ABSTRACT

We present cluster counts and corresponding cosmological constraints from the Planck full mission data set. Our catalogue consists of 439 clusters detected within the Sunyaev-Zeldovich (SZ) signal down to a signal-to-noise of six, and is more than a factor of two larger than the 2013 Planck cluster cosmology sample. The counts are consistent with those from 2013 and yield compatible constraints under the same modelling assumptions. Using advantage of the larger catalogue, we extend our analysis to the two-dimensional distribution in redshift and signal-to-noise. We use mass estimates from two recent studies of gravitational lensing of background galaxies by Planck clusters to provide priors on the hydrostatic bias parameter, 1 – b. In addition, we use lensing of cosmic microwave background (CMB) temperature fluctuations by Planck clusters as a third independent constraint on this parameter. These various calibrations imply constraints on the present-day amplitude of matter fluctuations in varying degrees of tension with those coming from Planck analysis of primary and secondary CMB power spectra. For the lowest estimated values of 1 – b the tension is mild, only a little over one standard deviation, while for the largest estimated value it remains substantial. We also examine constraints on extensions to the base flat ΛCDM model by including the cluster and CMB constraints. The combination appears to favour non-minimal neutrino masses, but this possibility does little to relieve the overall tension because it simultaneously lowers the implied value of the Hubble parameter, thereby exacerbating the discrepancy with most current astrophysical estimates. Improving the precision of cluster mass calibrations from the current 10% to 1% would significantly strengthen these combined analyses and provide a stringent test of the base ΛCDM model.

1. Introduction

Galaxy cluster counts are a standard cosmological tool that has found powerful application in recent Sunyaev-Zeldovich (SZ) surveys performed by the Atacama Cosmology Telescope (ACT). Swetz et al. 2011; Hasselfield et al. 2013), the South Pole Telescope (SPT, Carlstrom et al. 2011; Benson et al. 2013; Reichardt et al. 2013; Bocquet et al. 2014), and the Planck satellite (Taub er et al. 2010; Planck Collaboration I 2011). The abun-

dance of clusters and its evolution are sensitive to the cosmic matter density, $\Omega_m$, and the present amplitude of density fluctuations, characterised by $\sigma_8$, the rms linear overdensity in spheres of radius $8 h^{-1}$ Mpc. The primary cosmic microwave background (CMB) anisotropies, on the other hand, reflect the density perturbation power spectrum at the time of recombination. This difference is important because a comparison of the two tests the evolution of density perturbations from recombination until today, enabling us to look for possible extensions to the base CDM model, such as non-minimal neutrino masses or non-zero curvature.

Launched on 14 May 2009, Planck scanned the entire sky twice a year from 33' to 5' with two instruments: the Low Frequency Instrument (LFI; Bersanelli et al. 2010; Mennella et al. 2011), covering bands centred at 30, 44, and 70 GHz, and the High Frequency Instrument (HFI; Lamarre et al. 2010; Planck HFI Core Team 2011), covering bands centred at 100, 143, 217, 353, 545, and 857 GHz.

A initial set of cosmology results appeared in 2013 based on the first 15.5 months of data (Planck Collaboration I 2014), including cosmological constraints from the redshift distribution of 189 galaxy clusters detected at signal-to-noise (SNR) $> 7$ (hereafter, our "first analysis" or the "2013 analysis", Planck Collaboration XX 2014). The present paper is part of the second set of cosmology results obtained from the full mission data set; it is based on an updated cluster sample introduced in an accompanying paper (the PSZ2, Planck Collaboration I 2015).

Our first analysis found fewer clusters than predicted by Planck's base CDM model, expressed as tension between the cluster constraints on ($\Omega_m$, $\sigma_8$) and those from the primary CMB anisotropies (Planck Collaboration XVI 2014). This could reflect the need for an extension to the base CDM model, or indicate that clusters are more massive than determined by the SZ signal-mass scaling relation adopted in 2013.

The cluster mass scale is the largest source of uncertainty in interpretation of the cluster counts. We based our first analysis on X-ray mass proxies that rely on the assumption of hydrostatic equilibrium. Simulations demonstrate that this assumption can be violated by bulk motions in the gas or by nonthermal sources of pressure (e.g., magnetic fields or cosmic rays, Nagai et al. 2007; Piffaretti & Valdarnini 2008; Meneghetti et al. 2010). Systematics in the X-ray analyses (e.g., instrument calibration, temperature structure in the gas) could also bias the mass measurements significantly. We quantified our ignorance of the true mass scale of clusters with a mass bias parameter that was varied over the range [0 – 30]%, with a baseline value of 20% (see below for the definition of the mass bias), as suggested by numerical simulations (see the Appendix of Planck Collaboration XX 2014).

Gravitational lensing studies of the SZ signal-mass relation are particularly valuable in this context because they are independent of the dynamical state of the cluster (Marrone et al. 2012; Planck Collaboration Int. III 2013), although they also, of course, can be affected by systematic effects (e.g., Becker & Kravtsov 2011). New, more precise lensing mass measurements for Planck clusters have appeared since our 2013 analysis (von der Linden et al. 2014b; Hoekstra et al. 2015). We incorporate these new results as prior constraints on the mass bias in the present analysis. Two other improvements over 2013 are use of a larger cluster catalogue and analysis of the counts in signal-to-noise as well as redshift.

In addition, we apply a novel method to measure cluster masses through lensing of the CMB anisotropies. This method, presented in Melin & Bartlett (2014), enables us to use Planck data alone to constrain the cluster mass scale. It provides an important independent mass determination, which we compare to the galaxy lensing results, and one that is representative in the sense that it averages over the entire cluster cosmology sample, rather than a particularly chosen subsample.

Our conventions throughout the paper are as follows. We specify cluster mass, $M_{500}$, as the total mass within a sphere of radius $R_{500}$, defined as the radius within which the mean mass over-density of the cluster is 500 times the cosmic critical density at its redshift, $z$: $M_{500} = (4\pi/3)R_{500}^3[500(\rho_c(z))$, with $\rho_c(z) = 3H^2(z)/(8\pi G)$, where $H(z)$ is the Hubble parameter with present-day value $H_0 = 6 \times 100 \text{ km s}^{-1} \text{ Mpc}^{-1}$. We give SZ signal strength, $Y_{500}$, in terms of the Compton y-profile integrated within a sphere of radius $R_{500}$, and we assume that all clusters follow the universal pressure profile of Arnaud et al. (2010). Density parameters are defined relative to the present-day critical density, e.g., $\Omega_m = \rho_m/\rho_c(z = 0)$ for the total matter density, $\rho_m$.

We begin in the next section with a presentation of the Planck 2015 cluster cosmology samples. In Sect. 3 we develop our model for the cluster counts in both redshift and signal-to-noise, including a discussion of the scaling relation, scatter and the sample selection function. Section 4 examines the overall cluster mass scale in light of recent gravitational lensing measurements; we also present our own calibration of the cluster mass scale based on lensing of the CMB temperature fluctuations. Construction of the cluster likelihood and selection of external data sets is detailed in Sect. 5. We present cosmological constraints in Sect. 6 and then summarize and discuss our results in Sect. 7. We examine the potential impact of different modeling uncertainties in the Appendix.

---

Fig. 1: Mass-redshift distribution of the Planck cosmological samples colour-coded by their signal-to-noise, $q$. The baseline MMF3 2015 cosmological sample is shown as the small filled circles. Objects which were in the MMF3 2013 cosmological sample are marked by crosses, while those in the 2015 intersection sample are shown as open circles. The final samples are defined by $q > 6$. The mass $M_{500}$ is the Planck mass proxy (see text, Arnaud et al. 2015).

2. The Planck cosmological samples

We detect clusters across the six highest frequency Planck bands (100 – 857 GHz) using two implementations of the multi-frequency matched filter (MMF3 and MMF1; Melin et al. 2006; Planck Collaboration XXIX 2014) and a Bayesian extension, (PwS, Carvalho et al. 2009) that all incorporate the known (non-relativistic) SZ spectral signature and a model for the spatial profile of the signal. The latter is taken as the so-called universal pressure profile from Arnaud et al. (2010) — with the non standard self-similar scaling — and parameterized by an angular scale, \( \theta_{500} \).

We empirically characterize noise (all non-SZ signals) in localized sky patches (10° on a side for MMF3) using the set of cross-frequency power-spectra, we construct the filters with the resulting noise weights, and we then filter the set of six frequency maps over a range of cluster scales, \( \theta_{500} \), spanning 1–35 arcmin. The filter returns an estimate of \( Y_{500} \) for each scale, based on the adopted profile template, and sources are finally assigned the \( \theta_{500} \) (and hence \( Y_{500} \)) of the scale that maximizes their signal-to-noise. Details are given in Planck Collaboration XXIX (2014) and in an accompanying paper introducing the Planck full-mission SZ catalogue (PSZ2, Planck Collaboration XXVII 2015).

We define two cosmological samples from the general PSZ2 catalogues, one consisting of detections by the MMF3 matched filter and the other of objects detected by all three methods (the intersection catalogue). Both are defined by a signal-to-noise cut of \( \sigma > 6 \) for the mass calculation. We then apply a mask to remove regions of high dust emission and point sources, leaving 65% of the sky unmasked. The general catalogues, noise maps and masks can be downloaded from the Planck Legacy Archive\(^2\).

The cosmological samples can be easily constructed from the PSZ2 union and MMF3 catalogues. The MMF3 cosmology sample is the subsample of the MMF3 catalogue defined by \( \sigma > 6 \) and for which the entry in the union catalogue has COSMO=’T’. The intersection catalogue sample is defined from the union catalogue by the criteria COSMO=’T’, PIPEDET=111, and \( \sigma > 6 \).

Fig. 1 shows the distribution of these samples in mass and redshift, together with the 2013 cosmology sample. The mass here is the Planck mass proxy, \( M_{500}^{\odot} \), defined in Arnaud et al. (2015) and taken from the PSZ2 catalogue. It is calculated using the Planck size-flux posterior contours in conjunction with X-ray priors to break the size-flux degeneracy inherent to the large Planck beams (see, e.g. Fig. 16 of Planck Collaboration XXVII (2015)). The samples span masses in the range \([2−10] \times 10^{14} M_{\odot}\) and redshifts from \( z = 0 \) to \( 3 \). The MMF3 (intersection) sample contains 439 (493) detections. Note that the intersection catalogue has more objects than the MMF3 catalogue because of the different definitions of the signal-to-noise in the various catalogues. The signal-to-noise for the intersection catalogue corresponds to the highest signal-to-noise of the three detection algorithms (MMF1, MMF3 or PwS), while for the MMF3 catalogue we use its corresponding signal-to-noise. As a consequence, the lowest value for the MMF3 signal-to-noise in the intersection sample is 4.8. We note that, while being above our detection limit, the Virgo and the Perseus clusters are not part of our samples. This is because Virgo is too extended to be blindly detected by our algorithms and Perseus is close to a masked region.

The 2015 MMF3 cosmology sample contains all but one of the 189 clusters of the 2013 MMF3 sample. The missing cluster is PSZ1 980, which falls inside the 2015 point source mask. Six

3 We fix \( h = 0.7 \) and \( \Omega_m = 1 − \Omega_{\Lambda} = 0.7 \) for the mass calculation.

4 Note that this form assumes, as we do throughout, that the distribution depends on \( z \) and \( M_{500} \) only through the mean value \( \bar{q}_{m} \), specifically, that the intrinsic scatter, \( \sigma_{m} \), of Eq. (9) is constant.

3. Modelling cluster counts

From the theoretical perspective, cluster abundance is a function of halo mass and redshift as specified by the mass function. Observationally, we detect clusters in Planck through their SZ signal strength or, equivalently, their signal-to-noise and measure their redshift with follow-up observations. The observed cluster counts are therefore a function of redshift, \( z \), and signal-to-noise, \( \sigma \). While we restricted our 2013 cosmology analysis to the redshift distribution alone (Planck Collaboration XX 2014), the larger catalogue afforded by the full mission data set offers the possibility of an analysis in both redshift and signal-to-noise. We therefore develop the theory in terms of the joint distribution of clusters in the \((z, \sigma)\)-plane and then relate it to the more specific analysis of the redshift distribution to compare with our previous results.

3.1. Counts as a function of redshift and signal-to-noise

The distribution of clusters in redshift and and signal-to-noise can be written as

\[
\frac{dN}{dzdq} = \int dM_{500} \frac{dN}{dM_{500}d\Omega} P(q|\bar{q}_{m}(M_{500}, z, l, b)),
\]

with

\[
\frac{dN}{dM_{500}d\Omega} = \frac{dN}{dVdM_{500} d\Omega} \equiv \bar{Y}_{500}(M_{500}, z), \quad \text{as given in Eq. (7)},
\]

and the detection filter noise, \( \sigma_{m} \), and redshift distribution alone (Planck Collaboration XX 2014), the term counts are therefore a function of redshift, \( z \), and signal-to-noise, \( \sigma \). While we restricted our 2013 cosmology analysis to the redshift distribution alone (Planck Collaboration XX 2014), the larger catalogue afforded by the full mission data set offers the possibility of an analysis in both redshift and signal-to-noise. We therefore develop the theory in terms of the joint distribution of clusters in the \((z, \sigma)\)-plane and then relate it to the more specific analysis of the redshift distribution to compare with our previous results.
mass and redshift. More detail on $\sigma_\ell$ can be found in Planck Collaboration XX (2014) (see in particular Fig. 4 therein).

The distribution $P[q|\bar{q}]$ incorporates noise fluctuations and intrinsic scatter in the actual cluster $Y_{500}(M_{500}, z)$, predicted from the scaling relation. We discuss this scaling relation and our log-normal model for the intrinsic scatter below, and Sect. 4 examines the calibration of the overall mass scale for the scaling relation.

The redshift distribution of clusters detected at $q > q_{\text{cat}}$ is the integral of Eq. (1) over signal-to-noise,

$$\frac{dN}{d\bar{z}}(q > q_{\text{cat}}) = \int_{\bar{z}_{\text{min}}}^{\bar{z}_{\text{max}}} dq \frac{dN}{dq} \frac{dN}{d\Omega} \int dM_{500} \chi(M_{500}, z, l, b) \frac{dN}{d\Omega},$$

with

$$\chi(M_{500}, z, l, b) = \int_{\bar{z}_{\text{min}}}^{\bar{z}_{\text{max}}} dq P[q|\bar{q},\theta_5(M_{500}, z, l, b)].$$

Equation (4) is equivalent to the expression used in our 2013 analysis if we write it in the form

$$\hat{\chi} = \int d\ln Y_{500} \int d\theta_5 P[\ln Y_{500}, \theta_5; M_{500}] \chi(Y_{500}, \theta_5, l, b),$$

where $\chi(Y_{500}, \theta_5, l, b)$ is the survey selection function at $q > q_{\text{cat}}$ in terms of true cluster parameters (Sect. 3.3), and $P[\ln Y_{500}, \theta_5; M_{500}]$ is the distribution of these parameters given cluster mass and redshift. We specify the relation between Eq. (5) and Eq. (6) in the next section.

### 3.2. Observable-mass relations

A crucial element of our modelling is the relation between cluster observables, $Y_{500}$ and $\theta_5$, and halo mass and redshift. Due to intrinsic variations in cluster properties, this relation is described by a distribution function, $P[\ln Y_{500}, \theta_5; M_{500}, z]$, whose mean values are specified by the scaling relations $\bar{Y}_{500}(M_{500}, z)$ and $\bar{\theta}_5(M_{500}, z)$.

We use the same form for these scaling relations as in our 2013 analysis:

$$E^{-\beta}(z) \left[ D_\Lambda(z) \bar{Y}_{500} \right]^{10^{-4} \text{ Mpc}^2} = Y_{500} \left[ \frac{h}{0.7} \right]^{2-\alpha} \left[ \frac{(1 - b) M_{500}}{6 \times 10^{14} \text{ M}_\odot} \right]^{\gamma} \left[ \frac{\bar{D}_\Lambda(z)}{500 \text{ Mpc}} \right]^{-\frac{1}{3}},$$

and

$$\bar{\theta}_5 = \theta_5 \left[ \frac{h}{0.7} \right]^{-2/3} \left[ \frac{(1 - b) M_{500}}{3 \times 10^{14} \text{ M}_\odot} \right]^{1/3} E^{-2\beta}(z) \left[ D_\Lambda(z) \right]^{1/3},$$

where $h = 6.997$ arcmin, and fiducial ranges for the parameters $Y_{500}$, $\alpha$, and $\beta$ are listed in Table I; these values are identical to those used in our 2013 analysis. Unless otherwise stated, we use Gaussian distributions with mean and standard deviation given by these values as prior constraints; one notable exception will be when we simultaneously fit for $\alpha$ and cosmological parameters. In the above expressions, $D_\Lambda(z)$ is the angular diameter distance and $E(z) \equiv H(z)/H_0$.

These scaling relations have been established by X-ray observations, as detailed in the Appendix of Planck Collaboration XX (2014), and rely on mass determinations, $M_X$, based on hydrostatic equilibrium of the intra-cluster gas. Mass bias parameter, $b$, assumed to be constant in both mass and redshift, allows for any difference between the X-ray determined masses and true cluster halo mass: $M_X = (1 - b)M_{500}$. This is discussed at length in Sect. 4.

We adopt a log-normal distribution for $Y_{500}$ around its mean value $\bar{Y}_{500}$, and a delta function for $\bar{\theta}_5$ centred on $\bar{\theta}_5$:

$$P(\ln Y_{500}, \theta_5; M_{500}, z) = \frac{1}{\sqrt{2\pi}\sigma_{\ln Y}} e^{-\ln^2(\bar{Y}_{500}/\bar{Y}_{500})/(2\sigma_{\ln Y}^2)} \delta[\theta_5 - \bar{\theta}_5],$$

where $\bar{Y}_{500}(M_{500}, z)$ and $\bar{\theta}_5(M_{500}, z)$ are given by Eqs. (7) and (8). The $\delta$-function maintains the empirical definition of $R_{500}$ that is used in observational determination of the the profile.

We can now specify the relation between Eqs. (5) and (6) by noting that

$$P[q|\bar{q}_m(M_{500}, z, l, b)] = \int d\ln q_m P[q|\bar{q}_m] P[\ln q_m|\bar{q}_m].$$

where $P[q|\bar{q}_m]$ is the distribution of observed signal-to-noise, $q$, given the model value, $\bar{q}_m$. The second distribution represents intrinsic cluster scatter, which we write in terms of our observable-mass distribution, Eq. (9), as

$$P[\ln q_m|\bar{q}_m] = \int d\theta_5 P[\ln Y_{500}(\ln q_m, \theta_5, l, b), \theta_5; M_{500}, z] = \frac{1}{\sqrt{2\pi}\sigma_{\ln Y}} e^{-\ln^2(q_m/\bar{q}_m)/(2\sigma_{\ln Y}^2)}.$$

Performing the integral of Eq. (5), we find

$$\hat{\chi} = \int d\ln q_m P[\ln q_m|\bar{q}_m] \chi(Y_{500}, \theta_5, l, b),$$

with the definition of our survey selection function

$$\chi(Y_{500}, \theta_5, l, b) = \int q_{\text{max}} dq P[q|\bar{q}_m, Y_{500}, \theta_5, l, b].$$

We then reproduce Eq. (6) by using the first line of Eq. (11) and Eq. (3).
3.3. Selection function and survey completeness

The fundamental quantity describing the survey selection is $P[q_{\text{in}}]$, introduced in Eq. (10). It gives the observed signal-to-noise, used to select SZ sources, as a function of model (“true”) cluster parameters through $q_{\text{in}}(Y_{500}, \theta_{500}, l, b)$, and it defines the survey selection function $\chi(Y_{500}, \theta_{500}, l, b)$ via Eq. (13). We characterize the survey selection in two ways. The first is with an analytical model and the second employs a Monte Carlo extraction of simulated sources injected into the Planck maps. In addition, we perform an external validation of our selection function using known X-ray clusters.

The analytical model assumes pure Gaussian noise, in which case we simply have $P[q_{\text{in}}] = e^{-(q_{\text{in}})^2/2}$. The survey selection function is then given by the Error Function (ERF),

$$
\chi(Y_{500}, \theta_{500}, l, b) = \frac{1}{2} \left[ 1 - \text{erf} \left( \frac{q_{\text{in}} - q_{\text{in}}(Y_{500}, \theta_{500}, l, b)}{\sqrt{2}} \right) \right].
$$

This model can be applied to a catalogue with well-defined noise properties, i.e., $\sigma$, such as our MMF3 catalogue, but not to the intersection catalogue based on the simultaneous detection with three different methods. This is our motivation for choosing the MMF3 catalogue as our baseline.

In the Monte Carlo approach, we inject simulated clusters directly into the Planck maps and (re)extract them with the complete detection pipeline. Details are given in the accompanying 2015 SZ catalogue paper, Planck Collaboration XXVII (2015). This method provides a more comprehensive description of the survey selection by accounting for a variety of effects beyond noise. In particular, we vary the shape of the SZ profile at fixed $Y_{500}$ and $\theta_{500}$ to quantify its effect on catalogue completeness.

We also perform an external check of the survey completeness using known X-ray clusters from the MCXC compilation (Piffaretti et al. 2011) and also SPT clusters from Bleem et al. (2014). Details are given in the 2015 SZ catalogue paper, Planck Collaboration XXVII (2015). For the MCXC compilation, we rely on the expectation that at redshifts $z < 0.2$ any Planck-detected cluster should be found in one of the ROSAT catalogues (Chamballu et al. 2012), because at low redshift ROSAT probes to lower masses than Planck. The MCXC catalogue provides a truth table, replacing the input cluster list of the simulations, and we compute completeness as the ratio of objects in the cosmology catalogue to the total number of clusters. As discussed in Planck Collaboration XXVII (2015), the results are consistent with Gaussian noise and bound the possible effect of profile variations. We arrive at the same conclusion when applying the technique to the SPT catalogue.

Planck Collaboration XXVII (2015) discusses completeness checks in greater detail. One possible source of bias is the presence of correlated IR emission from cluster member galaxies. Planck Collaboration XXIII (2015) suggests that IR point sources may contribute significantly to the cluster SED at the Planck frequencies, especially at higher redshift. The potential impact of this effect warrants further study in future work.

This gives us different estimations of the selection function for MMF3 and the intersection catalogues. We test the sensitivity of our cosmological constraints to the selection function in the Appendix by comparing results obtained with the different methods and catalogues. We find that our results are insensitive to the choice of completeness model (Fig A.1), and we therefore adopt the analytical ERF completeness function for simplicity throughout the paper.

4. The cluster mass scale

The characteristic mass scale of our cluster sample is the critical element in our analysis of the counts. It is controlled by the mass bias factor, $1 - b$, accounting for any difference between the X-ray mass proxies used to establish the scaling relations and the true (halo) mass: $M_X = (1 - b) M_{500}$. Such a difference could arise from cluster physics, such as a violation of hydrostatic equilibrium or temperature structure in the gas, from observational effects, e.g., instrumental calibration, or from selection effects biasing the X-ray samples relative to SZ- or mass-selected samples (Angulo et al. 2012).

In our 2013 analysis, we adopted a flat prior on the mass bias over the range $1 - b = [0.7, 1.0]$, with a reference model defined by $1 - b = 0.8$. This was motivated by a comparison of the $Y - M_X$ relation with published $Y - M$ relations derived from numerical simulations, as detailed in the Appendix of Planck Collaboration XX (2014); this estimate was consistent with most predictions for any violation of hydrostatic equilibrium (although not all) as well as observational constraints from the available lensing observations. Effects other than cluster physics can contribute to the mass bias, as discussed in the paper, and as emphasized by the survey of cluster multi-band scaling relations by Rozo et al. (2014a,b,c).

The mass bias was the largest uncertainty in our 2013 analysis, and it severely hampered understanding of the tension found between constraints from the primary CMB and the cluster counts. Here, we incorporate new lensing mass determinations of Planck clusters to constrain the mass bias. We also apply a novel method to measure object mass based on lensing of CMB temperature anisotropies behind clusters (Melin & Bartlett 2014). These constraints are used as prior information in our analysis of the counts. As we will see, however, uncertainty in the mass bias remains our largest source of uncertainty, mainly because these various determinations continue to differ from 10 to 50%.

In general, the mass bias could depend on cluster mass and redshift, although we will model it by a constant in the following. Our motivation is one of practicality: the limited size and precision of current lensing samples makes it difficult to constrain any more than a constant, i.e., the overall mass scale of our catalogue. Large lensing surveys like Euclid, WFIRST, and the Large Synoptic Survey Telescope, and CMB lensing will improve this situation in coming years.

4.1. Constraints from gravitational shear

Several cluster samples with high quality gravitational shear mass measurements have appeared since 2013. Among these, the Weighing the Giants (WtG, von der Linden et al. 2014a), CLASH (Postman et al. 2012; Merten et al. 2014; Umetsu et al. 2014), and the Canadian Cluster Comparison Project (CCCP, Hoekstra et al. 2015) programmes offer constraints on our mass bias factor, $1 - b$, through direct comparison of the lensing masses to the Planck mass proxy, $M_{500}$.

The analysis by the WtG programme of 22 clusters from the 2013 Planck cosmology sample yields $1 - b = 0.688 \pm 0.072$. Their result lies at the very extreme of the range explored in Planck Collaboration XX (2014) and would substantially reduce the tension found between primary CMB and galaxy cluster constraints. Hoekstra et al. (2015) report a smaller bias of...
1 - b = 0.78 ± 0.07 (stat) ± 0.06 (sys) for a set of 20 common clusters, 
which is in good agreement with the fiducial value adopted in our 2013 analysis. In our analysis we add the statistical and systematic uncertainties in quadrature (see Table 2).

### 4.2. Constraints from CMB lensing

Measuring cluster mass through CMB lensing has been discussed in the literature for some time since the study performed by Zaldarriaga & Seljak (1999) (see also Lewis & Challinor 2006). We apply a new technique for measuring cluster masses through lensing of CMB temperature anisotropies (Melin & Bartlett 2014), allowing us to calibrate the scaling relations using only Planck data. This is a valuable alternative to the galaxy lensing observations because it is independent and affected by different possible systematics. Additionally, we can apply it to the entire cluster sample to obtain a mass calibration representative of an SZ flux selected sample. Similar approaches using CMB lensing to measure halo masses were recently applied by Zaldarriaga & Seljak (1999) (see also Lewis & Challinor 2006). We apply a new technique for measuring cluster masses as independent Poisson random variables, our log-likelihood is constructed on counts in the (z_i, dN) and \( \Delta L \). Our 2013 analysis employed a likelihood built on the cluster redshift distribution, \( dN/dz \). With the larger 2015 catalogue, our baseline likelihood is now constructed on counts in the (z, q_i) plane. We divide the catalogue into bins of size \( \Delta z = 0.1 \) (10 bins) and \( \Delta \log q = 0.25 \) (5 bins), each with an observed number \( N(z_i, q_i) = N_{ij} \) of clusters. Modelling the observed counts, \( N_{ij} \), as independent Poisson random variables, we log-likelihood is

\[
\ln L = \sum_{i,j}^{N=N_{ij}} \left[ N_{ij} \ln \tilde{N}_{ij} - \tilde{N}_{ij} - \ln[N_{ij}!] \right].
\]

The values can be negative due to noise fluctuations and the low signal-to-noise of the individual measurements.

Figure 2 shows \( M_{\text{lens}}/M_{\text{SZ}} \) as a function of \( M_{\text{SZ}} \) for all clusters in the MMF3 cosmology sample. Each point is an individual cluster. For clarity, only some of the error bars are shown; the error bars vary from 1.8 at the high mass end to 8.5 at the low mass end with a median of 4.2. There is no indication of a correlation between the ratio and \( M_{\text{SZ}} \), and we therefore fit for a constant ratio of \( M_{\text{lens}}/M_{\text{SZ}} \) by taking the weighted mean (using the individual measurement uncertainties as provided by the filter) over the full data set. If the ratio differs from unity, we apply a correction to account for the fact that our filter aperture was not perfectly matched to the clusters. The correction is calculated assuming an NFW profile and is the order of a percent. The final result is 1 - b = 0.99 ± 0.19, traced by the blue band in the figure. Note that the method constrains 1 - b rather than 1 - b as in the case of the shear measurements. The calculated uncertainty on the weighted mean is consistent with a bootstrap analysis where we create new catalogues of the same size as the original by sampling objects from the original catalogue with replacement; the uncertainty from the bootstrap is then taken as the standard deviation of the bootstrap mean.

### 5. Analysis methodology

#### 5.1. Likelihood

Our 2013 analysis employed a likelihood built on the cluster redshift distribution, \( dN/dz \). With the larger 2015 catalogue, our baseline likelihood is now constructed on counts in the (z, q_i) plane. We divide the catalogue into bins of size \( \Delta z = 0.1 \) (10 bins) and \( \Delta \log q = 0.25 \) (5 bins), each with an observed number \( N(z_i, q_i) = N_{ij} \) of clusters. Modelling the observed counts, \( N_{ij} \), as independent Poisson random variables, we log-likelihood is
where \( N_i \) and \( N_q \) are the total number of redshift and signal-to-noise bins, respectively. The mean number of objects in each bin is predicted by theory according to Eq. (1):

\[
\bar{N}_{ij} = \frac{dN}{d\Omega d\alpha} \Delta z_i \Delta q_j,
\]

which depends on the cosmological (and cluster modelling) parameters. In practice, we use a Monte Carlo Markov chain (MCMC) to map the likelihood surface around the maximum and establish confidence limits.

Eq. (15) assumes the bins are uncorrelated, while a more complete description would include correlations due to large-scale clustering. In practice, our cluster sample contains mostly high mass systems for which the impact of these effects is weak (e.g., Hu & Kravtsov 2003, in particular their Fig. 4) for the impact on constraints in the \((\Omega_m, \sigma_8)\) plane).

5.2. External data sets

Cluster counts cannot constrain all pertinent cosmological parameters. They are most sensitive to \( \Omega_m \) and \( \sigma_8 \), and when analysing the counts alone we must apply additional observational constraints as priors on other parameters. For this purpose, we adopt Big Bang nucleosynthesis (BBN) constraints from Steigman (2008), \( \Omega_b h^2 = 0.022 \pm 0.002 \), and constraints from baryon acoustic oscillations (BAO). The latter combine the 6dF Galaxy Survey (Beutler et al. 2011), the SDSS Main Galaxy Sample (Padmanabhan et al. 2012; Anderson et al. 2012) and the BOSS DR11 (Anderson et al. 2014). We refer the reader to Sect. 5.2 in Planck Collaboration XIII (2015) for details of the combination. We also include a prior on \( n_s \) from Planck Collaboration XVI (2014), \( n_s = 0.9624 \pm 0.014 \). When explicitly specified in the text, we add the supernovae constraint from SNLS-II and SNLS3: the Joint Light-curve Analysis constraint (JLA, Betoule et al. 2014). The BAO are particularly sensitive to \( H_0 \), while the supernovae allow precise constraints on the dark energy equation-of-state parameter, \( w \).

6. Cosmological constraints

We begin by verifying consistency with the results of Planck Collaboration XX (2014) (Sect. 6.1) based on the one-dimensional likelihood over the redshift distribution, \( dN/dz \) (Eq. 4). We then examine the effect of changing to the full two-dimensional likelihood, \( dN/d\Omega d\alpha \) (Eq. 1) in Sect. 6.2. For this purpose we compare constraints on the total matter density, \( \Omega_m \), and the linear-theory amplitude of the density perturbations today, \( \sigma_8 \), using the cluster counts in combination with external data and fixing the mass bias.

The two-dimensional likelihood \( dN/d\Omega d\alpha \) is then adopted as the baseline in the rest of the paper. We extract constraints on \( \Omega_m \) and \( \sigma_8 \) from the cluster counts in combination with external data, imposing the different cluster mass scale calibrations as prior distributions on the mass bias. After comparing these new constraints to those from the CMB anisotropies in the base ΛCDM model (Sect. 6.3), we move to joint analysis of the cluster counts and CMB anisotropies to study, for example, extensions to the base ΛCDM model, such as non-minimal neutrino mass (Sect. 6.4). In these studies we vary all six parameters of the (flat) base ΛCDM model, except when considering model extensions for which we include the relevant parameters. Figures display contours delineating marginalized constraints.

6.1. Constraints on \( \Omega_m \) and \( \sigma_8 \): comparison to 2013

Figure 3 presents constraints from the MMF3 cluster counts combined with the BAO and BBN priors of Sect. 5.2; we refer to this data combination as “SZ+BAO+BBN”. To compare to results from our 2013 analysis (the grey, filled ellipses), we use a one-dimensional likelihood based on Eq. (4) over the redshift distribution and have adopted the reference scaling relation of 2013, i.e. Eqs. (7) and (8) with \( 1 - b = 0.8 \). For the present comparison, we use the updated BAO constraints discussed in Sect. 5.2; these are stronger than the BAO constraints used in the 2013 analysis, and the grey contours shown here are consequently smaller than in Planck Collaboration XX (2014).

Limiting the 2015 catalogue to \( q > 8.5 \) produces a sample with 190 clusters, similar to the 2013 cosmology catalogue (189 objects). The two sets of constraints demonstrate good consistency, and they remain consistent while becoming tighter as we decrease the signal-to-noise threshold of the 2015 catalogue. Under similar assumptions, our 2015 analysis thus confirms the 2013 results reported in Planck Collaboration XX (2014).

The area of the ellipse from \( q = 8.5 \) to \( q = 6 \) decreases by a factor of 1.3. This is substantially less than the factor of 2.3 expected from the ratio of the number of objects in the two samples. This difference may be related to the decreasing goodness-of-fit of the best model as the signal-to-noise decreases.

Figure 4 overlays the observed cluster redshift distribution on the predictions from the best-fit model in each case. We see that the models do not match the counts in the second and third redshift bins (counting from \( z = 0 \)), and that the discrepancy, already marginally present at the high signal-to-noise cut corresponding to the 2013 catalogue, becomes more pronounced towards the lower signal-to-noise thresholds. This dependence on signal-to-noise may suggest that the data prefer a different slope, \( \alpha \), of the scaling relation than allowed by the prior of Table 1. We explore the effect of relaxing the X-ray prior on \( \alpha \) in the next section.

6.2. Constraints on \( \Omega_m \) and \( \sigma_8 \): two-dimensional analysis

In Fig. 5 we compare constraints from the one- and two-dimensional likelihood with \( \alpha \) either free or with the prior of Table 1. For this comparison, we continue with the “SZ+BAO+BBN” data set, but adopt the CCCP prior for the mass bias and only consider the full 2015 MMF3 catalogue at \( q > 6 \).

The grey and black contours and lines show results from the one-dimensional likelihood fit to the redshift distribution using, respectively, the X-ray prior on \( \alpha \) and leaving \( \alpha \) free. The redshift counts do indeed favour a steeper slope, and we find a posterior median of \( \alpha = 2.68 \pm 0.17 \) in the latter case.

We define a generalized \( \chi^2 \) measure of goodness-of-fit as

\[
\chi^2 = \sum_i N_i \Delta N_i^2 = \left( \frac{N_i - \bar{N}_i}{\sigma_i} \right)^2,
\]

determining the probability to exceed \( (PTE) \) the observed value using Monte Carlo simulations of Poisson statistics for each bin with the best-fit model mean \( \bar{N}_i \). The observed value of the fit drops from 17 (\( PTE = 0.07 \)) with the X-ray prior, to 15 (\( PTE = 0.11 \)) when leaving \( \alpha \) free. When leaving \( \alpha \) free, \( \Omega_m \) increases and \( \sigma_8 \) decreases, following their correlation with \( \alpha \) shown by the contours, and their uncertainty increases due to the added parameter.

The two-dimensional likelihood over \( dN/d\Omega d\alpha \) better constrains the slope when \( \alpha \) is free, as shown by the violet curves and contours. In this case, the preferred value drops back towards the X-ray prior: \( \alpha = 1.89 \pm 0.12, \) just over 1 \( \sigma \) from the central

Article number, page 7 of 17
X-ray value. Re-imposing the X-ray prior on \( \alpha \) with the two-dimensional likelihood (blue curves) does little to change the parameter constraints. Although the one-dimensional likelihood prefers a steeper slope than the X-ray prior, the two-dimensional analysis does not, and the cosmological constraints remain robust to varying \( \alpha \).

We define a generalized \( \chi^2 \) statistic as described above, now over the two-dimensional bins in the \((z,q)\)-plane. This generalized \( \chi^2 \) for the fit with the X-ray prior is 43 \((PTE = 0.28)\), compared to \( \chi^2 = 45 \((PTE = 0.23)\) when \( \alpha \) is a free parameter.

Fig. 5 displays the redshift distribution of the best-fit models in all four cases. Despite their apparent difficulty in matching the second and third redshift bins, the PTE values suggest that these fits are moderately good to acceptable. Note that, as mentioned briefly in Sect. 5.1, clustering effects will increase the scatter in each bin slightly over the Poisson value we have assumed, causing our quoted PTE values to be somewhat smaller than the true ones.

6.3. Constraints on \( \Omega_m \) and \( \sigma_8 \): comparison to primary CMB

Our 2013 analysis brought to light tension between constraints on \( \Omega_m \) and \( \sigma_8 \) from the cluster counts and those from the primary CMB in the base \( \Lambda \)CDM model. In that analysis, we adopted a flat prior on the mass bias over the range \( 1 - b = [0.7, 1.0] \), with a reference model defined by \( 1 - b = 0.8 \) (see discussion in the Appendix of Planck Collaboration XX 2014). Given the good consistency between the 2013 and 2015 cluster results (Fig. 3), we expect the tension to remain under the same assumptions concerning the mass bias.

Figure 7 compares our 2015 cluster constraints (MMF3 \( \Sigma+\)BAO+BBN) to those for the base \( \Lambda \)CDM model from the Planck CMB anisotropies. The cluster constraints, given the three different priors on the mass bias, are shown by the filled contours at 1 and 2\( \sigma \), while the dashed black contours give the Planck TT, TE, EE, lowP constraints (hereafter Planck primary CMB, Planck Collaboration XIII 2015); the grey shaded regions add BAO to the CMB. The central value of the WtG mass prior lies at the extreme end of the range used in 2013 (i.e., \( 1-b=0.7 \)).
6.4. Joint Planck 2014 primary CMB and cluster constraints

We now turn to a joint analysis of the cluster counts and primary CMB. We begin by finding the mass bias required to remove tension with the primary CMB, and then consider one-parameter extensions to the base ΛCDM model, varying the curvature, the Thomson optical depth to reionization, the dark energy equation-of-state, and the neutrino mass scale. Unless otherwise stated, “CMB” in the following means Planck TT, TE, EE + lowP as defined in Planck Collaboration XIII (2015). All intervals are 68% confidence and all upper/lower limits are 95%.

6.4.1. Mass bias required by CMB

In Fig. 8 we compare the three prior distributions to the mass bias required by the primary CMB. The latter is obtained as the posterior on the mass bias, \(1 - b\). The solid black curve shows the distribution of values required to reconcile the counts and primary CMB in ΛCDM; it is found as the posterior on the \(1 - b\) from a joint analysis of the Planck cluster counts and primary CMB when leaving the mass bias free. The coloured dashed curves show the three prior distributions on the mass bias listed in Tab. 2.

6.4.2. Curvature

By itself the CMB only poorly determines the spatial curvature (Sect. 6.2.4 of Planck Collaboration XIII 2015), but by including another astrophysical observation, such as cluster counts, it can be tightly constrained. Our joint cluster and CMB analysis, without external data, yields \(\Omega_k = -0.012 \pm 0.008\), consistent with the constraint from Planck CMB and BAO \(\Omega_k = 0.000 \pm 0.002\).

6.4.3. Reionization optical depth

Primary CMB temperature anisotropies also provide a precise measurement of the parameter combination \(A_\tau e^{-2\tau}\), where \(\tau\) is
the optical depth from Thomson scatter after reionization and the Planck Collaboration XIII (2015). Low-\ell polarization anisotropies break the degeneracy by constraining \( \tau \), but this measurement is delicate given the low signal amplitude and difficult systematic effects; it is important, however, in the determination of \( \sigma_8 \). It is therefore interesting to compare the Planck primary CMB constraints on \( \tau \) to those from a joint analysis of the cluster counts and primary CMB without the low-\ell polarization data (lowP). Battye et al. (2014), for instance, pointed out that a lower value for \( \tau \) than suggested by WMAP could reduce the level of tension between CMB and large scale structure.

The comparison is shown in Fig. 9. We see that the Planck TT + SZ constraints are in good agreement with the value from Planck CMB (i.e., TT, TE, EE+lowP), with the preferred value for WtG slightly higher and CMB lensing pushing towards a lower value. The ordering CMB lensing/CCCP/WtG from lower to higher \( \tau \) posterior values matches the decreasing level of tension with the primary CMB on \( \sigma_8 \). These values remain, however, larger than what is required to fully remove the tension in each case. The posterior distributions for the mass bias are \( 1 - b = 0.60 \pm 0.042, 1 - b = 0.63 \pm 0.047, 1 - b = 0.66 \pm 0.045 \), respectively, for WtG, CCCP and CMB lensing, all significantly shifted from the corresponding priors of Table 2. Allowing \( \tau \) to adjust offers only minor improvement in the tension reflected by Fig. 8. Interestingly, the Planck TT posterior shown in Fig. 8 of Planck Collaboration XIII (2015) peaks at significantly higher values, while our Planck TT +SZ constraints are consistent with the constraint from Planck TT + lensing, an independent constraint on \( \tau \) without lowP.

6.4.4. Dark energy

In Fig. 10 we examine constraints on a constant dark energy equation-of-state parameter, \( w \). Analysis of the primary CMB alone yields the grey contours that are highly degenerate. Adding either BAO or supernovae to the CMB breaks the degeneracy, giving constraints around \( w = -1 \). Adding SZ cluster counts from the MMF3 2015 catalogue instead to the CMB results in the rose-coloured contours. The green contours are constraints from joint analysis of the SZ counts and BAO; although much less constraining they agree with the CMB+JLA combinations and are completely independent.

combined with the CMB, but when combined with BAO they do yield interesting constraints (green contours) that are consistent with the independent constraints from the primary CMB combined with supernovae. We obtain \( \Omega_m = 0.313 \pm 0.025 \) and \( w = -1.00 \pm 0.18 \) for SZ+BAO, and \( \Omega_m = 0.306 \pm 0.013 \) and \( w = -1.10 \pm 0.06 \) for CMB+BAO.

6.4.5. \( \sum m_\nu \)

An important, well-motivated extension to the base \( \Lambda \)CDM model that clusters can help constrain is a non-minimal sum of neutrino masses, \( \sum m_\nu > 0.06 \) eV. Given the primary CMB anisotropies, the amplitude of the density perturbations today, characterized by the equivalent linear theory extrapolation, \( \sigma_8 \), is model dependent; it is a derived parameter depending, for example, on the composition of the matter content of the universe. Cluster abundance, on the other hand, provides a direct measurement of \( \sigma_8 \) at low redshifts, and comparison to the value derived from the CMB tests the adopted cosmological model.

By free-streaming, neutrinos damp the growth of matter perturbations. Our discussion thus far has assumed the minimum mass for the three known neutrino species. Increasing their mass, \( \sum m_\nu > 0.06 \) eV, lowers \( \sigma_8 \) because the neutrinos have larger gravitational influence on the total matter perturbations. This goes in the direction of reconciling tension — the strength of which depends on the mass bias — between the cluster and primary CMB constraints. Cluster abundance, or any measure of \( \sigma_8 \) at low redshift, is therefore an important cosmological constraint to be combined with those from the primary CMB.

Figure 11 presents a joint analysis of the cluster counts for the CCCP mass bias prior with primary CMB, the Planck TT, TEE+lowP, and the joint analysis of WtG. The SZ counts and BAO; although much less constraining they agree with the CMB+JLA combinations and are completely independent.
in mild tension with the value predicted for the ΛCDM model, $A_L = 1.22 \pm 0.10$

just above $\Sigma m_\nu = 0.2 \text{ eV}$. We also notice some interesting correlations: the amplitude, $\sigma_8$, anti-correlates with neutrino mass, as does the Hubble parameter, and larger values of $\alpha$ correspond to larger neutrino mass, lower $H_0$ and lower $\sigma_8$.

As discussed in detail in Planck Collaboration XIII (2015), the anti-correlation with the Hubble parameter maintains the observed acoustic peak scale in the primary CMB. Increasing neutrino mass to simultaneously accommodate the cluster and primary CMB constraints by lowering $\sigma_8$, while allowed in this joint analysis, would therefore necessarily increase tension with some direct measurements of $H_0$ (see discussion in Planck Collaboration XIII (2015)). Including the BAO data greatly restricts this possibility, as shown by the solid and dashed black curves.

The solid and dashed, red and black curves in Fig. 12 reproduce the marginalized posterior distributions on $\sum m_\nu$ from Fig. 11. The solid blue curve is the result of a similar analysis where in addition the artificial parameter $A_L$ is allowed to vary. This parameter characterizes the amount of lensing in the temperature power spectrum relative to the best fit model (Planck Collaboration XIII 2015). Planck TT + lowP alone constraints $A_L = 1.22 \pm 0.10$

in mild tension with the value predicted for the ΛCDM model, $A_L = 1$. In the base ΛCDM model, this parameter is fixed to unity, but it is important to note it is degenerate with $\sum m_\nu$. Left free, it allows less lensing power, which is also in line with the direct measurement of the lensing power spectrum (labelled as Lensing PS) from the four-point function (see Planck Collaboration XIII 2015). In that light, we see that adding $A_L$ as a free parameter accentuates the peak in the CMB+SZ+Lensing PS posterior. The small internal tension between CMB+SZ and CMB+SZ+$A_L$ posteriors may point towards a need for an extension of the minimal six-parameter ΛCDM.

These posteriors lead to the following constraints: $\sum m_\nu < 0.53 \text{ eV (95%)}$ for CMB+SZ+Lensing PS and $\sum m_\nu < 0.22 \text{ eV (95%)}$ for CMB+SZ+BAO.

We may compare these with the constraints from the primary CMB presented in Planck Collaboration XIII (2015). The Planck primary CMB by itself places an upper limit of $\sum m_\nu < 0.49 \text{ eV (95%)}$, and the addition of BAO tightens this to $\sum m_\nu < 0.17 \text{ eV (95%)}$. Addition of the Planck lensing power spectrum to the primary CMB weakens the constraint to $\sum m_\nu < 0.59 \text{ eV (95%)}$, as we would expect given the results and discussion above. The final constraint adopted by Planck Collaboration XIII (2015), for its robustness to possible remaining low level systematics in the polarization data, is $\sum m_\nu < 0.23 \text{ eV (95%),}$ not too different from the peak suggested in CMB+SZ+lensing PS posterior.

Adding neutrino mass should lower $\sigma_8$, letting it move towards values favoured by the cluster counts. We might expect that the CMB+SZ combination would therefore find clear evidence for non-minimal neutrino mass. In spite of this, the green curve only places an upper limit on $\sum m_\nu$. We may understand this by looking at the posterior on the mass bias $1 - b$. The allowed values are well separated from the prior distribution,
meaning that the primary CMB has sufficient statistical weight to strongly override the prior. The lensing power spectrum, in favouring slightly lower \(\sigma_8\), reinforces the cluster trend so that a peak appears in the posterior for \(\Sigma m\), in the red curve; it is not enough, however, to bring the posterior on the mass bias in line with the prior. This indicates that the tension between the cluster and primary CMB constraints is not fully resolved.

One may then ask, how tight must the prior on the mass bias be to make a difference? To address this question, we performed an analysis assuming a projected tighter prior constraint on the mass bias. The informal target precision for cluster mass calibration with future large lensing surveys, such as Euclid and the Large Synoptic Survey Telescope, is 1%, and we consider the impact of a prior of \(1 - b = 0.80 \pm 0.01\) on the present Planck cluster cosmology sample in Figs. 12 and 13.

The latter figure compares the constraints from cluster counts for this mass bias to the present primary CMB constraints in the \((\Omega_m,\sigma_8)\) -plane for the base \(\Lambda\)CDM model. The bold, black dotted line in Fig. 12 shows the predicted posterior on the neutrino mass from a joint analysis of the present Planck cluster counts and primary CMB. The same prior on a much larger catalogue would demonstrate a corresponding increase in sensitivity to neutrino mass. This simple projection highlights the importance and value of the more precise cluster cosmology expected in the future, and it provides clear motivation for significant effort in mass calibration. This effort will continue with larger samples of clusters with gravitational shear measurements, and also with the new technique of CMB lensing cluster mass measurements.

7. Summary and discussion

Our 2015 analysis incorporates a number of improvements and new information relative to our first study in Planck Collaboration XX (2014). With more data, we have a larger cluster cosmology sample, increased by more than a factor of two, and we implement a two-dimensional likelihood over the counts in both redshift and signal-to-noise. We have also performed new tests of the selection function using MCXC and SPT cluster catalogs as truth tables. The selection function from these external checks and internal simulations of the Planck catalogue construction agree with each other and can be reasonably modelled by a simple analytical expression derived by assuming noise is the dominant factor (see the Appendix). One possible systematic effect that warrants further study is IR emission from cluster member galaxies. Finally, we have examined the implications of three recent determinations of the cluster mass bias parameter, \(1 - b\). The two-dimensional likelihood with the 2015 catalogue and mass bias priors will be implemented in CosmoMC.

Our analysis confirms the results of the 2013 study. The counts are consistent with those of 2013, illustrated by the agreement in the constraints on \(\Omega_m\) and \(\sigma_8\) when using the same SZ observable-mass relations (see Fig. 3). The gain in statistical precision is less than expected from the larger catalogue, which is likely related to the fact that the fit to the redshift distribution with the X-ray prior on \(\alpha\) is only marginal. Our new two-dimensional approach yields consistent, but more robust constraints than the one-dimensional likelihood over just the redshift distribution; it is less sensitive to the slope of the scaling relation, \(\alpha\), and it provides a better fit to the counts than in the one-dimensional case.

Using the two-dimensional likelihood as our baseline, we extracted new cosmological constraints using three different cluster mass scales represented by the mass bias prior distributions given in Table 2. The first two come from galaxy shear observations of samples of Planck clusters. They differ by about 1\(\sigma\), with the WtG result favoring larger mass bias. We have also implemented a novel method for measuring cluster masses based on the CMB temperature anisotropies behind clusters (Melin & Bartlett 2014). It gives a mass bias averaged over the entire cluster cosmology sample, although with larger statistical uncertainty.

As a new method requiring further exploration, we consider CMB lensing less robust at present than galaxy lensing mass measurements, but highly promising. Similar CMB-based
mass measurements have recently been published by SPT (Baxter et al. 2014) and ACT (Madhavacheril et al. 2014). The approach is appealing because it is subject to different systematic effects than gravitational shear and because it can be applied to large cluster samples thanks to the extensive sky coverage of the CMB experiments, with Planck of course covering the entire sky. Gravitational shear surveys will soon attain large sky coverage in the near future with the Dark Energy Survey (DES), and in the more distant future with the Euclid and WFIRST space missions and the Large Synoptic Survey Telescope.

Our central result from analysis of the 2015 Planck cluster counts is shown in Fig. 7. Depending on the mass bias prior, we find varying degrees of tension with the primary CMB, as in 2013. The mass bias required to bring the cluster counts and CMB into full agreement is larger than indicated by any of the three priors and corresponds to $1 - b = 0.58 \pm 0.04$. Fig. 8 illustrates the situation. The WtG prior almost eliminates the tension, but not quite, while both the CCCP and CMB lensing priors remain in noticeable tension. Our largest source of modelling uncertainty is, as in 2013, the mass bias.

Tension between low redshift determinations of $\sigma_8$ and the Planck primary CMB are not unique to the Planck cluster counts. Among SZ cluster surveys, both SPT and ACT are in broad agreement with our findings, the latter depending on which SZ-mass scaling relation is used, as detailed in our 2013 analysis Planck Collaboration XX (2014). And the new SPT cosmological analysis (Bocquet et al. 2014) shows a significant shift between the cluster mass scale determined from the velocity dispersion or $Y_X$ and what is needed to satisfy Planck or WMAP9 CMB constraints (e.g., Fig. 2 Bocquet et al. 2014). In a study of the REFLEX X-ray luminosity function, Böhringer et al. (2014) also report general agreement with our cluster findings. On the other hand, Mantz et al. (2014) find the their X-ray cluster counts, when using the WtG mass calibration, match the primary CMB constraints.

The situation is thus not yet satisfactory. It is unclear if these modest tensions arise from low-level systematics in the astrophysical studies, or are the first glimpse of something more important. The most obvious extension to the base ΛCDM model that could in principle reconcile the differences is a non-minimal sum of neutrino masses. This, unfortunately, does not provide such a straightforward solution. While it is true that adding neutrino mass does lower $\sigma_8$ relative to the base ΛCDM prediction from the primary CMB, it does so at the the cost of increasing tension in other parameters; for example, it lowers Planck’s already rather low value for the Hubble parameter.

Figure 14 highlights these points by showing constraints in the $(\Omega_m, \sigma_8)$- and the $(H_0, \sigma_8)$-planes for each of the mass bias parameters. Adding variable neutrino mass relaxes constraints from the primary CMB (shaded contours, which are the same in all three pairs of panels) towards lower $\sigma_8$, but by simultaneously increasing $\Omega_m$ and decreasing $H_0$. The remaining tension is mild in the case of the WtG mass prior, but more pronounced for the other two mass priors regardless of the neutrino mass.

Another possibility is that baryonic physics influences the late-time evolution of the density perturbations. Strong feedback from active galactic nuclei (AGN) (Nagai et al. 2007; van Daalen et al. 2011; Martizzi et al. 2014) can potentially damp growth and lower $\sigma_8$ through expulsion of matter from dark matter halos. This same effect could also reduce the mass of cluster halos and hence the prediction for their abundance, which is based on dark matter only simulations. It does not appear, however, that these effects are sufficiently large to explain the tension between low redshift and primary CMB constraints hinted at by the different observations. In addition, the violent feedback necessary for important impact might be difficult to reconcile with observations of the baryon content of dark matter halos (e.g., Planck Collaboration Int. XI 2013).

As conclusion, we return to the main uncertainty in interpretation of the cluster counts, namely the mass bias. It could be that the current accuracy is at the level of ~ 10 – 15%, based on the difference between different analyses and somewhat larger than their quoted statistical uncertainties. Progress will certainly follow with improvement in these measurements. We illustrate the potential impact of a 1% determination of the mass bias in Figs. 12 and 13. Such a result would, depending on the central value, significantly clarify the extent of any tensions and possible necessity for extensions to the base ΛCDM model. This precision is the avowed target of the large lensing surveys, such as Euclid, WFIRST and LSST. In the shorter term, we may expect valuable movement in this direction from DES and CMB lensing cluster mass measurements.
Appendix A: Modelling uncertainties

We examine the robustness of our cosmological constraints to modelling uncertainties. We first consider sensitivity to the cosmological sample and to our modelling of the completeness function in Sect. A.1, and then look at the effect of using a different mass function in Sec. A.2. In Sec. A.3, we show that our constraints are robust against redshift evolution of the scaling relations.

Appendix A.1: Choice of the sample and selection function

For our baseline analysis, we use the MMF3 cosmological sample and its associated completeness based on the analytical approximation using the Error Function (Eq. 14). In Fig. A.1 we show how the Monte Carlo determined selection function changes the cosmological constraints (labelled QA for “Quality Assessment” in the figure). We also present the constraints obtained from the intersection sample defined in Sec. 2. The figure is based on the 1D $N(z)$ likelihood, for which the Monte Carlo completeness can be easily computed, and we use the baseline SZ+BAO+BBN data set and fix $(1-b) = 0.8$. The MMF3 ERF contour is thus close to the $q = 6$ contour of Fig. 3, the only difference being that $\sigma_{\text{int}}$ is fixed to zero in Fig. A.1. while it is constrained by the Table 1 prior in Fig. 3. The impact of adopting the intersection sample and/or the QA completeness function is small ($< 0.5\sigma$) for both $\Omega_m$ and $\sigma_8$.

Appendix A.2: Mass function

We use the Tinker et al. mass function for our baseline analysis. To characterize the influence of this choice, we examine constraints when adopting the mass function from Watson et al. (2013) instead. We employ our 2D $N(z,q)$ likelihood (with the CCCP mass bias prior and $\alpha$ constrained) and combine with BAO and BBN prior constraints, and show the result in Fig. A.2.

The Tinker et al. contour of Fig. A.2 is thus identical to the $N(z,q)$ contour with $\alpha$ free, as given in Fig. 5. The new mass function shifts our constraints by about $1\sigma$ towards higher $\Omega_m$ and lower $\sigma_8$, along the main degeneracy line, hence increasing the tension with the Planck primary CMB constraints. Note that we use the general fit from Eq. (12) of Watson et al. (2013) (independent of redshift). This was not the case for our 2013 paper (Planck Collaboration XX 2014) where we adopted the AHF fit with parameters varying with redshift in the first ArXiv version of the paper, which was subsequently found to be incorrect (fourth version of the paper on ArXiv).
Fig. A.3: Robustness to redshift evolution in the SZ-mass scaling relation. The different contours show the constraints when relaxing the redshift evolution exponent, $\beta$, of Eq. (7). The black contours result from fixing $\beta = 0.66$, our fiducial value throughout, with $\alpha$ constrained by the Gaussian X-ray prior of Tab. 1. Applying a Gaussian prior on $\beta$ instead, from Tab. 1, produces the blue contours, while the red contours result when we also leave $\alpha$ free. In this figure we adopt the SZ+BAO+BBN data set and the CCCP mass bias prior.

Appendix A.3: Redshift evolution of the Y-M relation

Throughout our baseline analysis, we fix the redshift evolution exponent $\beta = 0.66$ (self-similar prediction) in Eq. (7). Here we examine the impact of allowing this parameter to vary. Constraints when leaving $\beta$ free are shown in Fig. A.3. The "$\beta$ fixed, $\alpha$ constrained" case corresponds to the 2D $N(z, q)$ likelihood (CCCP mass bias prior and $\alpha$ constrained) combined with BAO and BBN, as in Fig. A.2. This contour is also identical to the $N(z, q)$ contour with $\alpha$ free, shown in Fig. 5. For the "$\beta$ constrained" cases, $\beta$ is allowed to vary over the range $0.66 \pm 0.50$ (Table 1). This increases the size of our constraints along the major degeneracy between $\Omega_m$ and $\sigma_8$, but does not bring them into any closer agreement with the primary CMB.
