The relationship between dietary factors and liver disease remains poorly understood. This study evaluated the associations of whole grain and dietary fiber intake with liver cancer risk and chronic liver disease mortality. The National Institutes of Health–American Association of Retired Persons Diet and Health Study cohort recruited 485,717 retired U.S. participants in 1995–1996. Follow-up through 2011 identified 940 incident liver cancer cases and 993 deaths from chronic liver disease. Compared with the lowest, the highest quintile of whole grain intake was associated with lower liver cancer risk (Hazard ratio [HR]_{Q5 vs. Q1} = 0.78, 95% confidence interval [CI]: 0.63–0.96) and chronic liver disease mortality (HR_{Q5 vs. Q1} = 0.44, 95% CI: 0.35–0.55) in multivariable Cox models. Dietary fiber was also associated with lower liver cancer risk (HR_{Q5 vs. Q1} = 0.69, 95% CI: 0.53–0.90) and chronic liver disease mortality (HR_{Q5 vs. Q1} = 0.37, 95% CI: 0.29–0.48). Fiber from vegetables, beans and grains showed potential protective effect. Here, we show that higher intake of whole grain and dietary fiber are associated with lower risk of liver cancer and liver disease mortality.

Primary liver cancer is the sixth most common cancer and the third most common cause of cancer-related mortality worldwide¹, and its incidence and mortality have been increasing in the United States². The five-year survival rate of liver cancer has only improved from 11.7% to 21.3% during 2000–2011³, suggesting the importance of primary prevention for this fatal disease. Hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (ICC) are the two most common histologic types of primary liver cancer, accounting for 75–80% and 10–15% of cases, respectively^{4,5}. Major known risk factors for HCC include chronic hepatitis B virus (HBV) infection, chronic hepatitis C virus (HCV) infection, aflatoxin, heavy alcohol consumption, tobacco smoking, obesity, nonalcoholic fatty liver disease (NAFLD), and type 2 diabetes mellitus (T2DM)^{6,7}. These factors are also associated, although not as strongly, with ICC. Certain biliary tract conditions, including choledochal cyst, cholelithiasis, and cholelithiasis, are strongly associated with ICC⁸. Chronic liver diseases (CLD), including cirrhosis, fibrosis, alcoholic liver disease, and chronic hepatitis, are important precursors of HCC. Additionally, CLD may lead to death itself and is also a significant public health concern⁹. Non-HBV/non-HCV-related HCC is common in the U.S., with the etiology poorly understood⁶. More HCC and CLD are probably attributable to obesity, T2DM and NAFLD in this population⁶, which are closely associated with behaviors including dietary patterns and composites. Thus, identifying dietary factors that could reduce the risk of liver cancer and CLD mortality is of interest. However, to date, such research is limited^{10,11}.

Whole grains contain the endosperm, as do refined grains, but also bran and germ. Thus, whole grains serve as valuable food sources of dietary fiber, vitamin B, E, selenium, zinc, copper, magnesium, and phytochemicals¹². Whole grains and dietary fiber have long been considered beneficial in lowering the risks of T2DM^{13,14}, cardiovascular diseases^{15,16}, and some types of human cancers^{17–20}. Intake of whole grains has also shown a potential beneficial impact on the risk or progression of NAFLD^{21,22}. A recent systematic review suggested a protective role for whole grain intake in HCC risk²³. So far, two prospective cohort studies have reported inverse associations between dietary fiber intake and liver cancer risk^{24,25}, and one reported an inverse association for whole grain intake²⁵. However, these two studies included a limited number of cases. Specifically, the European Prospective Investigation into Cancer and Nutrition (EPIC) included 191 HCC and 66 ICC, while the Nurses' Health Study (NHS) and the Health Professionals Follow-up Study (HPFS) included 141 HCC cases. No study has yet examined the association between whole grain and dietary fiber intake and risk of CLD death.

In this work, we report inverse associations of whole grain and dietary fiber intake with both incident liver cancer and CLD deaths by utilizing the National Institutes of Health (NIH)–American Association of Retired Persons (AARP) Diet and Health Study with over 900 cases each.

Results

Baseline characteristics of the cohort participants. A total of 290,484 men (59.8%) and 195,233 (40.2%) women were included in this study. The mean age at study entry was 61.5 years old (SD = 5.4 y). The majority of the participants were white (92.8%), and 39.8% had, at least, a college degree or above. Participants in the highest quintile of whole grain intake or total dietary fiber intake compared with those in the lowest quintile were more physically active, had lower alcohol and tobacco consumption, and were more likely to have a self-reported history of diabetes (Table 1). Similar patterns were also observed for men (Supplementary Table 1) and for women (Supplementary Table 2).

Table 1 Baseline characteristics according to whole grain and total fiber intake among participants of National Institute of Health, American Association of Retired Persons (NIH–AARP) Diet and Health Study.

Values are means (SD) for continuous variables, percentages for categorical variables, and are standardized to the age distribution of the study population. *Value is not age-adjusted.

Whole grain, dietary fiber intake, and risk of liver cancer. After a median follow-up time of 15.5 years, a total of 940 participants developed primary liver cancer, including 635 HCC and 164 ICC. Whole grain intake was associated with a 22% risk reduction of liver cancer (HR_{Q5 vs. Q1} = 0.78, 95% CI: 0.63–0.96, *P*_{trend} = 0.01) after multivariable adjustment. Total dietary fiber intake was associated with 31% risk reduction (HR_{Q5 vs. Q1} = 0.69, 0.53–0.90, *P*_{trend} < 0.001) (Table 2). For different sources of fiber, significantly inverse associations were observed for vegetables (HR_{Q5 vs. Q1} = 0.65, 95% CI: 0.52–0.83, *P*_{trend} < 0.001) and grains (HR_{Q5 vs. Q1} = 0.78, 95% CI: 0.62–0.99, *P*_{trend} = 0.04), but not for fruits (HR_{Q5 vs. Q1} = 0.94, 95% CI: 0.76–1.17, *P*_{trend} = 0.82) or beans (HR_{Q5 vs. Q1} = 0.89, 95% CI: 0.71–1.10, *P*_{trend} = 0.02). The inverse associations for total dietary fiber and fiber from vegetables were observed for men (Supplementary Table 3), and to a less extent for women (Supplementary Table 4). Significant inverse associations were found between total dietary fiber and fiber from vegetables and risk of HCC (Supplementary Table 5), but not risk of ICC (Supplementary Table 6).

In stratified analyses, the inverse associations of whole grains and risk of liver cancer were generally observed in different subgroups (Fig. 1).

Whole grain, dietary fiber intake, and CLD mortality. A total of 993 CLD deaths were identified. Whole grain intake was associated with a 56% reduction of CLD mortality (HR_{Q5 vs. Q1} = 0.44, 95% CI: 0.35–0.55, *P*_{trend} < 0.001) after multivariable adjustment. Total dietary fiber intake was associated with a 63% reduction of CLD mortality (HR_{Q5 vs. Q1} = 0.37, 95% CI: 0.29–0.48, *P*_{trend} < 0.001) (Table 3). For different sources of fiber, the inverse

associations were observed for vegetables (HR_{Q5 vs. Q1} = 0.55, 95% CI: 0.44–0.69, *P*_{trend} < 0.001), beans (HR_{Q5 vs. Q1} = 0.67, 95% CI: 0.54–0.84, *P*_{trend} = 0.03) and grains (HR_{Q5 vs. Q1} = 0.29, 95% CI: 0.23–0.36, *P*_{trend} < 0.001), but not for fruits (HR_{Q5 vs. Q1} = 0.98, 95% CI: 0.79–1.20, *P*_{trend} = 0.92). Similar results were observed in both men (Supplementary Table 7) and women (Supplementary Table 8).

In stratified analyses, the significant inverse associations of whole grain, dietary fiber, and CLD mortality were observed across most subgroups (Fig. 2).

Sensitivity analyses observed similar results. In sensitivity analyses, most of the inverse associations for risk of liver cancer and CLD mortality remained essentially unchanged when we further adjusted for HEI-2015, or excluded cases diagnosed within the first 2 or 5 years of follow-up, or excluded heavy alcohol drinkers.

Discussion

In this cohort study, participants with the highest quintile of whole grain intake had a 22% reduced risk of liver cancer and a 56% reduction in CLD mortality. Participants with the highest quintile of total dietary fiber intake had a 31% reduced risk of liver cancer and a 63% reduction in CLD mortality. These inverse associations were observed for fiber from vegetables, beans, and grains but not from fruits.

A recent systematic review reported an inverse association between higher whole grain intake and HCC risk²³. Thus far, two cohort studies have reported associations between dietary fiber intake and risk of liver cancer. The European Prospective Investigation into Cancer and Nutrition (EPIC) (*n* = 191 HCC cases)

The SDs of intake were 0.86 oz/day for whole grains, 10.9 g/day for total dietary fiber, 3.6 g/day for fiber from fruits, 4.8 g/day for fiber from vegetables, 2.9 g/day for fiber from beans, and 4.0 g/day for fiber from grains.

Cox proportional hazard regression models were used. All *P*-values were two-sided. Model 1 were stratified by sex, adjusted for age at baseline (continuous). Model 2 further adjusted for level of education ('≤11 years', 'high school', 'vocational technology school', 'some college', 'college/postgraduate'), race ('non-Hispanic white', 'non-Hispanic black', 'Hispanic', 'Asian, Pacific Islander, or American Indian/Alaskan native'), BMI ('<25', '25-30', '30+' kg/m²), alcohol use ('non-drinker', '0.1-4.9', '5-9.9', '10+' gram/day), tobacco smoking ('never smoked', 'former smoker', 'current smoker'), physical activity ('never', 'rarely', '1-3 times per month', '1-2 times per week', '3-4 times per week', '5+ times per week'), history of diabetes ('no', 'yes') and total energy intake (continuous).

Fig. 1 Stratified analyses for association between whole grain and dietary fiber intake with risk of liver cancer among the participants of NIH-AARP Diet and Health Study. Cox proportional hazard regression models were used. All *P*-values were two-sided. Models were stratified by sex and adjusted for age at baseline (continuous), level of education (' ≤ 11 years', 'high school', 'vocational technology school', 'some college', 'college/postgraduate'), race ('non-Hispanic white', 'non-Hispanic black', 'Hispanic', 'Asian, Pacific Islander, or American Indian/Alaskan native'), BMI (' < 25 ', '25-30', '30+' kg/m²), alcohol use ('Non-drinker', '0.1-4.9', '5-9.9', '10+' g/day), tobacco smoking ('never smoked', 'former smoker', 'current smoker'), physical activity ('never', 'rarely', '1-3 time per month', '1-2 times per week', '3-4 times per week', '5+ times per week'), history of diabetes ('no', 'yes') and total energy intake (continuous), except when the variable is used for stratification. The *P* for interaction between whole grain or fiber intake and characteristics for stratification in risk of liver cancer were as follows: Whole grain: 0.22 for BMI, 0.25 for diabetes, 0.20 for alcohol use, 0.42 for smoking, and 0.98 for physical activity. Total fiber: 0.87 for BMI, 0.18 for diabetes, 0.02 for alcohol use, 0.76 for smoking, and 0.53 for physical activity. Fiber from fruits: 0.71 for BMI, 0.36 for diabetes, < 0.01 for alcohol use, 0.41 for smoking, and 0.29 for physical activity. Fiber from vegetables: 0.68 for BMI, 0.54 for diabetes, 0.05 for alcohol use, 0.37 for smoking, and 0.57 for physical activity. Fiber from beans: 0.15 for BMI, 0.33 for diabetes, 0.35 for alcohol use, 0.63 for smoking, and 0.02 for physical activity. Fiber from grains: 0.69 for BMI, 0.02 for diabetes, 0.44 for alcohol use, 0.51 for smoking, and 0.23 for physical activity. Abbreviations: BMI body mass index; SD standard deviation; NIH-AARP: National Institutes of Health-American Association of Retired Persons.

reported significant associations for total fiber (HR_{Q4 vs. Q1} = 0.51, 95% CI: 0.31-0.83) and fiber from cereals, but not from vegetables, fruits, and other sources²⁴. The Nurses' Health Study (NHS) and the Health Professionals Follow-up Study (HPFS) ($n = 141$ HCC cases) reported a suggestive association between fiber from cereals (HR_{T3 vs. T1} = 0.68, 95% CI: 0.45-1.03, $P_{\text{trend}} = 0.07$), but not fiber from fruits or vegetables and HCC risk²⁵. Moreover, the NHS/HPFS study also found an inverse association between whole grain intake and HCC risk (HR_{T3 vs. T1} = 0.63, 95% CI: 0.41 to 0.96)²⁵. In this current study, no association was found for fiber from fruits, and an inverse association was found for whole grains and total fiber, which were consistent with the observation from the EPIC²⁴ and NHS/HPFS studies²⁵. Moreover, inverse associations were observed for fiber from vegetables and grains in this study, adding to the knowledge that fiber from different food sources might have different associations with liver cancer. Furthermore, this study reports the inverse associations between whole grains, total dietary fibers, fibers from vegetables, and grains with CLD mortality, expanding the potential benefit of whole grain and dietary fiber intake from the risk of liver cancer to a wide range of chronic liver diseases.

The biologic mechanisms for the inverse associations of whole grains and dietary fiber with the liver disease remain to be fully elucidated. Whole grains are good sources of dietary fiber, resistant starch, and oligosaccharides, which may increase stool bulk, speed intestinal transit and reduce the exposure to

carcinogens in the colon³⁵. Whole grains contain antioxidants and phytoestrogens and have been reported to have a protective effect among certain gastrointestinal cancers and hormone-sensitive cancers³⁶. Dietary fiber has been reported to have beneficial effects on conditions related to liver disease and liver cancer, including blood glucose³⁷, insulin sensitivity³⁷, liver fat content³⁸, and metabolic syndrome³⁹⁻⁴¹. Oligosaccharides as fermentable carbohydrates are fermented in the colon and increase the production of short-chain fatty acids, which are important in the maintenance of gut integrity and regulation of inflammation^{36,42}. Recent studies discovered that the effects of dietary fiber might be mediated by the alteration in gut microbiota, such as an increased abundance of *Prevotella*, *Treponema*, and *Succinivibrio*⁴³⁻⁴⁵. Moreover, increasing evidence revealed the existence of a gut-liver axis, which exchanges signals between the bowel and liver. The portal vein allows transporting products generated by microbial communities to the liver, and the microbial communities are critical in the homeostasis of the gut-liver axis. Given that evidence accumulates for the pathogenic role of microbe-derived metabolites in NAFLD, a similar mechanism may apply to more advanced liver diseases⁴⁶. Our results also found heterogeneous associations for fiber from different food sources. Beans, vegetables, and fruits are good sources of dietary fiber. Interestingly, fiber from fruits did not show an inverse association with liver disease mortality, as did fiber from other sources. Although the underlying mechanism was unclear,

The SDs of intake were 0.86 oz/day for whole grains, 10.9 g/day for total dietary fiber, 3.6 g/day for fiber from fruits, 4.8 g/day for fiber from vegetables, 2.9 g/day for fiber from beans, and 4.0 g/day for fiber from grains.

Cox proportional hazard regression models were used. All P-values were two-sided. Model 1 were stratified by sex, adjusted for age at baseline (continuous). Model 2 further adjusted for level of education ('≤11 years', 'high school', 'vocational technology school', 'some college', 'college/postgraduate'), race ('non-Hispanic white', 'non-Hispanic black', 'Hispanic', 'Asian, Pacific Islander, or American Indian/Alaskan native'), BMI ('<25', '25-30', '30+', kg/m²), alcohol use ('Non-drinker', '0.1-4.9', '5-9.9', '10+', gram/day), tobacco smoking ('never smoked', 'former smoker', 'current smoker'), physical activity ('never', 'rarely', '1-3 time per month', '1-2 times per week', '3-4 times per week', '5+ times per week'), history of diabetes ('no', 'yes') and total energy intake (continuous).

excess fructose has been reported to be associated with increased insulin resistance, fatty acid production, oxidative stress, and fatty liver⁴⁷. Fruits high in fructose might cancel out the beneficial effect of fiber due to an adverse effect of fructose⁴⁸. Collectively, our study suggests that the inverse association between dietary fiber and liver disease mortality may vary depending on the source of fiber. More investigation is needed to further clarify the potential mechanisms.

The present study is the largest cohort study to date to evaluate the associations between whole grain and dietary fiber intake with liver cancer risk. In addition, it reports an association between dietary fiber intake and CLD mortality. With the large sample size, dietary fiber from different food sources was examined in detail, and two major subtypes of primary liver cancer (i.e., HCC and ICC) were studied. Many of the important lifestyle confounders for liver cancer and CLD, including age, alcohol, tobacco use, obesity, and diabetes, were included in the analyses. However, there are several limitations to this study. First, as important risk factors for liver cancer and CLD, HBV/HCV was not measured in the full cohort, neither was information on history of hepatitis collected. It is estimated that the prevalence is 0.1% for HBV and 1.0% for HCV in the US population^{49,50}. Using the data from the Liver Cancer Pooling Project and NHS/HPFS cohorts, we and others have reported no correlations between HBV/HCV infections with BMI⁵¹, smoking⁵², alcohol use⁵², coffee intake⁵³, fiber²⁵, nuts⁵⁴, fatty acids⁵⁵, dairy foods⁵⁶, or meats⁵⁷. Furthermore, previous studies have reported similar findings with or without adjustment for HBV/HCV for associations of liver cancer risk with tooth loss⁵⁸, fish intake⁵⁹, and coffee⁶⁰. Thus, the relationship between diet and liver cancer risk in this study is unlikely to be substantially confounded by HBV/

HCV infection status. Second, whole grain and dietary fiber intake were derived from the self-reported FFQ. The FFQ was validated by using two non-consecutive 24-h dietary recalls. The energy-adjusted correlation coefficients for dietary fiber intake were 0.72 among men and 0.66 among women³¹. Measurement errors cannot be ruled out. We examined the associations for dietary fiber and whole grain based on ranking instead of absolute intake levels, because the FFQ is better suited to ranking according to relative intake than assessing precise intake quantitatively. Third, the food intake questionnaire was self-administered at baseline. Thus, the change of diet during the follow-up was not recorded or analyzed. We cannot evaluate the associations between changes of whole grain and dietary fiber intake with the outcomes. Fourth, people who had higher whole grain or fiber intake were more likely to have a healthier diet and lifestyle overall, which might contribute to the reduced risk. Residual confounding might exist. Fifth, in this analysis, the outcomes of interest were liver cancer incidence and CLD mortality. While it would have been ideal for examining CLD incidence in addition to mortality, CLD registries do not exist in the US, nor is there a single medical records system to permit the identification of CLD diagnoses. As a result, CLD mortality was analyzed in the current study. Finally, the study participants are predominantly persons of European ancestry and are individuals aged 50–71 years old at the beginning of the follow-up, which potentially limited the generalizability of the results to other populations.

In conclusion, we found significant inverse associations between whole grain and dietary fiber intake with liver cancer incidence and CLD mortality in a US population. The associations between dietary fiber were particular for fiber from

Fig. 2 Stratified analyses for association between whole grain and dietary fiber intake with CLD mortality among the participants of NIH-AARP Diet and Health Study. Cox proportional hazard regression models were used. All *P*-values were two-sided. Models were stratified by sex and adjusted for age at baseline (continuous), level of education ('≤11 years', 'high school', 'vocational technology school', 'some college', 'college/postgraduate'), race ('non-hispanic white', 'non-hispanic black', 'hispanic', 'asian, Pacific Islander, or American Indian/Alaskan native'), BMI ('<25', '25-30', '30+', kg/m²), alcohol use ('non-drinker', '0.1-4.9', '5-9.9', '10+', gram/day), tobacco smoking ('never smoked', 'former smoker', 'current smoker'), physical activity ('never', 'rarely', '1-3 time per month', '1-2 times per week', '3-4 times per week', '5+ times per week'), history of diabetes ('no', 'yes') and total energy intake (continuous), except when the variable is used for stratification. The *P* for interaction between whole grain or fiber intake and characteristics for stratification in CLD mortality were as follows: Whole grain: 0.01 for BMI, 0.07 for diabetes, <0.01 for alcohol use, <0.01 for smoking, and 0.73 for physical activity. Total fiber: 0.03 for BMI, 0.05 for diabetes, <0.01 for alcohol use, 0.96 for smoking, and 0.52 for physical activity. Fiber from fruits: <0.01 for BMI, 0.10 for diabetes, <0.01 for alcohol use, 0.97 for smoking, and 0.16 for physical activity. Fiber from vegetables: 0.83 for BMI, 0.11 for diabetes, 0.72 for alcohol use, 0.63 for smoking, and 0.76 for physical activity. Fiber from beans: 0.87 for BMI, 0.84 for diabetes, 0.23 for alcohol use, 0.07 for smoking, and 0.07 for physical activity. Fiber from grains: <0.01 for BMI, 0.13 for diabetes, <0.01 for alcohol use, 0.15 for smoking, and 0.40 for physical activity. Abbreviations: BMI body mass index; SD standard deviation; NIH-AARP National Institutes of Health-American Association of Retired Persons.

vegetables, beans, and grains. These findings, if confirmed by future studies, indicate that a diet rich in whole grain and dietary fiber could be recommended for reducing liver cancer incidence and CLD mortality. Further studies are warranted to clarify the underlying mechanisms and determine specific dietary components associated with benefit in diverse racial/ethnic populations.

Methods

Study population. The NIH-AARP Diet and Health Study recruited men and women aged 50-71 years old by mailing questionnaires to its 3.5 million members from six US states (California, Florida, Louisiana, New Jersey, North Carolina, and Pennsylvania) and two metropolitan areas (Atlanta, GA and Detroit, MI) in 1995-1996²⁶. A total of 566,398 persons (339,666 men and 226,732 women) returned the baseline questionnaire and were included in the final cohort. In this analysis, we excluded participants with: (1) prevalent cancer ($n = 50,118$) at baseline; (2) extreme caloric intakes (<500, or >3,500 for women; <800, or >4,000 for men; $n = 29,983$); and (3) participants who were diagnosed with liver cancer or died from CLD before their baseline survey questionnaires were scanned ($n = 580$). Thus, the analytic cohort included 485,717 (290,484 men and 195,233 women). The study was approved by the Special Studies Institutional Review Board of the U.S. National Cancer Institute. Informed consent has been obtained from all participants.

Case ascertainment

Liver cancer. Cases of primary liver cancer (defined by International Classification of Diseases, 10th edition [ICD-10] diagnostic code C22) were identified by linkage with state cancer registries through December 31st, 2011²⁶. Cases of HCC were further defined by morphology codes 8170-8175. Cases of ICC were defined by morphology codes 8032, 8033, 8070, 8071, 8140, 8141, 8160, 8161, 8260, 8480,

8481, 8490 and 8560²⁷. Prior examination reported that these codes have a sensitivity of 90% and a specificity of nearly 100% for cancer identification²⁸.

Deaths due to chronic liver diseases. The National Death Index Plus (NDIP) was used to identify causes of death through December 31st, 2011. Consistent with previous studies in the same cohort^{28,29}, deaths due to chronic liver diseases included deaths from fibrosis, cirrhosis, alcoholic liver diseases, and chronic hepatitis (ICD-9: 571.0, 571.2-571.6, 571.8, and 571.9; ICD-10: K70, K73, and K74). Classification of CLD from the NDIP was validated using the electronic medical records from members of the Kaiser Permanente Medical Care Program of Northern California, and specificity was found to be 89%³⁰.

Dietary assessment. The information on diet was collected via a 124-item food-frequency questionnaire (FFQ)²⁶. The FFQ was validated among 2,000 NIH-AARP participants using two 24-h dietary recalls and a second FFQ^{26,31}. The energy-adjusted correlation coefficients for dietary fiber intake were 0.72 in men and 0.66 in women³¹. Food groups were created with the MyPyramid Equivalents Database (MPED) version 1.0, and component ingredients were disaggregated from food mixtures, assigned to food groups, and calculated to cup or ounce equivalents³². Nutrients were calculated with the 1994-1996 U.S. Department of Agriculture's Continuing Survey of Food Intakes by Individuals (CSFII)³³. The assessments of whole grain and fiber intake were described in the previous study from the same cohort³⁴. Specifically, whole grains were defined and extracted as the whole grain part of each food item, including ready-to-eat cereals, high-fiber cereals, cooked cereals, other fiber cereals, whole-grain bread or dinner rolls, popcorn, pancakes, waffles, French toast or crepes, rice, or other cooked grains, bagels, English muffins, tortillas, pasta, crackers, chips, cookies, or brownies, sweet pastries, and pies. Whole grain intake was presented as MPED number of whole grains in ounce equivalents per day (oz eq/day). The USDA's Pyramid Servings Database was used to estimate whole grain intake from all foods collected in the FFQ, even from those foods with small amounts of whole grain. Total fiber from fruits, vegetables, beans and grains

was estimated by summing dietary fiber from these foods. In the questionnaire, the participants were asked about the frequency and amount of intake for different kinds of vegetables and fruits. They were also asked about beans including 'beans, such as baked beans, refried beans, pintos, kidney, lima, lentils, or soybeans (not including bean soup)' and 'bean-based soups'. For fruits and vegetables, a 1-cup equivalent is defined as 1-cup raw or cooked fruits or vegetables, 1-cup fruit or vegetable juice, 0.5 cup dried fruits, or 2-cups leafy greens. For beans, a 1-cup equivalent is defined as 1-cup cooked dry beans or peas. For grains, a 1-ounce equivalent is defined as one regular slice of yeast bread, or 0.5-cup rice, pasta, or cooked cereal, or 1 cup ready-to-eat cereal. The equivalents were further converted into gram amounts³².

Covariate assessment. Socio-demographic characteristics including age, race (self-reported), weight, height, level of education, and other potential risk factors including tobacco smoking, alcohol drinking, physical activity, self-reported history of diabetes were also collected in the baseline questionnaire²⁶. Participants reported their highest level of education from the following categories: <8 years; 8–11 years; 12 years, or completed high school; post-high school training other than college (e.g., vocational or technical training); some college; college graduate; postgraduate. The frequency and amount of reported alcohol consumption (including beer, wine, or wine coolers, and liquor or mixed drinks) were converted to grams per day in analyses. Participants reported whether they had ever smoked 100 or more cigarettes during lifetime and if they currently smoked or had stopped. Frequency (never, rarely, 1–3 times per month, 1–2 times per week, 3–4 times per week, 5+ times per week) in the past 12 months of physical activity at work or home (including exercise, sports, and activities such as carrying heavy loads) \geq 20 minutes that caused increases in breathing or heart rate or sufficient to work up a sweat was asked.

Statistical analyses. For liver cancer, person-years to the event was calculated for each participant from baseline to date of diagnosis of primary liver cancer, date of death, or end of follow-up (December 31st, 2011), whichever came the first. For CLD mortality, person-years to the event was calculated from baseline to date of CLD death, date of death from other reasons, or end of follow-up (December 31st, 2011), whichever came the first. Cox proportional hazard regression models were used to estimate hazard ratios (HRs) and 95% confidence intervals (CIs) for events comparing across quintile categories of whole grain or dietary fiber intake with the lowest intake quintile as the reference group. The proportional hazards assumption was tested using a cross-product term of log(time) and whole grain or dietary fiber intake; no violations were observed ($P > 0.05$). P for trend was calculated per SD increase in whole grain or dietary fiber intake. The associations of whole grain and fiber intake with liver cancer incidence and CLD mortality were not modified by sex (P for heterogeneity > 0.05). Therefore, we report pooled estimates, with sex-specific results presented in Supplementary Tables.

Multivariable models included the following a priori covariates: age at baseline (continuous), level of education (\leq 11 years; high school; vocational technology school; some college; college/postgraduate), race (non-Hispanic white; non-Hispanic black; Hispanic; Asian, Pacific Islander, or American Indian/Alaskan Native), body mass index (BMI; < 25 ; 25 – 30 ; ≥ 30 kg/m²), alcohol consumption (non-drinker; 0.1–4.9; 5–9.9; ≥ 10 g/day), tobacco smoking (never smoked; former smoker; current smoker), physical activity (never; rarely; 1–3 time per month; 1–2 times per week; 3–4 times per week; 5 or more times per week), self-reported history of diabetes (no; yes), and total energy intake (continuous).

Subgroup analyses were conducted across categories of BMI, self-reported history of diabetes, alcohol drinking, tobacco smoking, and physical activity. P for interaction was tested by introducing a product term of the two variables examined in the regression models.

In sensitivity analyses, the healthy eating index (HEI-2015) was added to the multivariable regression models to control for overall dietary quality. Second, we excluded cases diagnosed within the first 2 or 5 years of follow-up to address the possible reverse causation. We also excluded heavy alcohol drinkers, defined as men who consumed more than 4 drinks and women who consumed more than 3 drinks per day, to further control for confounding from alcohol drinking.

SAS 9.4 software was used for all analyses (SAS Institute Inc., Cary, NC, USA). All P -values were two-sided.

Reporting Summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Acknowledgements

This work was supported by the Intramural Research Program of Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health. X.Z. is supported by the National Institutes of Health (grant numbers K07 CA188126, R21CA238651), American Cancer Society Research Scholar Grant (grant number RSG NEC-130476), the Dana-Farber Harvard Cancer Center (DF/HCC) as well as the Zhu Family Center at Harvard Chan School. J.L.P. is supported by the Karin Grunbaum Cancer Research Foundation. Cancer incidence data from the Atlanta metropolitan area were collected by the Georgia Center for Cancer Statistics, Department of Epidemiology, Rollins School of Public Health, Emory University. Cancer incidence data from California were collected by the California Department of Health Services, Cancer Surveillance Section. Cancer incidence data from the Detroit metropolitan area were collected by the Michigan Cancer Surveillance Program, Community Health Administration, State of Michigan. The Florida cancer incidence data used in this report were collected by the Florida Cancer Data System (FCDS) under contract with the Florida Department of Health (FDOH). Cancer incidence data from Louisiana were collected by the Louisiana Tumor Registry, Louisiana State University Medical Center in New Orleans. Cancer incidence data from the New Jersey were collected by New Jersey State Cancer Registry, Cancer Epidemiology Services, New Jersey State Department of Health and Senior Services. Cancer incidence data from North Carolina were collected by the North Carolina Central Cancer Registry. Cancer incidence data from Pennsylvania were supplied by the Division of Health Statistics and Research, Pennsylvania Department of Health, Harrisburg, Pennsylvania. The Pennsylvania Department of Health specifically disclaims responsibility for any analyses, interpretations, or conclusions. Cancer incidence data from the Arizona were collected by Arizona Cancer Registry, Division of Public Health Services, Arizona Department of Health Services. Cancer incidence data from Texas were collected by the Texas Cancer Registry, Cancer Epidemiology and Surveillance Branch, Texas Department of State Health Services. Cancer incidence data from Nevada were collected by the Nevada Central Cancer Registry, Center for Health Data and Research, Bureau of Health Planning and Statistics, State Health Division, State of Nevada Department of Health and Human Services. Author contributions

X.Z. designed the study. J.L.P., L.M.L. and K.A.M. were involved in the data collection. X.L., W.Y., J.L.P., E.G. and X.Z. provided statistical expertise. X.L. wrote the first draft of the manuscript. W.Y., J.L.P., L.M.L., K.A.M., P.T.C., Z.F.Z., W.W., N.H., E.G. and X.Z. revised the manuscript or provided comments or suggestions. All authors contributed to the interpretation of the results and critical revision of the manuscript for important intellectual content and approved the final version of the manuscript.

Competing interests

The authors declare no competing interests.
