Calibrating Independence Goals and Partner Support: Couples Adjust to Functional Limitations After Tumor Surgery

Abstract:

Background. When patients recover from disease-related functional limitations, support received from partners may not always match patients’ changing independence goals. Prostate cancer patients’ independence goals, or lines of defense, were tested as moderators of the association between partner support and patients’ and partners’ affect during patients’ recovery from postsurgical functional limitations.

Methods. Data from 169 couples were assessed at four measurement points within seven to eight months following patients’ tumor surgeries. Patients completed questionnaires on post-surgery functional limitations (i.e., incontinence), lines of defense, affect, and received partner social support. Partners reported on affect and support provided to patients.

Results. In patients with less ambitious lines of defense, higher levels of received support were associated with lower negative affect. Also, not endorsing overambitious lines of defense while receiving strong partner support was related to patients’ lower negative and higher positive affect. Partners’ support provision to patients tended to be associated with increases in partners’ negative affect when patients had endorsed more ambitious lines of defense and with increases in positive affect when patients had endorsed less ambitious lines of defense.

Conclusions. Findings indicate that matching lines of defense of patients with partners’ support is beneficial for patients’ and partners’ affective well-being.

Calibrating Independence Goals and Partner Support:

Couples Adjust to Functional Limitations After Tumor Surgery

Disease-related and post-surgery functional limitations pose substantial challenges to patients and their partners. Patients need to flexibly adjust their goals for regaining functioning to the concurrent functional limitations and their change over time. The complexity of this self-regulatory challenge may be reduced or enhanced by their social partners -- typically their spouse -- providing care and support. In this study, prostate cancer patients’ health-related independence goals, so-called lines of defense (Heckhausen, 2005; Heckhausen, Wrosch, & Schulz, 2013), were investigated as moderators of the associations between support interactions and their assumed consequences for both patients’ and partners’ affective well-being. Couples were examined in the context of patients’ convalescence from post-surgical functional limitations following radical prostatectomy.

The Lines of Defense (LoD) Model

Heckhausen’s (2005; Heckhausen et al., 2013) lines of defense model proposes that during adaptation to changing health and functional capacity, individuals pursue health-related independence goals that are hierarchically organized, reflecting successive lines of defense (LoDs). LoDs are chosen in accordance with the individuals’ control capacity. Control capacity refers to the “extent to which the individual realizes control over his/her environment (i.e., primary control) across different domains of life and across the life-span” (Heckhausen et al., 2013, p. 35). From a health-domain perspective, control capacity can be severely limited by disease and associated functional limitations (Schulz & Heckhausen, 1996; Wahl, Becker, & Burmedi) or enhanced by recovery and rehabilitation from disease (xxx, in press), both times prompting the adjustment of goals for independence and
functioning. For the case of deteriorating health, the LoD Model\(^1\) proposes that as long as health is good, the individual will strive to avoid disease or disability (highest LoD). Once chronic disease sets in and accompanying functional limitations are no longer avoidable, the protection of self-reliance becomes the next LoD. If the disease progresses and independence becomes severely challenged, the next adaptive LoD should be to use help and aids to maintain functional ability. Finally, minimizing discomfort as well as delaying death (lowest LoD) are assumed to be the last resorts of control when health takes an (irreversible) downturn. Within this framework, an individual experiencing progressive decline with a given illness will select the appropriate level of functioning to strive for and hold on to this level as long as possible. The individual should disengage from a more ambitious LoD when it is no longer maintainable and only then engage with the next lower LoD. On the other hand, when health improves, for instance during convalescence and rehabilitation, individuals should readjust their independence goals upwardly, i.e., towards higher LoDs, and claim more ambitious functioning as soon as control capacity increases again (XXX, in press).

Fortunately for many, the above-described challenging process of goal adjustment in the face of changing disease-related functional impairment does not take place in social isolation, but is attended and supported by close others, usually partners (Resendes & McCorkle, 2006). Although this often produces beneficial synergistic effects, it may also interfere with the recovering partners’ self-regulatory efforts (Gray, Fitch, Phillips, Labreque, & Fergus, 2000).

**Partner Support: Match or Mismatch with Changing Lines of Defense?**

Whereas partners’ support is usually much appreciated and appraised as useful by support recipients (Rini & Dunkel-Schetter, 2010), its efficacy in promoting patients’

\(^1\) Note that the present study was based on a version of the LoD-model first proposed by Heckhausen (2005). Meanwhile, Heckhausen et al. (2013) proposed a more differentiated and elaborated revised model.
adjustment may sometimes fall short (e.g., Martire, Stephens, Druley, & Wojno, 2002; Martire, Stephens, & Schulz, 2011). Predictors for inefficacious support attempts with regard to recipients’ well-being are manifold and can include prolonged phases of inequity of supportive interaction among partners (Knoll, Burkert, Roigas, & Gralla; Kuijer, Buunk, & Ybema, 2001), misfits between types of support provided and types of support required by the recipient (e.g., Cutrona & Russell, 1990), or wrongly dosed support (Brock & Lawrence, 2009). The latter is likely to happen when there is a discrepancy between patients’ and partners’ perceptions of patients’ functional ability, such as caregivers’ overestimation of patients’ functional limitations resulting in overprotection (Coyne, Ellard, & Smith 1990; Hagedoorn, Kuijer, Buunk, De Jong, Wobbes, & Sanderman, 2000). Also, there is a risk for wrongly dosed support attempts when patients’ strivings for independence are not correctly observed by their caregivers. For instance, Martire and colleagues (2002, 2011) found in two studies that persons with osteoarthritis for whom functional independence was central (i.e. who were used to being highly independent in the pursuit of their daily activities) reacted negatively to received support by their partners in terms of well-being, functional ability, and pain self-efficacy. Similarly, Nagurney, Reich, and Newsom (2004) reported that a higher desire for independence coupled with high amounts of received support were related with worse affect and self-esteem in older men, but not women with health-related functional impairment. Difficulties in meeting the independence needs of a person who copes with functional impairment and making support available at the same time were also indirectly illustrated by findings by Cimarolli, Boerner, Reinhardt, and Horowitz (2013). In older individuals with vision loss, authors identified longitudinal relations between perceived overprotection on the one side and instrumental support on the other. While perceived overprotection was initially associated with instrumental support, this association disappeared over the course of 12 months, yet, perceived overprotection increased during this time.
The difficulties of calibrating caregiver support to patient needs may even be augmented for both partners when patients’ perceived level of independence and functional ability fluctuate over time or increase such as during rehabilitation. Findings by Gray and colleagues (2000) from a qualitative longitudinal study with prostate cancer patients and their spouses indicated that changes in patients’ independence goals during rehabilitation from treatment may interfere with the efficacy of supportive interactions on both sides of the support dyad. Findings showed that patients struggled to regulate their emotions and perform daily activities, vacillating between independence and need for support to reduce the impact of the illness’ and treatment’s sequelae on everyday life. At the same time, their partners were distressed by caring and being supportive while also respecting their partners’ need for independence.

Although evidence is accumulating on the necessary characteristics of support that furthers recipients’ perceptions of autonomy (i.e., autonomy support; Ryan & Deci, 2000; Warner et al., 2011), to date relatively little is known about the role of recipients’ independence goals in support interactions in the context of changing illness-related functional limitations. In this study, Heckhausen’s (2005; Heckhausen et al., 2013) lines of defense model is used to investigate the role of patients’ health-related independence goals, or LoDs, as potential moderators of the association between partner support and affective well-being of prostate cancer patients and their partners.

**Incontinence Following Radical Prostatectomy: Challenges to Functional Capacity and Independence**

Radical prostatectomy (RP) is a standard treatment for prostate cancer that involves the surgical removal of the prostate gland. Frequent postoperative sequelae include urinary incontinence and erectile dysfunctions (e.g., Resnick et al., 2013). As long as incontinence persists, patients typically report more limitations in the maintenance of functional capacity due to incontinence than due to sexual dysfunction (Resendes & McCorkle, 2006).
Accordingly, the present study focused on patients’ adaptation to the onset and gradual recovery from incontinence following surgery.

Incontinence sets in following the removal of a postsurgery catheter. Although in 80% to 90% of patients, incontinence recedes within the following 6 to 12 months, to date, aside from factors such as patient age or mode of operation, relatively little is known about predictors of its duration and course (Prabhu, Sivarajan, Taksler, Laze, & Lepor, in press; Resnick et al., 2013). Moreover, about 10% of patients remain incontinent beyond 12 and even 24 months following RP (Resnick et al., 2013). Findings indicate that postoperative incontinence is related to lower functional capacity and lower overall health-related quality of life in patients, especially within the first six months following surgery (e.g., Eton & Lepore, 2002; Resendes & McCorkle, 2006). While incontinence persists, patients use technical aids (e.g., sanitary pads) and initially restrict their daily activities to environments with sanitary facilities for a change of pads and/or clothes.

Following the onset of incontinence, patients often utilize support from their partners to maintain functional capacity, including delegation of chores to partners, securing availability of supplies for management of incontinence, but also to disclose their emotions, to seek reassurance, and to discuss decisions concerning the treatment’s sequelae (Gray et al., 2000, Resendes & McCorkle, 2006). When incontinence subsides during recovery, the utilization of caregiver support also decreases (e.g., Knoll, Burkert, Luszcynska, Roigas, & Gralla, 2011).

Moreover, an earlier report on parts of the present data (xxx, in press) about developments of patients’ endorsements of lines of defense (LoDs) during rehabilitation from incontinence following RP has shown that patients’ incontinence and LoDs were closely linked. While incontinence receded during the first 7 to 8 months following surgery, patients were generally striving for higher self-reliance as indicated by upward adjustments of LoDs over time.

**Aim and Hypotheses**
The aim of this study was to investigate whether the association between support for patients and patients’ and partners’ affective well-being depends on the LoD the patient is currently engaged with. It was expected that higher levels of support are associated with worse affect in patients and partners if patients are currently engaged with more ambitious LoDs. Moreover, we expected that a better match between patients’ less ambitious LoDs and support may not only protect patients’ but also partners’ affect, as it might reduce doubts about the appropriateness of the provided assistance and make support provision more effective.

To adapt Heckhausen’s (2005) LoDs to the context of rehabilitation from sequelae following prostatectomy, only three of the originally proposed LoDs (cf. Heckhausen, 2005) were used and one goal was split up, resulting in the following subset of four LoDs, that will henceforth be referred to as LoD1 through LoD4: (LoD1) protect self-reliance (highest LoD), that is, pursuing daily activities without technical aids or external help; (LoD2) rely on technical aids, such as sanitary pads, to maintain functional ability; (LoD3) rely on technical aids and help from others to maintain functional ability (LoDs 2 and 3 represent the split-up version of the original LoD3; cf. Heckhausen, 2005); LoD4: minimize discomfort by disengagement, that is, rather give up activities than fearing negative consequences of incontinence. As reported above, data on LoDs were previously used in a study that focused on patterns of LoD endorsements using a latent class approach, patients’ transitions between LoD classes over time, and associations between class membership and concurrent levels of incontinence (cf. xxx, in press).

In the present study, the following hypotheses were tested:

**Hypothesis 1.** If higher levels of received partner support match with patients’ LoDs (i.e., LoD3: rely on aids and help, or LoD4: minimize discomfort by disengagement) patients should experience better affective well-being (i.e., more positive, less negative affect). If there is a mismatch between high levels of received support and patients’ more ambitious LoDs
(i.e., LoD1: protect self-reliance, or LoD2: rely on technical aids) patients should report worse affect.

Hypothesis 2. Better affective well-being is also expected in partners whose strong support provision fits with patients’ more modest LoDs (i.e., LoD3: rely on aids and help, or LoD4: minimize discomfort by disengagement). A mismatch between patients’ more ambitious LoDs (i.e., LoD1: protect self-reliance, or LoD2: rely on aids) and partners’ strong support provision should be associated with worse affective well-being in partners.

Method

Participants and Procedure

A total of 209 patients receiving radical prostatectomy and their heterosexual partners were enrolled in the study. Recruitment of couples took place in two departments of urology in a large metropolitan area in Germany. Data were collected between 2009 and 2011. Overall inclusion criteria were undergoing radical prostatectomy and living in a stable relationship with a partner. Exclusion criteria were not giving informed consent, not having a partner, the partner’s refusal to participate in the study, and insufficient comprehension of the German language. Couples received a compensation of 110 Euros for full participation.

Of the 209 couples enrolled in the study, 169 couples (80.86%) returned some data at all measurement points in time. See Figure 1 for more information on the participant flow. Where data were available, couples who provided data at all assessments (continuers: coded 1) and those who did not (dropouts: coded 0) differed with regard to: patient-reported level of depressive symptoms (lower in continuers; \( r = -.18, p < .05 \)) and difficulty with performing activities of daily living (lower in continuers; \( r = -.24, p < .05 \)); number of partners’ children (lower in continuers; \( t (31.08) = 1.98 \quad p < .10 \)), and number of children living with their parents (lower in continuers; \( r = -.15, p < .05 \)), partner-reported vocational training (degree from a school providing higher vocational education: less often in continuing couples; \( r = -.18, p < .05 \)), and number of comorbidities (higher in continuers; \( r = .14, p < .10 \)). Unique
effects of these dropout-correlates were examined using a logistic regression with dropout-correlates as independent variables and a binary coded couple dropout variable as the outcome. Two unique effects emerged for partner-reported vocational training and patient-reported difficulty with performing activities of daily life.

Of the 169 couples who had provided data at all study assessments, between 0.60% and 3% of couples chose not to relay socio-demographic information at baseline. Patients’ mean age was 63.59 years, $SD = 6.68$, range 47 to 77, and partners’ mean age was 60.12 years, $SD = 7.89$, range 39 to 75 years. Most couples were married (88%), the remainder were in a long-standing relationship with a shared home. Mean relationship duration as reported by patients was 32.35 years, $SD = 13.96$ years. Most patients (88.60%) and partners (85.20%) reported to have children. Regarding school education, 52.10% of patients and 41.30% of partners reported more than ten years of schooling, the remainder reported nine or ten years of schooling, one partner reported less than nine years of schooling. About half of the patients (56.60%) and partners (48.80%) were retired. Patients’ tumors varied in size (as denoted by “T” = tumor size; “T” = 1: 0.60 %; “T” = 2: 67.30%; “T” = 3: 32.10 %), tumors of 17 patients had spread to lymph nodes (as denoted by “N” = nodes; “N” = 1: 10.06 %), and the tumor of one patient had spread further (as denoted by “M” = metastases; “M” = 1: 0.6 %).

Questionnaires were used at five measurement points during an approximate eight-month period around surgery. The first measurement (T0) took place upon admission, one day prior to surgery. Study research assistants approached patients and their partners at the departments of urology, presented information on the study, explained study materials, and asked for written consent to participate in the study. Baseline questionnaires were left with participants and picked up again on the same day. If partners were not present upon admission, they received information, consent forms, and study materials via mail with separate pre-stamped return envelopes for questionnaires and consent forms. The remaining
longer-term post-surgery measurements were scheduled at one month (T1), three months (T2), five months (T3), and seven months (T4) following the removal of the indwelling catheter that is, following the onset of incontinence. This duration was chosen as it represents the time frame with the steepest slope of recovery from post-surgery incontinence (e.g., Resnick et al., 2013). Participants were mailed study materials and separate pre-stamped return envelopes for patients and partners. In the present study, mainly data following the onset of incontinence were included (T1 to T4), as research aims pertained to assessments during rehabilitation after surgery. The study procedure was approved by an Institutional Review Board.

Measures

Patients’ and partners’ affect was measured by the German version of the Positive and Negative Affect Schedule (PANAS; Krohne, Egloff, Kohlmann, & Tausch, 1996). The positive and negative affect scales consist of ten adjectives that were rated on four-point scales with anchors do not agree at all (0) to agree completely (3). Internal consistencies ranged between $\alpha = .80$ and .92.

Patients’ LoDs were assessed with four single-items, one per incontinence-related independence goal (XXX, in press). The stem “During the past week...,” was followed by the items, LoD1: protect self-reliance (“...it was my goal to independently accomplish activities of daily life (e.g., work, household, shopping, social activities, hobbies) without using pads or other technical aids”), LoD2: rely on technical aids (“...it was my goal to independently accomplish activities of daily life by using pads or other technical aids”), LoD3: rely on technical aids and help (“...it was my goal to accomplish activities of daily life by using pads or other technical aids and support by others [e.g., my partner, close others]”), and LoD4: minimize discomfort by disengagement (“...it was my goal to even also refrain from pursuing pleasurable activities rather than worry about unpleasant consequences of incontinence all the time”). LoDs were endorsed on seven-point scales, with the anchors do not agree at all (1)
and agree completely (7). Due to U-shaped distributions of item responses, we dichotomized responses at response option 4, the middle category (1-4 were coded 0, and 5-7 were coded 1). LoDs were not independent of one another, but inter-related. Mean correlations across all measurements ranged in absolute values from $|0.23|$ to $|0.60|$, the latter being the relation between LoD2 and LoD3.

Patients’ received and partners’ provided spousal support were assessed by two subscales of the Berlin Social Support Scales (BSSS; Schulz & Schwarzer, 2003), that is, patient-reported received support (11 items) and partner-reported provided support (11 items). Both versions assess emotional (soothing, comforting) and instrumental (help in everyday chores) support, were adapted to gender, and framed in parallel ways. Due to high inter-correlations between emotional and instrumental support components of the respective scales (received emotional support $<>$ received instrumental support mean $r = 0.62$; partner provided emotional support $<>$ partner provided instrumental support mean $r = 0.69$), both support functions were collapsed in an overall score. Receipt and provision of support during the past week were reported on four-point Likert-type scales, ranging from do not agree at all (1) to agree completely (4). Internal consistencies ranged from $\alpha = 0.78$ to 0.89.

Patients’ urinary incontinence was measured by the German short form of the International Consultation of Incontinence Questionnaire (ICIQ-SF; Karantanis, Fynes, Moore, & Stanton, 2004). The ICIQ-SF weighted sum score, built of items assessing frequency of incontinence, amount of urine leaked, and burden by incontinence, ranges from 0 to 21 with higher values pointing to higher severity of incontinence and internal consistencies ranging from $\alpha = 0.75$ to 0.81.

Patient and partner comorbidity was assessed at T0 (prior to surgery) using a list of 34 chronic diseases (modelled after Charlson, Szatrowski, Peterson, & Gold, 1994). Participants were asked to indicate whether or not they suffered from these illnesses and to note additional
ones if necessary. A sum score representing total number of illnesses was created. Patients had a mean of 2.78, \( SD = 2.57 \), and partners a mean of 2.72, \( SD = 2.50 \), diseases.

**Analyses**

Only couples who had provided data at all 5 measurement points (T0 to T4) were included in the analyses (\( n = 169 \)). Of these, depending on the role of the actor (i.e., patient or partner) and outcome, between 3 and 5 respondents were excluded from analyses by the statistics package due to more than 25% missing data for the respective model. To account for the factors uniquely associated with dropout, we included these as covariates in the central analyses (i.e., partner-reported vocational training and patient-reported difficulty with performing activities of daily living; see above). This strategy was chosen to minimize bias due to drop out. Only unique correlates of dropout were accounted for to reduce the number of covariates in our central analyses.

Analyses testing Hypotheses 1 and 2 used two-level hierarchical linear models, with repeated assessments (level-1) nested in individuals (level-2). Outcomes were patients’ (Hypothesis 1) or partners’ (Hypothesis 2) affect indicators, assessed post-surgery, with separate models fitted for positive and negative affect. Level-1 lagged (T-1) time-varying predictors included: the respective affect measure, patient-reported incontinence, a linear TIME trend that was coded in months and centred on the first measurement point following surgery (TIME at T1 = 0), the respective support indicator, all four patient-reported LoDs and all four support x LoD interactions. As endorsements of LoDs were not independent of each other, all support x LoD interactions were tested competitively. Additionally, the following covariates were included: patients’ or partners’ comorbidity, patients’ or partners’ age (all level-2), and correlates of dropout. Except for the linear TIME trend, all other predictors were centred around their grand means. A first-order heterogeneous autoregressive error covariance structure was imposed and a maximum likelihood estimation procedure was used. Because there were set roles for patients and partners, models either used patient variables only (except
for partners’ correlates of dropout; tests of Hypothesis 1) or partner variables were complemented with patient variables (tests of Hypothesis 2).

Descriptive analyses for continuous variables used two-level hierarchical linear models, for dichotomous outcomes generalized estimating equations were employed. Again time points (level 1) were nested in individuals (level 2). On level-1, a linear TIME trend was introduced. Moreover, the two identified unique correlates of dropout were accounted for as covariates. In all descriptive analyses models, a first-order autoregressive error covariance structure was imposed and a maximum likelihood procedure was used.

For all two-level hierarchical linear models, all random effects were tested, but retained only when models converged. All analyses were done using SPSS 20.

Results

Descriptive Results

Patients’ incontinence decreased from one month to seven months following the onset of incontinence. The same was true for patients’ received support and partners’ provided support over time. Patients’ positive affect increased over time. Neither patients’ negative affect nor partners’ affect changed (see Table 1). Evidence for significant variability of intercepts between individuals emerged in all models.

--- Table 1 ---

Patients’ endorsement of the most ambitious LoD1 (protect self-reliance) increased whereas endorsements of LoD2 (rely on technical aids) and LoD3 (rely on technical aids and help) decreased as incontinence receded in the months following surgery. When introducing patient-reported severity of incontinence to the model, the linear TIME trend was no longer significant when LoD4 (minimize discomfort by disengagement) was the outcome. Additionally, patients reporting higher incontinence were less likely to endorse LoD1 (protect self-reliance), whereas they were more likely to endorse LoD2 (rely on technical aids) through LoD4 (minimize discomfort by disengagement; see Table 2).
LoDs as Moderators of the Support -- Affective Well-Being Relationship

Hypothesis 1 predicted that a better match between patients’ LoDs and receiving support from their partners should be associated with better affective well-being. Interaction terms between endorsements of LoDs and levels of patient-reported received support from partners were used as indicators of degree of this match. Interactions that were hypothesized to represent a worse LoD -- support match involved LoD1 (protect self-reliance) and LoD2 (rely on technical aids), those representing a better match between patients’ independence goals and support receipt involved LoD3 (rely on aids and help) and LoD4 (minimize discomfort by disengagement). As can be seen in Table 3, results partly supported the hypothesis.

With regard to patients’ negative affect, an LoD1 (protect self-reliance) x received support interaction yielded partial support for Hypothesis 1. Simple slope analyses indicated that patients who had disengaged from LoD1 responded more negatively to a lack of support from partners than those who received strong support (simple slope = -0.07, z = -3.65, p < .001). However, not in line with Hypothesis 1, patients who endorsed LoD1 did not report higher negative affect when they had received much support from their partners (simple slope = 0.01, z = 0.45, p = .656), but were unaffected by this support (Figure 2, Panel A).

Also in line with Hypothesis 1, simple-slope analyses of an LoD4 (minimize discomfort by disengagement) x support interaction revealed that patients who had endorsed LoD4, seemed to benefit from receiving support in terms of decreased negative affect (simple slope = -0.23, z = -4.39, p < .001). However, patients who did not endorse LoD4 did not (simple slope = -0.01, z = -0.42, p = .676; Figure 2, Panel B).

Using patients’ positive affect as an outcome, an interaction of LoD2 (rely on technical aids) x received support emerged (see Table 3). Partially in line with predictions, simple-slope
analyses showed that patients who had not endorsed LoD2 also reported higher positive affect when they had received much support (simple slope = 0.17, $z = 2.59, p = .009$). On the other hand, patients who endorsed LoD2 did not benefit from higher levels of received support in terms of later positive affect (simple slope < .01, $z = 0.01, p = .991$; see Figure 2, Panel C).

Also predicting patients’ positive affect, another LoD4 (minimize discomfort by disengagement) x support interaction trend ($p = .080$) was found. Matching predictions, simple slopes indicated that support receipt was associated with higher positive affect only if patients had endorsed LoD4 (simple slope = 0.18, $z = 2.21, p = .027$). For patients who had not endorsed LoD4, no relation between received support and positive affect emerged (simple slope = 0.03, $z = 0.80, p = .426$).

Hypothesis 2 predicted benefits for partners’ affect from a better match of patients’ endorsement of LoDs and support provided by partners. Using partners’ negative affect as an outcome, results partially supported these assumptions (see Table 4). An LoD1 (protect self-reliance) x partner provided support interaction emerged (at $p = .050$). Simple slope analyses indicated that when partners had provided support while patients pursued the goal to protect self-reliance (LoD1), partners’ negative affect tended to be higher (simple slope = 0.07, $z = 1.88, p = .061$; see Figure 3). This was not the case when patients had not endorsed LoD1 (simple slope = -0.02, $z = -0.87, p = .383$). None of the other LoD x partner-provided support interactions explained variance in partners’ negative affect.

Using partner-reported positive affect as an outcome, only the LoD4 (minimize discomfort by disengagement) x partner provided support interaction approached significance (at $p = .061$; see Table 4). Simple slopes indicated that partners of patients who had endorsed LoD4 tended to report higher positive affect if they had provided much as opposed to little
support to patients (simple slope = 0.16, z = 1.66, p = .098), whereas partners of patients who had not endorsed this goal did not (simple slope = -0.04, z = 1.10, p = .272).

Discussion

The process of adapting to urinary incontinence following radical prostatectomy requires adjustments of health-related independence goals from patients (cf. XXX, in press), but also coordination in supportive interaction between patients and their partners.

The present results partially indicated benefits of a better match between patients’ endorsement of LoDs and partners’ support in terms of both partners’ affective well-being. Hypothesis 1 predicted that for patients, a match between more received support and endorsements of LoD3 (rely on technical aids and help) or LoD4 (minimize discomfort by disengagement) would be associated with better affective well-being, whereas higher levels of support combined with patients’ endorsements of the more advanced LoD1 (protect self-reliance) or LoD2 (rely on technical aids) would not. Indeed, for patients who endorsed LoD4 (minimize discomfort by disengagement), more support was related with lower negative affect and tentatively with higher positive affect, whereas for patients who did not endorse this goal, no such relations emerged. However, an analogous interaction involving LoD3 (rely on technical aids and help) was not found, neither for negative nor for positive affect. This was especially unexpected as LoD3 explicitly entailed not only the use of technical aids, but also recruitment of external help to keep up activities of daily living. Intending to use support to manage life with incontinence and being provided with such support by one’s partner seems well-matched, but might still trigger embarrassment or pose problems for self-esteem in the support recipient that counteract potential positive effects (Bolger, Zuckerman, & Kessler, 2000; Resendes & McCorkle, 2006).

Indications for reduced efficacy of received support when it mismatched recipients’ LoDs (1 and 2; cf. Martire et al., 2011; Nagurney et al., 2004) also emerged. Fortunately, but
contrary to Hypothesis 2, this mismatch did not seem to be harmful to patients’ affective well-being. Instead, only patients who had not endorsed LoD1 (protect self-reliance) or LoD2 (rely on technical aids) seemed to benefit from received support in terms of their negative (LoD1 x received support) or positive (LoD2 x received support) affective well-being. Patients who had endorsed these more ambitious goals seemed unaffected by support receipt. An explanation for this might be found in the dominant affect components assessed with the PANAS. Even though support received was not in line with patients’ more ambitious independence goals (LoD1 or LoD2), it is unlikely that this should have hurt recipients’ self-esteem and thereby produced anxious or depressed affect (Bolger et al., 2000; Fisher, Nadler, & Whitcher-Alagna, 1982). More likely, it created a nuisance at the time that might have provoked an anger reaction. An important limitation is that anger is somewhat underrepresented in the PANAS version used in this study.

Looking at the other side of the support dyad, that is, partners’ affect correlates of their own support provision as a function of patients’ independence goals (Hypothesis 2), some evidence for the inefficiency of mismatched support emerged, albeit only as trends. When patients had set the goal to protect their self-reliance (i.e., endorsed LoD1) and partners had provided much support, partners’ negative affect tended to increase. Qualitative findings in the context of patients’ convalescence from prostatectomy suggest that partners are often uncertain and anxious about the appropriateness and quantity of their support provision as they witness patients’ struggle for self-reliance (Gray et al., 2000). Moreover, unwanted support is less likely to be encoded as such by the intended recipient who then fails to reciprocate, which might also contribute to disappointment or perceived unfairness in support providing partners (Kuijjer et al., 2001). On the other hand, partners’ higher support provision in the context of patients’ lowered lines of defense (i.e. when patients had endorsed LoD4: minimize discomfort by disengagement), tended to be associated with increases of partners’ positive affect and thus seemed to be a more gratifying experience. Note, that a
complementary set of findings was observed in patients who had reported to have received much support from their partners and had endorsed LoD4 (minimize discomfort by disengagement). Support provided in this context might have created new rewarding interactions for patients and their partners which compensated for patients’ goals to disengage from pleasurable activities to minimize discomfort by incontinence. However, effects involving partners’ data did not reach conventional levels of significance and were restricted to interactions with patients’ “most extreme” lines of defense only. In light of this and the remaining non-findings in the models predicting partner affect, it is likely that patient-reported goals were too distal as moderators to produce larger effects.

Limitations and Outlook

This study had several limitations. Contrary to findings from an earlier pilot study, the present operationalization of LoDs revealed problems with the continuous response format that had to be mended by dichotomizing responses. Moreover, due to the relatively brief assessment period, patients’ endorsement of LoDs related to longer-term developments of urinary incontinence could not be investigated. Also, this study would have benefited from partner-reports of patients’ LoDs to arrive at more proximal predictors of partners’ own emotional adaptation to support provision to patients. In addition to urinary incontinence, erectile dysfunctions are also a common sequel of radical prostatectomy. Future work should consider autonomy limitations due to these sexual dysfunctions. To accomplish this, larger time-frames should be considered, as recovery from sexual dysfunctions is less frequent and usually takes longer (Resnick et al., 2013). Finally, future work should study the LoD model within different patient populations who have to come to terms with varying prognoses and speed of decline or recovery.

Conclusions

Findings of this study indicate that a better fit between patients’ lines of defense and partner support has beneficial effects for patients’ and partners’ affective well-being.
