We report theoretical and experimental results for imaging of electromagnetic phase edge effects in lithography photomasks. Our method starts from the transport of intensity equation (TIE), which solves for phase from through-focus intensity images. Traditional TIE algorithms make an implicit assumption that the underlying in-plane power flow is curl-free. Motivated by our current study, we describe a practical situation in which this assumption breaks down. Strong absorption gradients in mask features interact with phase edges to contribute a curl to the in-plane Poynting vector, causing severe artifacts in the phase recovered. We derive how curl effects are coupled into intensity measurements and propose an iterative algorithm that not only corrects the artifacts, but also recovers missing curl components. © 2014 Optical Society of America

1. Introduction

The transport of intensity equation (TIE) describes how phase can be recovered from intensity images captured at different focus positions. Its experimental simplicity makes it amenable to existing microscopes in optical [1–6], x-ray [7,8], and electron [9–11] imaging. Subwavelength phase accuracy and real-time processing [12] are routinely achieved and errors can be reduced with multiple images [5,13,14]. One particularly convenient advantage of the TIE method is that it is fairly robust under partially coherent illumination [15,16], making it suitable for lithography aerial imaging tools, which we use here.

The TIE is directly derived from the paraxial wave equation to relate intensity variations over small defocus distances to gradients of phase as light propagates [1]. Being a partial differential equation, solving the TIE involves inverting the equation to recover phase. The traditional TIE solver has an implicit assumption that any curl component in the power flow is not captured in the intensity data. Thus, the TIE is thought to only recover the “scalar” part of the phase and fails for the “rotational” component [15,17]. In fact, the rotational (curl) component does affect the through-focus intensity and, therefore, causes phase artifacts in the traditional TIE solver. A standard example of a wave field with a curl is a phase vortex. This class of curl components has been studied in detail, and it was shown empirically that phase vortices can be recovered by either an iterative algorithm that uses many
images through-focus [18] or by modifying the traditional TIE solver [19], assuming small intensity gradients [20].

Here, we discuss a different class of curl effects (distinct from phase vortices) that arise in our application and in any situation where phase gradients are not collinear with intensity gradients. This case has been studied theoretically [21, 22], but a solution to the phase recovery problem was not presented. Here, we study the nonphysical phase recovery artifacts resulting from curl components induced by strong absorption. We then propose an iterative wrapper for the traditional TIE solver that corrects such errors to produce a more accurate phase result. This method was first described in [23, 24] and later appeared in [25]. We further derive how the curl component is coupled into the intensity measurements, and show that our proposed method also recovers part of the missing curl.

This work is motivated by our studies of electromagnetic phase edges in optical lithography masks [23, 24]. Unlike many other applications, photomasks are designed specifically to have strong absorption. An ideal mask would be infinitesimally thin, with no phase variations. Since material constraints mean that real-world masks are thick relative to the size of the feature, the optical field incurs unwanted 3D diffraction effects as it passes through the mask, termed “electromagnetic edge effects” [26–28] (Fig. 1). The result is that the field exiting the mask has added complex-field variations near the feature edges. The real component is easily measured as a line edge placement bias, but the phase component produces an asymmetrical, feature-dependent edge placement change through-focus, which is difficult to measure. As node sizes shrink, these undesired phase effects become more prominent and also more problematic, reducing the process window.

Mask designers often account for electromagnetic effects using an equivalent thin-mask model, which replaces the complicated 3D effects with a 2D complex field at the exit plane of the mask. For example, boundary layer models represent the added phase effects with quadrature (90 deg) phase strips along the feature edges [26–28], where the width of the strip depends on the mask shape and material. The phase edges are also polarization-dependent, being much stronger in the direction perpendicular to the electric field, so separate boundary layers must be used for each polarization.

In this work, we aim to physically measure phase edge effects using the TIE method in an aerial inspection tool. However, phase variations always occur at the edges of features, where intensity changes rapidly. Since the gradients of the intensity and phase are not collinear, significant curl components result near the feature corners, and we must correct the artifacts in order to recover the phase accurately.

2. Transport of Intensity Equation Solvers and Curl Effects

First, we describe the traditional TIE solver and derive how an absorption-induced curl can produce errors in the phase result. For a 2D complex object \( \sqrt{I e^{i\phi}} \) with intensity \( I \) and phase \( \phi \), the TIE describes the change of axial intensity as a divergence of the in-plane power flow [1, 2],

\[
\frac{dI}{dz} = -\frac{\lambda}{2\pi} \nabla \cdot I \nabla \phi.
\]

where \( \lambda \) is wavelength, \( \nabla \) is the lateral gradient, and \( z \) is the defocus distance. Thus, one can solve for phase after estimating the intensity derivative \( dI/dz \) from two or more intensity images at different \( z \).

Since \( \nabla, I, \) and \( \phi \) are in-plane, \( I \nabla \phi \) is the in-plane Poynting vector [15]. To solve Eq. (1), Teague’s solver [1] defines an auxiliary variable \( \psi \) such that \( I \nabla \phi = \nabla \psi \), which converts the TIE into a Poisson equation,

\[
\frac{dI}{dz} = -\frac{\lambda}{2\pi} \nabla^2 \psi.
\]

Equation (2) can use any Poisson solver (e.g., in the Fourier domain [29]) to solve for the auxiliary variable \( \psi \). Substituting this value back into its relation with phase gives \( \nabla \phi = \nabla \psi / I \), and taking another divergence yields a Poisson equation in phase,

\[
\nabla \cdot (\nabla \psi / I) = \nabla^2 \phi.
\]
intensity (e.g., a pure phase object), \( I(x, y) = I_0 \), and the phase is recovered directly after solving the first Poisson equation, \( \phi = \psi / I_0 \).

It has been noted \([21,22]\) that substituting the Poynting vector with the gradient of a scalar field [to obtain Eq. (2)] makes the implicit assumption that the Poynting vector is curl-free, requiring collinearity of the phase and intensity gradients:

\[
\vec{\nabla} \times (I \vec{\nabla} \phi) = \vec{\nabla} I \times \vec{\nabla} \phi = 0. \tag{4}
\]

As described previously, photomasks have both strong absorption and phase at the edges of features, resulting in a significant curl component (i.e., noncollinear phase and intensity gradients). This is illustrated in Fig. 2 for a simulated OMOG (Opaque MoSi on Silica)-type mask with a 2% transmitting block on a clear background. To model electromagnetic edge effects for horizontally polarized illumination, we add a boundary layer of width 20 nm with a 90° quadrature phase along the vertical direction. In this simulation, parameters have been chosen to match those of our experiment, described later. We use a deep UV wavelength \( \lambda = 193 \) nm, NA 1.35 at the wafer (0.3375 at the mask), and illumination coherence \( \sigma = 0.3 \). Since the phase strips are much smaller than the resolution of the optical system, they become blurred and result in smaller peak phase values. Here, we directly observe that the gradients of the intensity and phase are noncollinear at the corners, leading to a non-negligible curl for the in-plane Poynting vector, \( \vec{V} I \times \vec{V} \phi \neq 0 \). The curl components for this simulated mask are shown in Fig. 2, along with the phase recovered by Teague’s solver (using the Poisson solver in \([29,30]\)). This phase result incurs a significant error, due to curl effects.

To calculate the phase error due to the missing curl, consider the Helmholtz decomposition of the Poynting vector, with curl-free and divergence-free source terms \([15]\),

\[
I \vec{V} \phi = \vec{V} \psi + \vec{V} \times \vec{A}_1, \tag{5}
\]

where \( \psi \) and \( \vec{A}_1 \) are the scalar and vector potentials of the power flow, respectively. Since the TIE describes the divergence of the Poynting vector, the first Poisson equation \([\text{Eq. (2)}]\) of Teague’s solution is uniquely and exactly solved for the scalar potential \( \psi \), given appropriate boundary conditions. In the presence of a vector potential for the Poynting vector \([\text{Eq. (5)}]\), however, the second Poisson equation in Teague’s solution \([\text{Eq. (3)}]\) has an extra term due to the curl,

\[
\nabla \cdot \vec{V} \psi / I + \nabla \cdot \vec{V} \times \vec{A}_1 / I = \nabla^2 \phi, \tag{6}
\]

\[
\Rightarrow \nabla^2 \phi_{\text{TIE}} + \nabla^2 \phi_{\text{res}} = \nabla^2 \phi, \tag{7}
\]

where \( \phi_{\text{TIE}} \) is the phase returned by Teague’s solver and \( \phi_{\text{res}} \) is the residual error that occurs due to the curl component, shown in Fig. 2 to create a severe saddle-shaped artifact for a square feature.

3. Recovering Curl by Iterative Transport of Intensity Equation

Next, we describe our algorithm and prove analytically that the curl components of the power flow are not entirely lost in through-focus measurements, and can thus be recovered computationally. We demonstrate this on the simulated photomask described above, as well as in experimental measurements, showing its efficacy in the presence of strong absorption.

Our algorithm iterates back and forth through Teague’s solver, estimating both the phase and the curl component at each step. In the first step, we obtain an initial phase estimate using Teague’s method, \( \phi_{\text{TIE}} \), then plug it back into the TIE to estimate the axial intensity derivative that would have been produced by \( \phi_{\text{TIE}} \),

\[
a df \bigg|_{\text{est}} = -\frac{\lambda}{2\pi} \nabla \cdot \vec{V} \phi_{\text{TIE}}. \tag{8}
\]

The residual intensity derivative is then obtained by calculating the difference between the estimated and measured intensity derivatives.
and is expected to be 0 in the absence of curl, notwithstanding numerical errors and noise. The residual intensity derivative is then used as input to Teague’s solver for estimating the phase residual,

\[
\frac{dI}{dz}_{\text{res}} = \frac{dI}{dz} - \frac{dI}{dz}_{\text{est}},
\]

where \( \phi_{\text{est}} \) is the current estimate of the phase residual \([\phi_{\text{res}} \text { in Eq. (7)}] \), after the first iteration. The phase residual estimated is then subtracted from the phase \( \phi_{\text{res}} \) estimated previously to give an improved phase estimate. Additional iterations can then be used to further refine the result.

To understand how the curl of the Poynting vector couples into the next iteration of Teague’s solver, we examine the intensity derivative residual in Eq. (9). Consider the Helmholtz decomposition of the vector field \( \vec{\nabla} \psi/I \),

\[
\vec{\nabla} \psi/I = \vec{\nabla} \phi_{\text{res}} + \vec{\nabla} \times \hat{A}_2,
\]

where the scalar potential is simply \( \phi_{\text{res}} \) according to Eq. (3), and \( \hat{A}_2 \) denotes the vector potential. By substituting Eqs. (2) and (8) into Eq. (9), and considering the relation in Eq. (11), we obtain

\[
\frac{dI}{dz}_{\text{res}} = -\frac{\lambda}{2\pi} \vec{\nabla} \cdot \vec{I} \vec{e} \phi_{\text{res}},
\]

\[
\Rightarrow \frac{dI}{dz}_{\text{res}} = -\frac{\lambda}{2\pi} \vec{\nabla} \cdot \vec{I} \vec{e} \phi_{\text{res}}.
\]

The curl term \( \vec{\nabla} \times \hat{A}_2 \) is thus responsible for the derivative residual on plugging the solved phase back into the TIE. The TIE solution of the residual intensity derivative [Eq. (10)] will try to estimate the error arising due to this curl, which is in fact directly related to the Poynting vector curl \( \vec{\nabla} \times \hat{A}_1 \) from Eqs. (5) and (11),

\[
\vec{\nabla} \times \vec{\nabla} \times \hat{A}_2 = -\vec{\nabla} \times \left( \frac{\vec{\nabla} \times \hat{A}_1}{I} \right).
\]

which holds also for vector potentials of any two successive iterations. In the absence of a curl in the power flow, \( \hat{A}_1 = \hat{A}_2 = 0 \), and hence, the residual intensity derivative vanishes such that the solution converges immediately. In the presence of a curl, however, subsequent iterations will recover some of the curl missed in the previous iteration, the solution reaching convergence when the estimate of the phase gradient at the \( i \)th iteration, \( \vec{\nabla} \psi_1/I \), approaches zero curl, i.e., \( \hat{\lambda}_{i+1} \rightarrow 0 \). A more rigorous formulation of the convergence criteria would have to include the interplay of the object curl, numerical and focus sampling, and the severity of the curl.

A simulation of the phase residual estimated from the first iteration is shown in Fig. 3. After only one iteration, the improved phase estimate is already very close to the true phase (shown in Fig. 2), with the root mean square (RMS) phase error having dropped by about 42%, from 0.0087 rad/pixel for Teague’s solver to 0.005 rad/pixel for our iterative algorithm. Subsequent iterations further improve the estimate of the phase and its residual.

Since the reduction in the error is due to the recovery of the curl, our algorithm also produces an estimate of the curl components, which were previously considered immeasurable. For the simulation case (where the true curl components are known), we plot the error in our curl estimate as iterations progress (see Fig. 4). The plots compare the Poynting vector curl, \( \vec{\nabla} \times \vec{I} \vec{e} \phi \), with that recovered by the iterative method. As expected, the error in the curl is progressively reduced, with diminishing gains at each iteration. Notice that the error does not go to 0, since not all of the curl effects were transferred into intensity measurements. However, these unobservable areas of the curl do not produce phase errors in our result. If the goal is to fully measure the curl terms, then a systematic variation of the intensity would be needed [31,32].

### 4. Experimental Results

Experiments were performed on an AIMS aerial imaging tool at AMTC/Toppan Photomasks at Dresden, Germany. The AIMS tool replicates the projection printing process, with demagnification to allow the wafer plane intensity to be captured by a camera. The experimental parameters and the mask match the simulations described earlier (240 nm square feature on an OMOG mask). Here, we use partially coherent illumination with \( \sigma = 0.3 \), which has been shown to produce accurate phase results [4], although larger or nonrotationally symmetric.
sources [2, 23] would require more sophisticated algorithms [34–37]. Images were captured with 10 nm defocus steps across a 200 nm range, building up a through-focus stack. Then, the intensity derivative was calculated using the fitting methods described in [6, 14]. Note that although the TIE equation is based on the paraxial approximation, it is justified for the mask-side NA of 0.3375 in the experiments here. More details on the experimental setup can be found in [23].

Images of the experimentally recovered phase are shown in Fig. 5. We clearly observe electromagnetic phase edge effects in all the results. In the experiments, we study two situations, one with horizontally polarized illumination and one with vertically polarized illumination. The phase recovered shows much stronger phase edge effects along the direction perpendicular to the illumination polarization, as predicted by rigorous electromagnetic field simulations [38].

In comparing our iterative algorithm to the traditional TIE method, we see that the phase images recovered by Teague’s solver have saddle-shaped artifacts that cause negative phase values. These clearly nonphysical artifacts resemble the error seen in simulation results in the earlier sections, indicating that they are indeed due to the power flow curl near the corners of the square feature. With our iterative solver, however, they are removed and we get a much cleaner picture of the phase edge effects.

The results match well the rigorous simulation-based boundary layer model theory [38], which assumes that the peak phase value of 40 deg in Fig. 5 is a convolution of the 90 deg boundary layer with the point spread function of the system. The smaller phase peaks for the edges parallel to the electric field in Fig. 5 likely indicate that OMOG is similar to attenuating phase shift mask (ATT-PSM), in that the diffraction at the primary edge reduces with the rotation of the polarization and the phase drops in magnitude by about a factor of 5. A detailed analysis can be found in [23].

5. Conclusion

We have demonstrated both theoretically and experimentally an iterative extension to the Transport of Intensity method that provides both accurate phase recovery and an estimate of the Poynting vector curl. Our method is particularly useful for the situation of curl-induced artifacts due to strong absorption, for which we provide a motivating example in lithography. We show that phase edge effects due to 3D electromagnetic interactions break the curl-free assumption of the traditional TIE (Teague’s method). However, by employing our iterative TIE solver, we can remove these artifacts and can also solve for curl components in the process. The solution removes...
curl-induced phase errors with only a few iterations, providing significantly improved results without much computational overhead. Results were demonstrated for a square feature on an OMOG mask, with experimental data being captured in an aerial imaging tool. The method serves to elucidate the influence of power-flow curl on defocus-based phase recovery, and should find general use in many applications, particularly those with strong absorption at the sample.
