of the system to injection. In this work, we carry out

coupled fluid flow and geomechanical simulations to understand the uplift at three different CO₂ injection wells (KB-501, KB-502, KB-503). Previous numerical studies focused on the KB-502 injection well, where a double-lobe uplift pattern has been observed in the ground-deformation data. The observed uplift patterns at KB-501 and KB-503 have single-lobe patterns, but they can also indicate a deep fracture zone mechanical response to the injection. The current study improves the previous modeling approach by introducing an injection reservoir and a fracture zone, both responding to a Mohr-Coulomb failure criterion. In addition, we model a stress-dependent permeability and bulk modulus, according to a dual continuum model. Mechanical and hydraulic properties are determined through inverse modeling by matching the simulated spatial and temporal evolution of uplift to InSAR observations as well as by matching simulated and measured pressures. The numerical simulations are in agreement with both spatial and temporal observations. The estimated values for the parameterized mechanical and hydraulic properties are in good agreement with previous numerical results. In addition, the formal joint inversion of hydrogeological and geomechanical data provides measures of the estimation uncertainty.

Keywords: Geomechanics, CO₂ sequestration, inverse modeling, coupled modeling, TOUGH-FLAC, iTOUGH-PEST

1. INTRODUCTION

Large-scale deep underground CO₂ injection represents a viable option for reducing carbon emissions to the atmosphere (Pacala and Socolow, 2004). The feasibility of geological carbon sequestration is, however, questioned by the potential for inducing seismicity and altering the sealing capacity of a storage site (Zoback and Gorelik, 2012), despite the fact that large events in sedimentary formations are unlikely (Vilarrasa and Carrera, 2015). Notwithstanding the potential for large events, microseismic events may still occur as observed at several CO₂ projects (e.g. at

57Weyburn in Canada, Decatur in USA, Lacq-Rousse in France), most of them with negative
58magnitude (Verdon and Stork, 2016).

59The presence of microseismicity indicates that rock stress and strain vary in response to carbon
60dioxide injection; a coupled fluid flow and geomechanics model may provide understanding of
61the various processes occurring at depth (Rutqvist, 2012). Recently, several efforts aimed at
62developing reliable codes for the study of coupled processes occurring during deep carbon
63injection (e.g. Rutqvist et al., 2002; Vilarrasa et al., 2010; Rutqvist, 2011; Bissell et al., 2011;
64Kolditz et al., 2012; Jha and Juanes, 2014). Sufficiently accurate characterization of a carbon
65storage site requires the integration of a large amount of data into a predictive model. An inverse
66modeling approach is needed to assess the relevance of parameters for reproducing the available
67data, determining the error of the estimated parameters and how this uncertainty is propagated to
68model predictions.

69In this study, we demonstrate the use of the coupled fluid flow and geomechanics inverse
70modeling approach by applying it to data from the In Salah CO₂ demonstration site.

71The In Salah CO₂ Storage Project in Algeria was in operation between 2004 and 2011 and was
72the first on-shore, industrial-scale demonstration site for CO₂ sequestration. Via three injection
73wells (KB-501, KB-502, KB-503), about 4 million tons of carbon dioxide were injected into a 20
74m thick, water-filled reservoir at a depth of about 2000 m. The three wells were drilled
75horizontally with a length between 1 and 1.5 km. A large caprock overburden with a thickness of
76about 900 m prevented the CO₂ from escaping to shallow depths (Ringrose et al., 2013).

77The In Salah demonstration site is also well known for the comprehensive characterization and
78monitoring effort, including wellhead sampling, down-hole logging, core analysis, surface gas
79and groundwater aquifer monitoring, tracers, 4D seismic, and satellite InSAR data (Mathieson et

80al., 2011). Such InSAR data provide essential information for the development of a reliable
81model through the inverse analysis of coupled fluid flow and geomechanics.
82In the first part of this study, we analyze the evolution of deformation and pressure at the KB-502
83injection well, where a double-lobe uplift feature has been observed by analysis of satellite data.
84Such a feature has been explained by both semi-analytical and numerical modeling as the
85opening of a deep fracture (Vasco et al., 2010; Rutqvist et al., 2011; Rinaldi and Rutqvist, 2013).
86Analysis of 3D seismic images also confirmed the presence of such a linear feature at reservoir
87depth (Gibson-Poole and Raikes, 2010; Wright, 2011). Recent numerical studies by Rinaldi and
88Rutqvist (2013) showed in more detail that this linear feature (modeled as a fracture zone near
89KB-502) is confined within the caprock, unlikely to have resulted in CO₂ leakage into the
90overlying aquifer. Assuming a fracture zone of limited height, previous studies were able to
91match most available field observations, including the transient evolution of uplift and pressure,
92as well as the shape of surface deformations. However, such previous studies did not address the
93error associated with parameter estimation, and no sensitivity analysis was performed to properly
94assess the relation between these uncertain parameters and predicted state variables.
95In the second part of this paper we perform inverse modeling of the injection and related ground
96surface uplift at injection wells KB-501 and KB-503. The earliest numerical simulations of KB-
97501 and KB-503 by Rutqvist et al., (2010), showed a good agreement between observations and
98simulations in terms of maximum surface uplift, without considering the extension of the fracture
99within the sealing formation. Recently Rucci et al. (2013), using more comprehensive surface
100deformation data including vertical and horizontal displacement components, showed that an
101extensional opening might have occurred within the caprock at injection wells KB-501 and KB-
102503, similarly to KB-502. Here we present inverse modeling results assuming both intact and
103partially fractured caprocks.
104Starting from the results achieved by Rinaldi and Rutqvist (2013) on KB-502, we first improve
105the forward model with TOUGH-FLAC (Rutqvist, 2011) by accounting for a reactivation

106 criterion for the fracture zone and the injection reservoir. We also account for the changes in
 107 permeability associated with the stress evolution. Afterwards, we use our model within an
 108 inverse modeling framework of iTOUGH2-PEST (Finsterle and Zhang, 2011), which includes
 109 parameter estimation, sensitivity and uncertainty analyses and apply it to all three injection wells
 110 On one hand, the TOUGH-FLAC simulator (Rutqvist, 2011) couples the TOUGH2 simulator for
 111 fluid flow in porous media (Pruess et al., 2011) with the FLAC3D simulator for geomechanics
 112 and deformation (Itasca, 2009). The applications of TOUGH-FLAC cover geothermal (e.g.,
 113 Jeanne et al., 2015; Rinaldi et al., 2015a), nuclear waste disposal (e.g., Rutqvist et al., 2014),
 114 compressed air storage systems (Rutqvist et al., 2012), shale gas (Rutqvist et al., 2013; 2015), as
 115 well as geologic carbon sequestration (Rutqvist et al., 2008; 2010) and related induced seismicity
 116 (Cappa and Rutqvist, 2011; Rinaldi et al., 2014a, 2014b, 2015b; Rutqvist et al., 2014, 2016; Urpi
 117 et al., 2016). On the other hand, iTOUGH2 (Finsterle, 2004; 2007; Finsterle et al., 2014) has
 118 been largely used for sensitivity analysis and parameter estimation for several hydrogeological
 119 application (e.g., Doetsch et al., 2013; Finsterle et al., 2013; Poskas et al., 2014; Wainwright et
 120 al., 2013; Yuan et al., 2015). Thanks to the PEST protocol (Doherty, 1994), the use of the inverse
 121 capabilities of iTOUGH2 can be extended to any numerical forward model; here, we apply for
 122 the first time the code iTOUGH2-PEST (Finsterle and Zhang, 2011) to a coupled fluid flow and
 123 geomechanics application.

124 **2. FIELD DATA AND MODELING APPROACH**

125 **2.1 Data from the In Salah CO₂ storage site**

126 Several data sets were collected at In Salah before and during injection. The principal stress
 127 orientation as well as the velocity model was obtained from seismic surveys and well log
 128 analyses, while *in-situ* leak-off tests provided the minimum stress magnitude (Gibson-Poole and

129Raikes, 2010; Iding and Ringrose, 2010; Wright, 2011; Gemmer et al., 2012; Shi et al., 2012;
 130White et al., 2014).

131Although these analyses are extremely useful to set model properties, the transient evolution of
 132uplift as well as injection rates and well pressures play a crucial role in developing a well-
 133constrained coupled fluid flow and geomechanical model. Fig. 1a shows an InSAR image
 134(MDA/Pinnacle Technologies, Wright, 2011) of the rate of satellite-to-ground distance change
 135between November 2003 and March 2010. The CO₂ injection caused a ground surface uplift up
 136to 20 mm after about 6 years of injection activity. The transient evolution of ground-surface
 137displacement along the satellite's Line of Sight (LOS) for the three injection wells is shown in
 138Fig. 1b, for a point located near the maximum uplift. We observe an almost linear increase in
 139uplift for injection wells KB-501 (orange line) and KB-503 (cyan line), reaching about 20 mm
 140and 15 mm in 2010, respectively. The transient evolution at KB-502 (red line) shows that the
 141uplift undergoes a strong increase after the first few months of injection (up to about 15 mm in 1
 142year), followed by a slower subsidence rate after shut in in mid-2007. Such transient evolution
 143(Fig. 1b) is used as observation for the inverse modeling, accounting for a standard deviation of 2
 144mm (Donald Vasco, LBNL, personal communication).

145A detailed view of the uplift at the three wells after about 2 years of injection (December 23,
 1462006) is shown in Figs. 1c-e. A bell-shaped, slightly elongated pattern of deformation arises for
 147KB-501 and KB-503 (Fig. 1c and 1e, respectively), and (as mentioned above), some authors
 148suggest that this deformation may result from a fracture zone opening at depth (Rucci et al.,
 1492013). In both cases, LOS displacement reaches about 8 mm of deformation at 500 m SE of the
 150injection well and is about 4 mm and 2 mm along a profile 1700 m SE of the injection well for
 151KB-501 and KB-503, respectively (Fig. 1f and 1h). Fig. 1d shows the above-mentioned double-
 152lobe feature that was observed at KB-502. This pattern of deformation has been interpreted as
 153arising from a vertical feature opening at depth of injection (Vasco et al., 2010; Rutqvist et al.,

1542011), a feature that was confirmed by 3D seismic images (Gibson-Poole and Raikes, 2010) and
 155corroborated by detailed numerical studies (Rinaldi and Rutqvist, 2013). The double-lobe uplift
 156is also clear in Fig. 1g, which shows the uplift along two profiles. The ground surface reached
 157about 16 mm and 12 mm displacement at 500 m and 1700 m NW of the injection well,
 158respectively. The displacement along these arbitrary profiles (Fig. 1f-h) is used as observational
 159data control for the inverse modeling, and compared to the results of numerical simulations. Also
 160in this case we account for 2 mm standard deviation (Donald Vasco, LBNL, personal
 161communication).
 162The In Salah storage site was not only characterized by InSAR monitoring. Indeed, wellhead
 163pressure and injection rate were continuously monitored. Fig. 2 shows the injection rate (red line)
 164and the wellhead pressure (black line) monitored at the three wells. The bottomhole pressure
 165(blue line) was calculated from wellhead pressure by using the code T2Well (Pan et al., 2011).
 166In this study we focus on the injection until August 2008. Fig. 2 shows how CO₂ was
 167continuously injected at KB-501 and KB-503. For KB-502 the injection was suspended in mid-
 1682007 after CO₂ was discovered at the wellhead of a nearby old appraisal well (Mathieson et al.,
 1692011); injection was restarted in mid-2009. The injection was definitively suspended in June
 1702011 due to concerns about the integrity of the sealing caprock (Ringrose et al., 2013). The
 171injection rates (red line in Fig. 2) are used as input for the model, and the calculated bottomhole
 172pressure (blue line) is used as further observation, to be compared with the numerical results.
 173Regarding the error associated with the bottomhole pressure, we consider a 2 MPa standard
 174deviation, which was calculated using a best fit (cubic relationship) of T2well results accounting
 175for injection rates and wellhead pressure measurements

176 **2.2 Coupled fluid flow and geomechanical forward modeling setup**

177Forward simulations were carried out with the simulator TOUGH-FLAC (Rutqvist, 2011), which
 178solves hydromechanical problems by sequentially linking the multiphase and multicomponent

and heat-transport simulator TOUGH2 (Pruess et al., 2011) with the geomechanical simulator
 FLAC3D (Itasca, 2009). The sequential approach between the simulators involves data exchange
 and calculation of parameter variation accounting for THM model. Data from TOUGH2 (namely
 pressure, temperature, and phase saturation) are passed to FLAC3D for calculation of effective
 stress and strain variation. Then, data from FLAC3D can be used to compute hydromechanical
 parameters variation through empirical model (e.g. Rinaldi et al., 2014). Changes in
 hydromechanical parameters will affect in turn the pressure and stress solution. A detailed
 formulation can be found elsewhere (Rutqvist, 2011).
 The modeling setup presented here closely follows the one proposed by Rinaldi and Rutqvist
 (2013). Fig. 3 shows the computational domain with x -direction corresponding to the NW-SE
 direction. The hydrogeological model consists of four layers, whose properties are listed in Table
 1. The mechanical model is slightly more detailed, accounting for more layers with the
 hydrogeological caprock section. The mechanical properties, listed in Table 2, closely follow
 estimates from well log analyses (Gemmer et al., 2012).
 Initial temperature and pressure gradients are taken from field investigations. The injection
 reservoir is at an initial temperature of 90 °C with a pore pressure of about 18 MPa. Lateral
 boundaries are at constant condition, while the bottom boundary is set as a no-flow and no-
 vertical displacement boundary.
 The CO₂ injection takes place in a 20 m thick reservoir at a depth of 1820 m. The injection rates
 closely following the values shown in Fig. 2, for the corresponding injection well, which was
 simulated as 1000 m-long.
 The medium is poroelastic, with the exception of the storage reservoir and deep fracture zone,
 both subjected to a failure criterion. The initial stresses also follow field observations, with:
 $\sigma_{xx}=25.1$ MPa/km, $\sigma_{yy}=15.8$ MPa/km, and $\sigma_{zz}=22.2$ MPa/km.
 Following the modeling approach by Rinaldi and Rutqvist (2013), we model, unless otherwise
 specified, the opening of a deep fracture zone at reservoir depth, extending for 350 m upward
 into the lower caprock. The length and position of this linear feature closely follow the findings

206by Rucci et al. (2013). The novelty of the approach presented here consists in the use of a Mohr-
 207Coulomb criterion to determine when such a pre-existing fracture zone reactivates. After
 208reactivation, the tensile opening is simulated by using an orthotropic model.
 209All the hydraulic and mechanical parameters are constant, with the exception of reservoir perme-
 210ability and bulk modulus, which change as a function of mean effective stress.

211 **2.2.1 Stress-dependent reservoir permeability and bulk modulus**

212Compared to the paper by Rinaldi and Rutqvist (2013), the coupled fluid flow and
 213geomechanical formulation is here improved by accounting for the evolution of the reservoir
 214permeability. While the previous work employed a step-wise permeability change, with values in
 215agreement with an analytical solution, here we fully coupled the permeability to the effective
 216stress subjected to a failure condition.
 217 We assume that the injection reservoir is highly fractured and subjected to the Mohr-Coulomb
 218failure criterion for a given friction angle ϕ_{res} , defined by:

$$219 \quad f = \sigma_1 - \frac{1 + \sin \phi_{res}}{1 - \sin \phi_{res}} \sigma_3 \quad (1)$$

220When the principal stresses σ_1 and σ_3 within the injection reservoir satisfy the criterion, the
 221permeability and the bulk modulus vary as a function of the mean effective stress.
 222Several approaches have been proposed to address the relationship between stress and
 223hydromechanical properties, mostly referring to in-situ or laboratory data (Rutqvist, 2015 – and
 224reference therein). Rock permeability is often related to changes in fracture aperture
 225(Whiterspoon et al., 1980), which is generally a function (exponential or inverse relationship) of
 226the normal effective stress (Rutqvist, 2015). Authors have also used such stress-relationships in
 227combination with dilation or slip-tendency approach (e.g. Zhou et al., 2008; Bond et al., 2013).
 228Here we employed coupling equations based on a relationship between fracture aperture and
 229normal effective stress originally derived by Liu and Rutqvist (2013). Assuming the cubic law
 230(Whiterspoon et al., 1980) holds, and referring to the relation between the initial state of stress

and the mean effective stress, a stress-dependent permeability can be derived (Rinaldi et al., 2014c):

$$\frac{\kappa}{\kappa_i} = \left(\frac{b}{b_i} \right)^3 = \left(\frac{\gamma_e + \gamma_t e^{\frac{\sigma'_m}{K_{t,f}}}}{\gamma_e + \gamma_t e^{\frac{\sigma'_{m,i}}{K_{t,f}}}} \right)^3 \quad (2)$$

where b and b_i are the current and initial apertures, and κ_{hm} and κ_i are the permeabilities at the current and initial state of stress, respectively. $K_{t,f}$ refers to the bulk modulus of the reservoir fractures, and σ'_m is the effective mean stress. γ_e and γ_t represent the unstressed volume fraction for the hard and soft parts of the rock mass, respectively. Following Liu and Rutqvist (2013) and assuming a constant bulk modulus for the porous matrix, we have an effective bulk modulus given by:

$$\frac{1}{K_{eff}} = \frac{1}{K_{eff}^i} + \Theta_f \frac{\gamma_t}{K_{t,f}} \left(e^{\frac{\sigma'_m}{K_{t,f}}} - e^{\frac{\sigma'_{m,i}}{K_{t,f}}} \right) \quad (3)$$

where K_{eff} and K_{eff}^i are the current and the initial bulk modulus, respectively, and Θ_f is the volume fraction occupied by fractures, assumed to be 1%.

2433.1 Inverse modeling with iTOUGH-PEST and TOUGH-FLAC

244The program iTOUGH2 is used as parameter estimation and optimization framework for the
 245TOUGH-FLAC coupled fluid flow and geomechanics simulator. The coupling approach
 246between the two codes is illustrated in Fig. 4. A parameter set estimation is performed in a series
 247of iterations. For a single iteration, parameters to be calibrated (such as permeability, coupling
 248parameters, and/or mechanical parameters) are given by iTOUGH2, which calls a PEST protocol
 249to write input files needed for running TOUGH-FLAC. After completion of the forward run, a
 250PEST protocol follows instructions to extract from the forward model output files. Finally the
 251simulated values are analyzed in iTOUGH, which computes residuals with observation and
 252calculates the parameters set for the next iteration.
 253In iTOUGH2, residuals are computed as the difference between the measured and simulated
 254observation (here including pressure and uplift in time and space):

$$255 \quad r_i = \hat{z}_i - z_i \quad (4)$$

256where $\hat{z}_i$ is the i -th measured observation and z_i is the i -th simulated observation. An overall
 257measure of the misfit between the data and the model is given by a so-called objective function,
 258which here is considered as the least-squares function:

$$259 \quad S = \sum_{i=1}^m \frac{r_i^2}{\sigma_{zi}^2} \quad (5)$$

260where σ_{zi}^2 is the variance associated with the i -th observation, and m represents the total number
 261of observations. The best estimated parameter set is the one that minimize such objective
 262function, and the error estimation on the estimated parameters is given by the topology of the
 263objective function around its minimum. In this work we use a Levenberg-Marquardt algorithm to
 264minimize the objective function. Among the iTOUGH2 capabilities, there is also the possibility

to evaluate the sensitivity coefficients showing the impact of a small parameter change on the model results. The main advantage of an inverse modeling approach it is not only limited to the estimation of the unknown parameters, but it can also provide uncertainties on such parameters providing a range of suitable values reproducing the observation. Exploring the uncertainty ranges in estimated parameters constitutes a significant step compared to the previous work (e.g. Rinaldi and Rutqvist, 2013). Moreover the enhanced sensitivity analysis performed during inversion helps choosing the most relevant and critical parameters, giving insights on the processes occurring at depth.

4.3. INVERSE MODELING FOR KB-502 INJECTION WELL

4.3.1 Parameter estimation

In this section we focus on the application of the approach for inverse modeling with iTOUGH2-PEST and TOUGH-FLAC to study the injection and deformation at well KB-502. Inverse modeling is conducted to estimate the values for some of the mechanical and hydraulic properties that minimize the misfit between simulated and observed data. For injection well KB-502, Rinaldi and Rutqvist (2013) were able to reproduce the observed uplift and pressure evolution with reasonable detail. However, the unknown parameters were estimated to obtain a reasonable match, and might not have constituted a unique solution. Here we extend the previous finding with a more accurate parameter estimation, error analysis, and sensitivity of the results to parameter variations. Parameters to be estimated for injection well KB-502 are: (i) friction angle of the injection reservoir, (ii) friction angle of the deep fracture zone, (iii) bulk modulus for stress-dependent permeability (Eq. 2), and (iv-vi) the three Young's moduli in the three directions for the deep fracture zone (E_x , E_y , and E_z), as needed for an orthotropic model. Initial guesses for the parameters can be found in Table 3; they closely follow the values by Rinaldi and Rutqvist

290(2013). The initial permeability of the injection reservoir is not considered an adjustable
 291parameter; it was taken from the previous work.
 292Simulation results are compared with four field observations, as described above: (i) bottom-hole
 293pressure, (ii) transient evolution of the LOS displacement on a single point located above the
 294injection well, and (iii) and (iv) two different profiles located at 500 m and 1700 m, respectively,
 295northwest and parallel to the injection well (Figs. 1 and 2).
 296We use the Levenberg-Marquardt algorithm to minimize the misfit between model results and
 297field data. A reasonably good match was achieved with six iterations.
 298The best estimate for the parameters after inversion can be found in Table 3. All the parameters
 299are estimated with a relative error smaller than 1%, with values consistent with previous
 300numerical results. The weighted least-square objective function is reduced from an initial value
 301of 1189.6 to 99.23, and the maximum weighted residual it reduced from about 45 to 15.
 302Fig. 5 shows the comparison between model results and field observations. We find an excellent
 303match for the bottomhole pressure (Fig. 5a), with the simulated pressure (orange line) consistent
 304with one standard deviation from field observations (2 MPa, gray area). Major differences are
 305found after shut-in, probably related to the fact that the model only accounts for the open section
 306of the well. Fig. 5b and 5c show the comparison between simulated and observed LOS ground
 307surface uplift, along the two profiles. Also in this case we achieve a good match, although we
 308overestimate the uplift in the region far from the double-lobe region. Finally, Fig. 5d shows the
 309resulting transient evolution of the LOS displacement at a single point. The simulated evolution
 310is in excellent agreement with the observed data within one standard deviation (2 mm, gray area).
 311For completeness, we also show the comparison between the simulated and observed pattern of
 312deformation (Fig. 6). Although we do not use the entire map as observation for the inverse
 313analysis, Fig. 6 shows how the simulation is able to reproduce the observed double-lobe uplift.

3143.2 Sensitivity analysis

315The results of a local sensitivity analysis are summarized in Fig. 7, which shows sensitivity
 316coefficients scaled by the expected parameter variation and the measurement error as a function
 317of time. Further information about the scaling of sensitivity coefficients can be found elsewhere
 318(Finsterle, 2015). Fig. 7a shows that the bottomhole pressure is very sensitive to a change in K_t
 319(parameter largely affecting the permeability). The pressure is also affected by mechanical
 320parameters, such as the bulk modulus of the deep fracture zone in vertical direction (E_z). The
 321friction angle of the fracture zone (ϕ_{res}) has a minor effect, visible only at the time of reactivation
 322(around 2006).
 323Fig. 7b and 7c show the sensitivities for the LOS displacement along the two profiles. As
 324expected, the surface uplift highly depends on the Young's moduli of the deep fracture zone in
 325the three different directions. The profiles are inversely correlated to E_z and directly correlated to
 326 E_y , suggesting more opening compared to the uplift of the fracture zone (an increase in the
 327vertical Young's modulus can be partly compensate by a decrease in the horizontal Young's
 328modulus). It is worth noting that the parameter K_t has also some effect on deformation,
 329suggesting that a coupled fluid and geomechanics model is essential to capture all the features of
 330a complex interacting system. Interestingly, the LOS displacement along the profiles is not
 331sensitive to parameter changes in the far field (i.e., 5 km from the injection region along the
 332profile). Finally, Fig. 7d shows the sensitivity analysis for the transient evolution of the LOS
 333displacement. This observation has a sensitivity similar to the one seen for the profiles. However,
 334the transient evolution of the LOS displacement is only slightly sensitive to the chosen
 335parameters before fracture reactivation.

3363.3 Residual analysis

337 The results of the analysis of the misfit between simulations and field observations are shown in
 338 Fig. 8. All the simulated results are in very good agreement with the field observations, with
 339 residuals within the assumed errors for each observation.

340 Fig. 8a shows the misfit for the bottomhole pressure. The misfit between simulation and data is
 341 limited to the range -2 to 2 MPa (i.e. one standard deviation), with only few exceptions after
 342 shut-in. We accounted for such large errors in pressure because the bottomhole pressure is
 343 calculated from wellhead pressures and the injection rate by using the code T2Well. Conceptual
 344 and parametric uncertainties in the wellbore simulator increase the expected residual between
 345 calculated and measured wellhead pressure. For the LOS displacement along the profiles, the
 346 misfit is limited to the range between -2 and 2 mm for most of the observations. Residuals are
 347 small in the double-lobe region (less than 2 mm), and increase in the far field, probably due to
 348 vertical expansion of the underburden, which has a non-zero permeability (10^{-19} m^2) and it might
 349 get pressurized over the 2 years injection (Fig. 8b and 8c). It is also worth noting that our model
 350 does not account for possible hydrogeological heterogeneities that may affect the pressure
 351 distribution in the injection reservoir. The analysis of the residuals for the temporal evolution of
 352 LOS displacement shows that the misfit between simulation and field data is always smaller than
 353 the 2 mm error associated with InSAR measurements (Fig. 8d).

3544. APPLICATION TO INJECTION WELLS KB-501 AND KB-503

3554.1 Inversion cases

356 Simulations at KB-501 and KB-503 are presented here to understand whether a fracture zone,
 357 similar to the one observed at KB-502, might have been reactivated at depth. For both injection
 358 wells we performed three inversions. The first inversion does not account for the presence of a
 359 fracture zone, and follows a simpler formulation with an intact caprock as used in the first In

Salah modeling by Rutqvist et al. (2010). The parameters estimated in this inversion are: (i) initial permeability, (ii) friction angle of the injection reservoir, (iii) bulk modulus for stress-dependent permeability (Eq. 2), and (iv) permeability of the caprock. The second inversion accounts for a reactivating fracture zone, whose dimensions closely follow the results by Rucci et al. (2013). Such a fracture zone can reactivate subject to a Mohr-Coulomb failure criterion, and once reactivated is modeled as an orthotropic elastic material, similarly to KB-502. For this inversion case, the following parameters are estimated: (i) initial permeability and (ii) friction angle of the injection reservoir, (iii) bulk modulus for stress-dependent permeability (Eq. 2), (iv) friction angle of the fracture zone, and (v-vii) the three Young's moduli in the three directions for the deep fracture zone. Finally, the third inversion case accounts for a deep opening that is pre-active at the start of injection operations; therefore, we do not consider the friction angle of the fracture zone as an adjustable parameter for this inversion case.

4.2 Inverse modeling of KB-501 injection well

The results of the inversion for injection well KB-501 for the three cases are summarized in Table 4, while the estimated parameters are listed in Table 4. The three inversion cases result in equally good matches as measured by the objective function (about 500). The maximum weighted residual has a value of about 35 for the inversion without considering a fracture zone, while it increases up to about 100 for both cases with a fracture zone.

The inversions result in an overall agreement between simulated and calculated bottomhole pressure, with residuals within one standard deviation (2 MPa) for all the three cases, and only a few minor differences among them (Fig. 9a). Although the inversions capture the general trend, the numerical results highly overestimate the pressure at early stage, i.e. before the reservoir permeability starts to change following Eqs. 1 and 2. Afterward the pressure decreases, following the general trend observed in the field, although underestimating the observation in the period

between 2007-2008. Figs. 9b and 9c show the resulting LOS displacement along two chosen profiles in comparison with the observed LOS deformation (Fig. 1g). Results suggest that a model without fracture may better reproduce the observations: indeed for the profile at 500 m, only the model with intact caprock is able to simulate the observed trend (Fig. 9b, orange line), while the model with fracture overestimates or underestimates the LOS displacement, for the case of fracturing and pre-fractured caprock, respectively (Fig. 9b purple and green lines). For the profile at 1700 m, the models with pre-fractured and intact caprock are similar (Fig. 9c orange and green lines, respectively), while the case of fracturing caprock results in an overestimated LOS displacement (Fig. 9c purple line). The model with intact caprock also well reproduces the observations throughout the entire simulation (Fig. 9d, orange line), within the associated standard deviation of 2 mm (gray area). The model with a reactivating fracture well represents the first month of injection (Fig. 9d purple line), while the model with pre-active fracture is able to reproduce the observation at late stage (Fig. 9d, green line).

The model with intact caprock seems to better reproduce the observed evolution, according to the results of the numerical inversion. However, the shape of deformation at the surface does not capture the observed pattern of LOS displacement. Indeed, as shown in Fig. 10, only a model with a fracture zone is able to reasonably well represent the observed pattern of deformation (i.e., elongated bell-shaped, Fig. 10c-d). The model with a pre-active fracture zone is also able to reproduce the overall average LOS displacement (i.e., around 9 to 10 mm).

4.2 Inverse modeling of KB-503 injection well

The inversions for KB-503 result in findings similar to what is observed for injection well KB-501. The results for the three cases analyzed are shown in Fig. 11. For this injection well, the pressure is slightly underestimated, especially for the case of the reactivating fracture (Fig. 11a, purple line). The cases of intact caprock and pre-active fracture zone well reproduce the

observation within the associated standard deviation of 2 MPa (Fig. 11a, orange and green lines, respectively). In terms of uplift, the case of an intact caprock well reproduces the maximum observed LOS displacement (Fig. 11b and 11c, orange line), while both models with fracture zones largely overestimate the displacement along the profiles (Fig. 11b and 11c, purple and green lines), with a simulated LOS displacement up to 15 mm, compared to the measured value of 9 mm. Finally, all the models fail to properly reproduce the transient evolution of the LOS displacement. In fact, while the observed variation presents a slight subsidence phase during active injection, all models simulate a somewhat linear increase in uplift. Although the observed subsidence can also be interpreted as related to the selected monitoring point, and it could vary quite a lot with the location, the final simulate uplift overestimate between 5 and 10 mm.

Similar to the case of KB-501, the model with intact caprock seems the most appropriate, given the lowest value of the objective function for the analyzed observations. However, also for KB-503, the pattern of deformation simulated for the case of intact caprock does not match the observation (Fig. 12b), while a model with fracture is able to reproduce the elongate bell-shape pattern of deformation (Fig. 12c and 12d).

35. CONCLUSIONS

We conducted joint inversions of coupled fluid flow and geomechanics associated with the CO₂ storage operations, accounting for the large amount of data collected at the In Salah on-shore demonstration site. Starting from numerical simulations performed in the past, we improved the forward model with TOUGH-FLAC. We then performed for the first time an inverse analysis using iTOUGH2-PEST to estimate uncertain parameters of a coupled fluid flow and geomechanics simulation. We also evaluated the error associated with the estimated parameters, and studied the sensitivity of the model output to the parameters of interest. This key step in

estimating the uncertainties on critical parameters constitutes the key novelty of the current approach compared to previous models (e.g. Rinaldi and Rutqvist, 2013). In the first part of this work, we applied the approach to the case of the KB-502 injection well. A model reproducing most of the observed transient data for this injection well was already presented in past works. We used the previous model to test our approach, but accounted for an improved relationship between stress and permeability. Results show that the inverse modeling approach is able to fit the observations after only a few iterations. A sensitivity analysis on the chosen parameters shows that hydraulic parameters (e.g., stress-dependent permeability parameters) may influence geomechanical observations. Results also show that the hydraulic observations (e.g., bottomhole pressure) depend on mechanical parameters, such as the bulk modulus of the fracture zone at depth. Such coupling between variables justifies the use of a coupled fluid flow and geomechanics model to study CO₂ sequestration. In the second part of this work, we tried to apply the approach to the injection wells KB-501 and KB-503. For these two wells the interpretation of the observed deformation is ambiguous, and some authors have suggested that a fracture zone might have been opened, similarly to KB-502. We investigated three different cases: (i) intact caprock, (ii) reactivating fracture zone, and (iii) pre-active fracture zone. Results for the injection well KB501 and KB-503 suggest that a model with an intact caprock can better reproduce the observations included in the modeling approach: transient evolution of LOS displacement and pressure, as well as the uplift along two arbitrarily chose profile at a specific time (about 2.5 years). However, although not formally accounted for in the inversions, the shape of deformation can only be obtained with a model accounting for a fracture zone, although overestimating (or underestimating) the observed LOS displacement. The reason for overestimating displacements most likely lies in the representation of the fracture zone: the current model simulates the entire fracture zone as reactivating simultaneously, while in the real field a transient process might have occurred. A secondary factor that could affect the

uplift is the expansion of the underburden, which might get pressurized over 4 years injection given its permeability (10^{-19} m²). These effects were probably negligible for KB-502, where the uplift rate was much faster compared to the other wells (Fig. 1b). Furthermore the fracture might have propagated in only one direction, before affecting the entire structure. Other authors also suggested that an anisotropic permeability field within the reservoir might have played a role in giving a preferential direction for the pressure distribution, which then would have caused the observed elongated shape of deformation that was observed at KB-501 and KB-503 (Shi et al., 2013). The current inverse modeling approach, coupling iTOUGH2-PEST with TOUGH-FLAC, is a powerful tool to estimate unknown properties for complex coupled fluid flow and geomechanics problems, providing the errors and sensitivities associated with such properties. Future work may include the study and parameterization of the deep fracture zone geometry, as well as the study of the effect of mesh discretization.

ACKNOWLEDGMENTS

This work was supported by the Assistant Secretary for Fossil Energy, Office of Natural Gas and Petroleum Technology, through the National Energy Technology Laboratory, under the U.S. Department of Energy Contract No. DE-AC02-05CH11231. A. P. Rinaldi is currently funded by SNSF Ambizione Energy grant (PZENP2_160555) Technical review comments by Luca Urpi at SED are greatly appreciated. The authors would like to thank the In Salah JIP and their partners BP, Statoil, and Sonatrach for providing field data and technical input over the past 8 years as well as for financial support during LBNL's participation in the In Salah JIP, 2011–2013.

698Tables

699Table 1. Hydrogeological properties used in the forward model (Rinaldi and Ruqtivist, 2013). Stress-
700dependent parameters in bold.

	Depth (m)	Φ_0 (-)	κ_0 (m ²)
Shallow	0-900	0.1	10^{-12}
Caprock	900-1800	0.01	10^{-21}
Reservoir	1800-1820	0.17	0.8×10^{-14}
Basement	>1820	0.01	10^{-19}

701

702Table 2. Geomechanical properties based on well log analysis (Gemmer et al., 2012). Depths were
703slightly modified to fit our geological model (Table 1). Stress-dependent parameters in bold.

Depth (m)	Young's modulus E (GPa)	Poisson's ratio ν (-)
0-900	3	0.25
900-1650	5	0.3
1650-1780	2	0.3
1780-1800	20	0.25
1800-1820	10	0.2
1820-4000	15	0.3

704

705Table 3. Estimated parameters for KB-502 injection well (initial guess E_x , E_y , and E_z from Rinaldi and
706Rutqvist, 2013).

	Initial Guess	Best estimate
K_t (Pa)	$10^{7.0253}$	$10^{6.90 \pm 0.01}$ (7.94 MPa)
ϕ_{res} (°)	31	27.9 ± 0.3
ϕ_{frac} (°)	31	30.6 ± 0.2
E_x (Pa)	0.17×10^9	$10^{8.71 \pm 0.05}$ (0.51 GPa)
E_y (Pa)	0.14×10^9	$10^{8.13 \pm 0.03}$ (0.13 GPa)
E_z (Pa)	10^9	$10^{9.06 \pm 0.02}$ (1.15 GPa)
Objective func.	1189.6	99.23
Max. Residual	44.89	14.52

707

708Table 4. Estimated parameters for KB-501 injection well. For each inversion the objective function and
709maximum residual of the initial guess is shown in parenthesis.

	Intact caprock	Fracture zone	Pre-active fracture
κ_{res} (m ²)	$10^{-14.16 \pm 0.03}$	$10^{-14.41 \pm 0.02}$	$10^{-14.43 \pm 0.01}$
κ_{cap} (m ²)	$10^{-23 \pm 5}$	-	-
ϕ_{res} (°)	31 ± 0.6	31 ± 1	31 ± 1
K_t (Pa)	$10^{7.3 \pm 0.1}$ (20.8 MPa)	$10^{7.40 \pm 0.02}$ (25.1 MPa)	$10^{7.38 \pm 0.02}$ (23.9 MPa)
ϕ_{frac} (°)	-	26 ± 1	-
E_x (Pa)	-	$10^{9.68 \pm 0.03}$ (4.7 GPa)	$10^{9.65 \pm 0.04}$ (4.5 GPa)

E_y (Pa)	-	$10^{8.76 \pm 0.01}$ (0.57 GPa)	$10^{8.75 \pm 0.03}$ (0.56 GPa)
E_z (Pa)	-	$10^{9.70 \pm 0.01}$ (5.01 GPa)	$10^{9.70 \pm 0.03}$ (5.01 GPa)
Objective func.	508.35	575.26	544.28
Max. Residual	35.77	106.85	99.19

710

711Table 5. Estimated parameters for KB-503 injection well. For each inversion the objective function and
712maximum residual of the initial guess is shown in parenthesis.

	Intact caprock	Fracture zone	Pre-active fracture
κ_{res} (m ²)	$10^{-13.77 \pm 0.05}$	$10^{-14.05 \pm 0.02}$	$10^{-13.98 \pm 0.01}$
κ_{cap} (m ²)	$10^{-22 \pm 1}$	-	-
ϕ_{res} (°)	29±1	27±2	28.0±0.5
K_t (Pa)	$10^{7.3 \pm 0.1}$ (20 MPa)	$10^{7.17 \pm 0.02}$ (25.1 MPa)	$10^{7.39 \pm 0.03}$ (24.5 MPa)
ϕ_{frac} (°)	-	30±10	-
E_x (Pa)	-	$10^{9.66 \pm 0.02}$ (4.6 GPa)	$10^{9.65 \pm 0.01}$ (4.5 GPa)
E_y (Pa)	-	$10^{9 \pm 1}$ (1 GPa)	$10^{8.68 \pm 0.01}$ (0.48 GPa)
E_z (Pa)	-	$10^{10 \pm 1}$ (10 GPa)	$10^{9.70 \pm 0.02}$ (5.01 GPa)
Objective func.	554.36	1438.6	1129.4
Max. Residual	47.93	67.23	62.18
