Chronic inflammatory demyelinating polyneuropathy (CIDP) and Guillain-Barre syndrome (GBS) are inflammatory neuropathies that affect humans and are characterized by peripheral nerve myelin destruction and macrophage-containing immune infiltrates. In contrast to the traditional view that the peripheral nerve is simply the target of autoimmunity, we report here that peripheral nerve Schwann cells exacerbate the autoimmune process through extracellular matrix (ECM) protein induction. In a spontaneous autoimmune peripheral polyneuropathy (SAPP) mouse model of inflammatory neuropathy and CIDP nerve biopsies, the ECM protein periostin (POSTN) was upregulated in affected sciatic nerves and was primarily expressed by Schwann cells. *Postn* deficiency delayed the onset and reduced the extent of neuropathy, as well as decreased the number of macrophages infiltrating the sciatic nerve. In an in vitro assay, POSTN promoted macrophage chemotaxis in an integrin-AM (ITGAM) and ITGAV-dependent manner. The PNS-infiltrating macrophages in SAPP-affected nerves were pathogenic, since depletion of macrophages protected against the development of neuropathy. Our findings show that Schwann cells promote macrophage infiltration by upregulating *Postn* and suggest that POSTN is a novel target for the treatment of macrophage-associated inflammatory neuropathies.

Introduction

Chronic inflammatory demyelinating polyneuropathy (CIDP) and acute inflammatory demyelinating polyneuropathy (AIDP, a form of Guillain-Barre syndrome [GBS]) are characterized by sensory impairment and disabling weakness (1, 2) and are the result of autoimmune demyelination of the PNS. Current therapies include plasmapheresis and intravenous Ig (IVIg) for CIDP and AIDP as well as corticosteroids for CIDP, all of which have nonspecific mechanisms of action and broadly suppress the immune system (3, 4). Patients with CIDP often require long-term treatment in order to maintain therapeutic effect (3), and even with these treatments, clinical remission is not achieved in approximately 30% of patients (5). Thus, the development of novel, mechanism-based therapies is desirable and would be greatly aided by the delineation of pathogenic mechanisms.

Through the use of mouse models of inflammatory neuropathies and patients' biopsy samples, the immune mechanisms that contribute to the development of autoimmune peripheral neuropathy have been partially illuminated. The prominence of T cells and F4/80⁺ macrophages in affected nerves of spontaneous autoimmune peripheral polyneuropathy (SAPP) mice (6, 7), experimental allergic neuritis (EAN) mice (8, 9), and human patients (10, 11) suggests that these cells are particularly important. Fur-

ther, in SAPP and EAN, CD4⁺ T cells isolated from neuropathic mice are sufficient to transfer disease to T and B cell-deficient (SCID) recipients, underscoring an important role for CD4⁺ T cells among lymphocytes (7, 12, 13). Both Th1 and Th17 have been implicated in the pathogenesis of CIDP and GBS, since the frequency of Th1 and Th17 cells is elevated in the blood and cerebrospinal fluid (CSF) of patients (14, 15), but the relative importance of Th1 and Th17 is still controversial. In models of SAPP, Th1 T cells predominate (7, 12), but in EAN, an important role for Th17 has also been suggested (16). Macrophages may also contribute to autoimmune destruction of the PNS, since macrophages in EAN exhibit an inflammatory phenotype, which includes the secretion of proinflammatory factors such as ROS and the cytokines IL-12, TNF- α , and IL-6 (17). The signals that recruit CD4⁺ T cells and macrophages into the PNS in inflammatory neuropathies, however, are currently unclear.

The extracellular matrix (ECM) is a prominent feature of the PNS and has been implicated in numerous developmental processes, including Schwann cell migration, radial sorting of axons, and myelination (18, 19). In light of recent reports that found a role for ECM proteins in inflammation (20–24), we investigated their possible role in the development of SAPP (7). We found increased expression of the ECM protein periostin (POSTN) by Schwann cells in affected nerves of SAPP mice and patients with CIDP. Moreover, *Postn* expression aggravates neuropathy, since *Postn*-deficient animals have delayed disease onset and improved nerve function by both electrophysiological and pathological analysis. Additionally, *Postn*-deficient sciatic nerves show reduced

infiltration of both T cells and macrophages. Macrophages, but not T cells, migrated across a Transwell membrane in response to POSTN, suggesting that POSTN primarily induces macrophage chemotaxis. Finally, macrophages recruited to affected sciatic nerves are pathogenic, as macrophage-depleted animals showed delayed disease onset and improved nerve function. Overall, our results demonstrate that Schwann cell-derived POSTN promotes neuropathy pathogenesis by directly recruiting pathogenic macrophages to the PNS.

Results

Postn expression is induced during SAPP. To investigate a possible role for ECM proteins in the development of inflammatory neuropathy, we used a strain of NOD mice that develops SAPP, owing to a dominant, loss-of-function G228W mutation in the autoimmune regulator gene (*NOD.Aire^{GW/+}* mice) (7). PNS autoimmunity in *NOD.Aire^{GW/+}* mice shares key features with human CIDP, including infiltration of peripheral nerves by CD4⁺ T cells and F4/80⁺ macrophages (25–27), IFN- γ production by CD4⁺ T cells (28, 29), and peripheral nerve demyelination (7, 30). We screened mRNA levels of 6 ECM genes with known roles in PNS development: laminin a2 (*Lama2*) (31), laminin a4 (*Lama4*) (31), laminin a5 (*Lama5*) (32), laminin b1 (*Lamb1*) (31), thrombospondin 2 (*Thbs2*) (33), and *Postn* (34, 35). We used quantitative reverse transcription PCR (qRT-PCR) to compare the relative expression levels of these genes between sciatic nerves from age-matched WT (*NOD.WT*) mice and those of affected *NOD.Aire^{GW/+}* mice. Sciatic nerves from *NOD.Aire^{GW/+}* mice were harvested when severe neuropathy (clinical score of 3 out of a maximum of 4) was observed. While the levels of *Lama2*, *Lama4*, *Lama5*, and *Lamb1* mRNA showed no change (Figure 1, A–D), the levels of *Thbs2* and *Postn* were significantly increased in neuropathic *NOD.Aire^{GW/+}* mice compared with levels in *NOD.WT* mice (Figure 1, E and F). Increased *Thbs2* expression with PNS inflammation was not surprising, given previous reports that *Thbs2* expression increases after nerve injury and that *Thbs2* may play a role in axonal regeneration (36). However, increased *Postn* expression was unexpected, since it has not been previously linked to peripheral nerve injury or inflammation.

A member of the fasciclin family, *Postn* is widely expressed during embryonic development (34, 37–40). POSTN promotes cell motility through interaction with integrins (41, 42) and has been linked to several inflammatory diseases (20–22, 43), making it an intriguing target to investigate. Increased *Postn* expression was associated with neuropathy, since 8-week-old preneuropathic mice expressed similar levels of *Postn* mRNA compared with levels in *NOD.WT* mice (Supplemental Figure 1; supplemental material available online with this article; <https://doi.org/10.1172/JCI99308DS1>). To examine POSTN expression in SAPP, we used Western blotting and immunostaining to characterize POSTN protein expression in the PNS of neuropathic mice. Western blot analysis showed significantly increased POSTN protein in whole sciatic nerves from neuropathic *NOD.Aire^{GW/+}* mice compared with nerves from *NOD.WT* mice (Figure 1, G and H). We verified that this 75-kDa band corresponded to POSTN, since it was absent in *Postn*-deficient mice (Supplemental Figure 2). Immunostaining showed that POSTN immunoreactivity was mostly restricted to the perineurium of *NOD.WT* nerves (Figure 1I, top left), whereas

POSTN immunoreactivity was also diffusely positive in the endoneurium of affected *NOD.Aire^{GW/+}* nerves (Figure 1I, top right). Thus, *Postn* mRNA and protein expression is increased in neuropathic *NOD.Aire^{GW/+}* nerves.

To determine whether increased *Postn* expression is specific to *NOD.Aire^{GW/+}* mice, we immunostained sciatic nerves from 2 additional models of inflammatory neuropathies: (a) autoimmune peripheral neuropathy induced in immunodeficient SCID mice upon transfer of splenocytes from neuropathic *NOD.Aire^{GW/+}* mice (7) and (b) transfer of CD4⁺ T cells from a myelin protein zero-specific (*Mpz*- or *PO*-specific) T cell receptor-Tg mouse line (*NOD.POT TCR-Tg*) (44). Reconstituted mice were sacrificed when severe neuropathy (clinical score of 3) was observed. We observed by immunohistochemistry that POSTN expression in sciatic nerves was increased in both of these models (Figure 1I, bottom 2 images), suggesting that induction of *Postn* is not unique to *NOD.Aire^{GW/+}* mice, but is a more generalizable feature of inflammatory peripheral neuropathies in mice. Interestingly, we observed no change in the expression of *Postn* 3 days after axotomy (Supplemental Figure 3), suggesting that *Postn* upregulation in the PNS may be specific to inflammatory neuropathies. Finally, to determine whether POSTN is upregulated in human CIDP, we immunostained nerve biopsies from 5 patients with CIDP and 5 patients with axonal (noninflammatory) neuropathy. We detected POSTN expression in 2 of the 5 CIDP patients' samples, but not in the samples from the patients with axonal neuropathy (Figure 1J). Therefore, POSTN upregulation is a feature of inflammatory neuropathy in both mice and humans.

Schwann cells express Postn during SAPP. To identify the cells expressing *Postn*, we generated *NOD Postn* reporter mice, which harbor a *Postn* allele into which a *lacZ* cassette is targeted (45). We performed histochemistry for β -gal using X-gal as a substrate (46) on nerves from neuropathic *NOD.Aire^{GW/+}* and age-matched *NOD.WT* mice that were heterozygous for this *Postn* allele (*Postn^{lacZ/+}*). In *NOD.WT Postn^{lacZ/+}* mice, X-gal crystals were restricted to the perineurium of sciatic nerves (Figure 2A, top left), but in severely neuropathic (clinical score of 3) *NOD.Aire^{GW/+ Postn^{lacZ/+}}* mice, X-gal crystals were also prominent in the endoneurium (Figure 2, A and B). In parallel, we used adoptive transfer (AT) of splenocytes from neuropathic *NOD.Aire^{GW/+}* mice to induce neuropathy in T and B cell-deficient *NOD.SCID Postn^{lacZ/+}* recipients; in reconstituted mice, non-T and non-B cell lineages derived from *NOD.SCID* hosts harbor the *Postn* reporter allele. Sciatic nerves from *NOD.SCID Postn^{lacZ/+}* recipient mice were examined when severe neuropathy (clinical score of 3) was observed and were compared with unreconstituted *NOD.SCID Postn^{lacZ/+}* control mice. In the AT model, we observed β -gal activity in a pattern that was similar to that of the spontaneous *NOD.Aire^{GW/+}* model. Namely, in unreconstituted, non-neuropathic control mice, we found that β -gal activity was absent in the endoneurium and was only seen in the perineurium. On the other hand, in reconstituted, neuropathic recipient mice, we found that β -gal activity was present in the endoneurium (Figure 2, A and B, bottom), confirming that endoneurial *Postn* expression was associated with neuropathy development and demonstrating that nonlymphocytes expressed *Postn*.

Light microscopic analysis of semithin sections of epoxy-embedded nerves from both neuropathic *NOD.Aire^{GW/+}* and *NOD.*

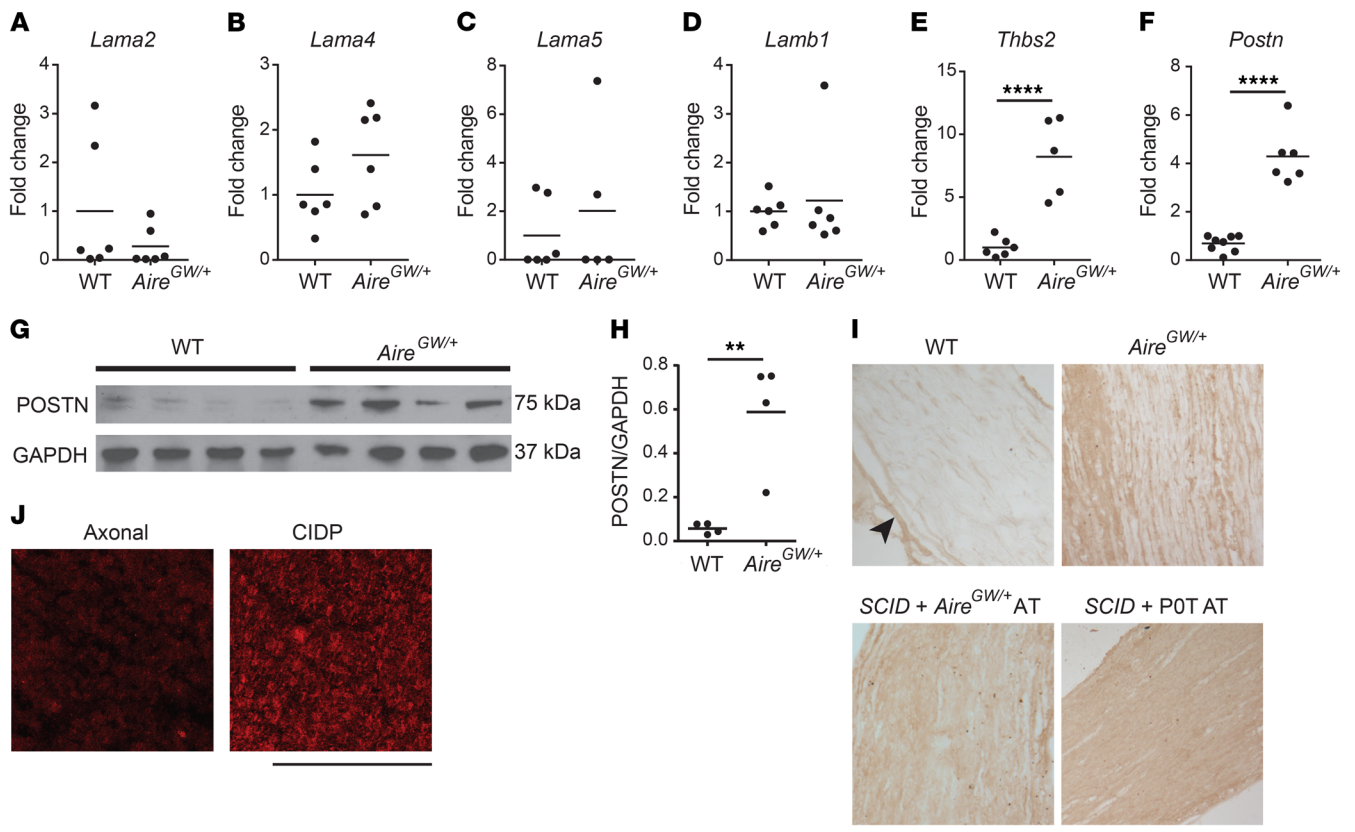

Figure 1. Increased *Postn* expression in SAPP. (A–F) RNA was isolated from the sciatic nerves of *NOD.WT* (WT) and *NOD.Aire^{GW/+}* neuropathic mice. *Lama2* (A), *Lama4* (B), *Lama5* (C), *Lamb1* (D), *Thbs2* (E), and *Postn* (F) expression relative to cyclophilin was measured by qRT-PCR. Values are expressed as the fold change compared with WT. (G) POSTN expression was measured by Western blotting of sciatic nerve lysates from *NOD.WT* (WT) and *NOD.Aire^{GW/+}* (*Aire^{GW/+}*) neuropathic mice. GAPDH was used as a loading control. Each lane represents an individual mouse. (H) Densitometric analysis of the Western blot in G. (I) POSTN immunohistochemical staining of sciatic nerves from WT mice, neuropathic *NOD.Aire^{GW/+}* mice, neuropathic SCID recipients of *NOD.Aire^{GW/+}* splenocytes, and neuropathic SCID recipients of POT splenocytes. Note that POSTN immunoreactivity was mostly found in the perineurium (arrowheads) of *NOD.WT* (WT) nerves, whereas the endoneurium was diffusively positive in nerves from *NOD.Aire^{GW/+}* mice, SCID recipients of *NOD.Aire^{GW/+}* splenocyte AT, and SCID recipients of *NOD.POT* splenocyte AT. Scale bar: 180 μ m. (J) Immunofluorescence staining of biopsy samples from patients with axonal neuropathy or CIDP. Increased endoneurial POSTN immunoreactivity was observed in the CIDP sample. Scale bar: 200 μ m. (A–F and H) Each dot represents an individual animal. ** $P < 0.005$ and **** $P < 0.0001$, by 2-tailed, unpaired *t* test. Individuals values and means are shown.

SCID Postn^{lacZ/+} AT recipient mice revealed diffuse endoneurial β -gal activity as well as areas of intense β -gal activity (Figure 2B). We next used electron microscopy (EM) to characterize the cell types expressing *Postn* in the endoneurium of neuropathic nerves. EM revealed that X-gal crystals were in neuropathic *NOD.Aire^{GW/+}* Schwann cells, which was inferred by their physical relationships with axons (Figure 2, C and D, top panels). We observed a similar pattern in nerves from reconstituted, neuropathic *NOD.SCID Postn^{lacZ/+}* recipient mice (Figure 2, C and D, bottom, and Figure 2E). We observed X-gal crystals in promyelinating Schwann cells that ensheathed large axons (Figure 2C), nonmyelinating Schwann cells associated with many small, unmyelinated axons (Figure 2D), and normal-appearing, myelinating Schwann cells (Figure 2E). We also observed X-gal crystals in endoneurial cells with features distinct from those of Schwann cells (Supplemental Figure 4). To rule out the possibility that X-gal crystals were a nonspecific staining artifact independent of the *lacZ* transgene, we performed histochemistry for β -gal on *NOD.SCID Postn^{+/+}* recipient mice lacking the *Postn^{lacZ}* reporter. Nerve sections from *NOD.SCID Postn^{+/+}* recipient mice did not exhibit X-gal crystals, even in regions with reduced numbers

of myelinated axons (Supplemental Figure 5), demonstrating that X-gal crystals are specific to the *lacZ* transgene. Together, these findings indicate that X-gal crystals seen in Schwann cells and non-Schwann endoneurial cells of neuropathic *NOD.Aire^{GW/+}* mice reflect *Postn* reporter expression.

To confirm that Schwann cells are a source of increased *Postn* expression in neuropathic nerves, we measured relative *Postn* mRNA expression by qRT-PCR in flow-sorted live CD45⁻CD3⁺p75⁺ (p75⁺) Schwann cells (gating strategy in Supplemental Figure 6). In *NOD.WT* mice, in which neuropathy is absent, this cell population consists of nonmyelinating Schwann cells (47). In neuropathic *NOD.Aire^{GW/+}* mice, on the other hand, this cell population probably also contains denervated (48, 49) and promyelinating (50) Schwann cells in addition to the normal nonmyelinating Schwann cells. In line with our EM results, p75⁺ Schwann cells from neuropathic *NOD.Aire^{GW/+}* mice expressed significantly more *Postn* mRNA than did p75⁺ Schwann cells isolated from *NOD.WT* animals (Figure 2F). Since X-gal crystals were also observed in non-Schwann cells (Supplemental Figure 4), we also measured *Postn* expression by qRT-PCR in CD3⁺ T

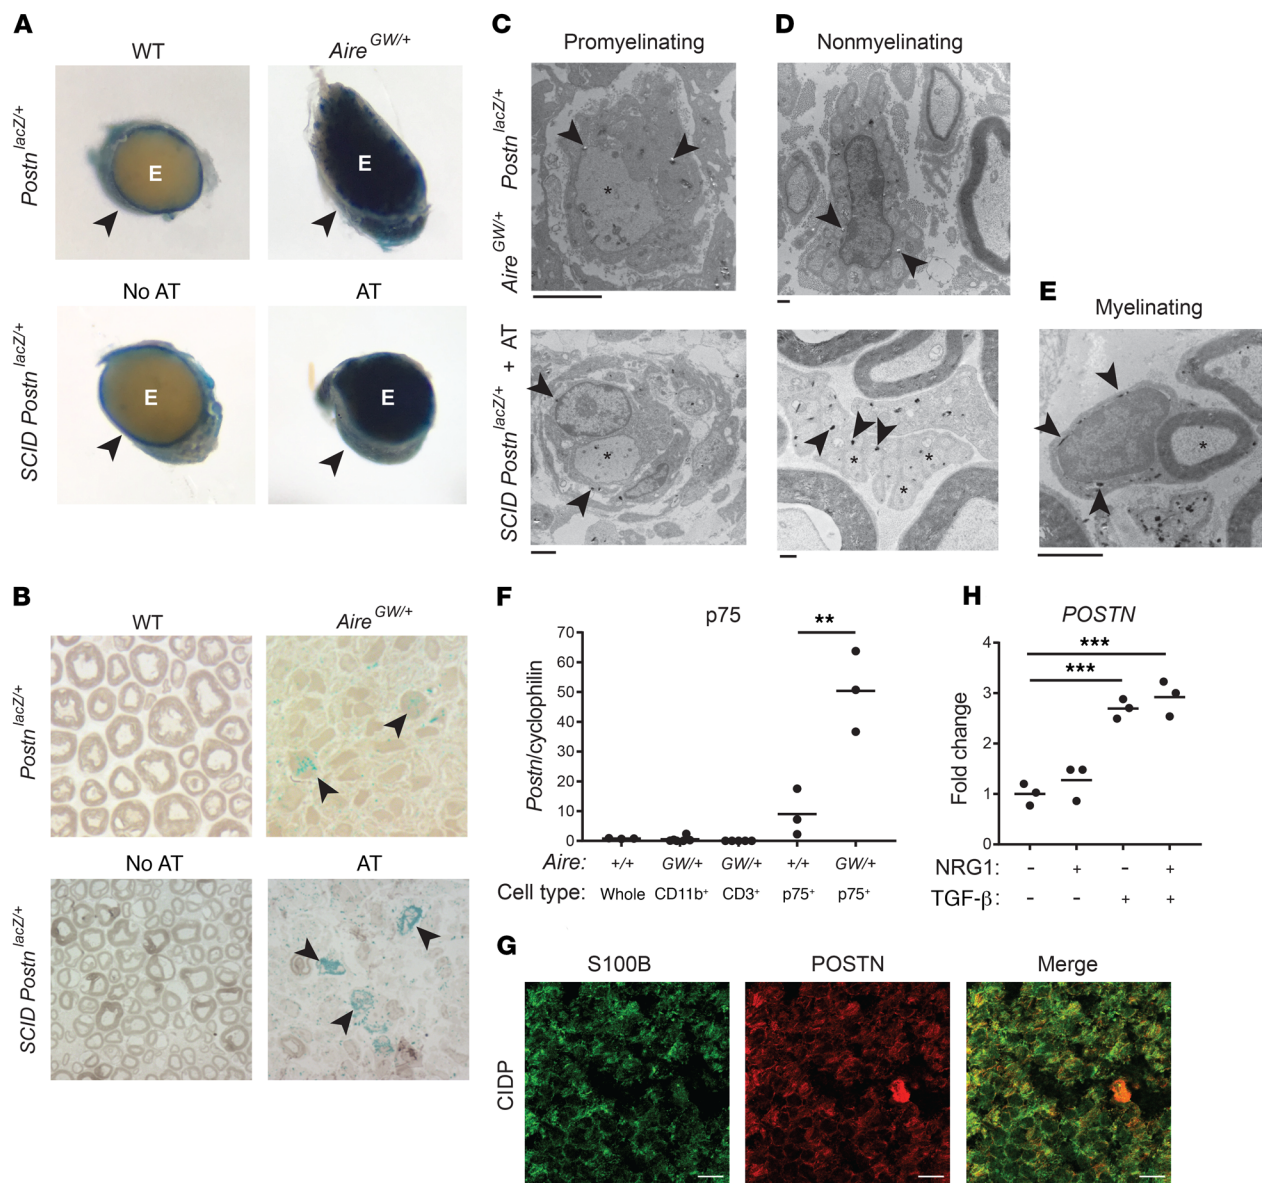

Figure 2. *Postn* is expressed by Schwann cells. Histochemistry for β -gal using X-gal was performed on sciatic nerves from *NOD.WT Postn*^{lacZ/+} mice (WT, $n = 4$) and *NOD.Aire*^{GW/+} *Postn*^{lacZ/+} mice ($n = 3$) as well as from *NOD.SCID Postn*^{lacZ/+} (*Postn*^{lacZ/+}) reporter mice without ($n = 4$) or with ($n = 8$) *NOD.Aire*^{GW/+} (*Aire*^{GW/+}) splenocyte AT. **(A)** Macroscopic view of sciatic nerve cross sections. The perineurium of WT and *NOD.SCID Postn*^{lacZ/+} nerves was X-gal positive (arrowheads); the endoneurium (E) was also X-gal positive in *NOD.Aire*^{GW/+} *Postn*^{lacZ/+} and *NOD.SCID Postn*^{lacZ/+} mice that underwent AT. Original magnification, $\times 4.5$. **(B)** Semithin sections were stained with paraphenylenediamine. X-gal crystals are blue, and some large clusters are indicated with arrowheads in a region with reduced myelinated axon density. Original magnification, $\times 100$. **(C–E)** EM images. Arrowheads indicate X-gal crystals, which are electron dense; asterisks indicate axons. X-gal crystals were found in promyelinating **(C)**, nonmyelinating **(D)**, and myelinating **(E)** Schwann cells. Scale bars: 2 μ m **(C and E)** and 500 nm **(D)**. **(F)** *Postn* expression relative to cyclophilin, measured by qRT-PCR. RNA was isolated from whole sciatic nerves from *NOD.WT* mice, CD11b⁺ or CD3⁺ cells enriched from *NOD.Aire*^{GW/+} neuropathic mice, or p75⁺ Schwann cells purified from sciatic nerves from WT and affected *NOD.Aire*^{GW/+} neuropathic mice. Each dot in **F** represents an individual mouse. **(G)** Immunofluorescence staining of S100B (green) and POSTN (red) in CIDP patients' biopsy samples. Scale bar: 20 μ m. **(H)** HSCs were cultured with NRG1, TGF- β , or both NRG1 and TGF- β . *POSTN* expression was measured by qRT-PCR. Each dot in **H** represents an individual well. ** $P < 0.005$ and *** $P < 0.0005$, by 1-way ANOVA with multiple comparisons test.

cells and CD11b⁺ macrophages isolated from the sciatic nerve of neuropathic *NOD.Aire*^{GW/+} mice. Neither CD3⁺ T cells nor CD11b⁺ macrophages expressed *Postn* (Figure 2F). Thus, we conclude that Schwann cells induce *Postn* expression in mouse models of inflammatory neuropathies and are the main source of POSTN in the sciatic nerve during neuropathy, whereas CD3⁺ T cells and CD11b⁺ macrophages do not express *Postn*.

While our data indicate that murine Schwann cells produce POSTN during neuropathy, the cellular source of POSTN in patients with CIDP is still unclear. To determine whether human Schwann cells (HSCs) are the source of POSTN in patients with CIDP, we immunofluorescently labeled patients' CIDP biopsy samples with antibodies against POSTN and the Schwann cell marker S100B (Figure 2G). We observed prominent overlap

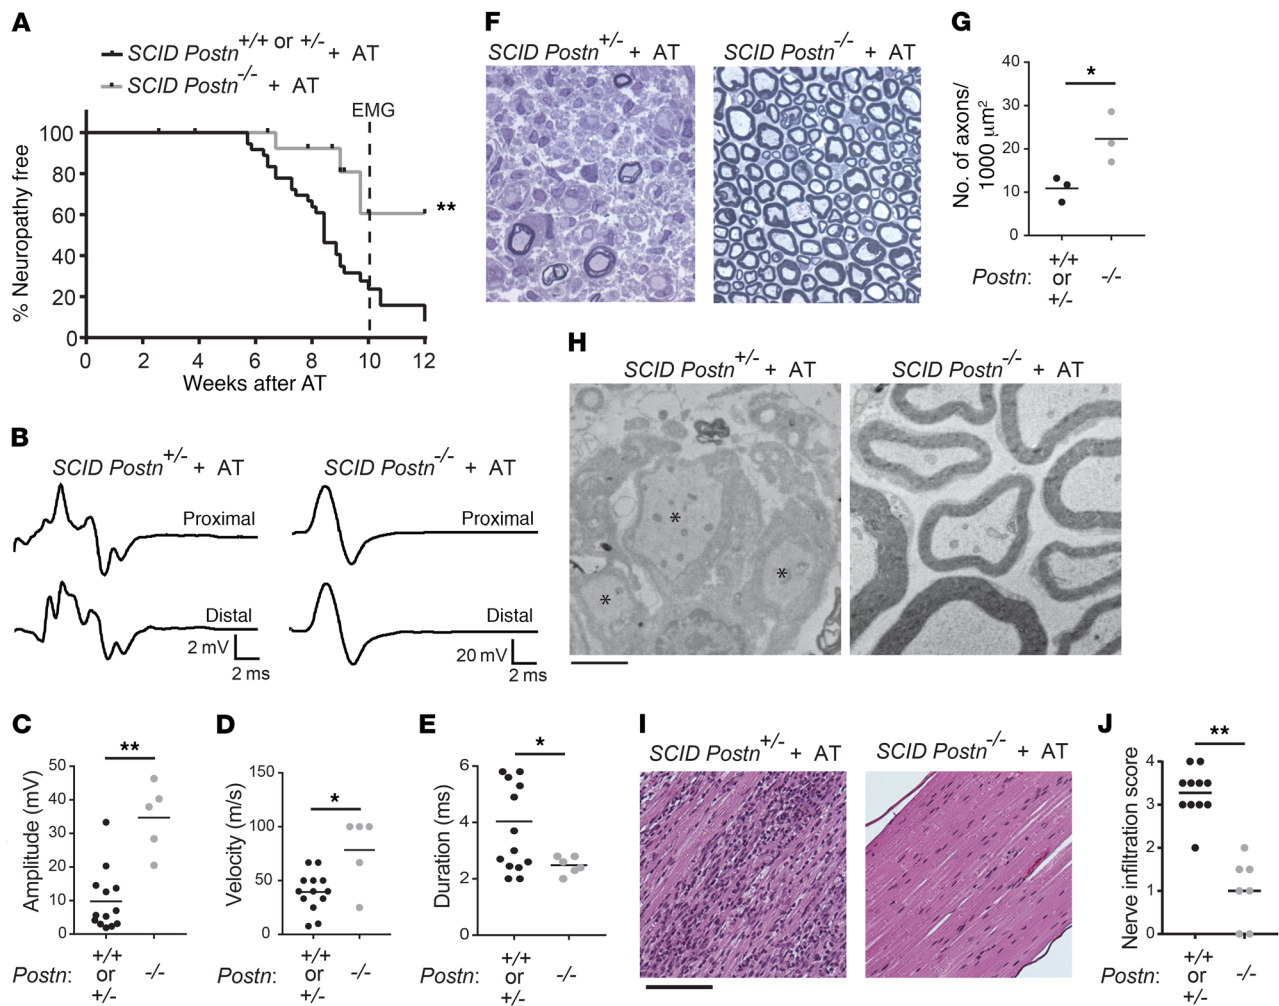

Figure 3. *Postn* deficiency protects against neuropathy. *NOD.SCID Postn*^{+/+}, *NOD.SCID Postn*^{+/-}, and *NOD.SCID Postn*^{-/-} mice after AT with *NOD.Aire*^{GW/+} activated splenocytes. *NOD.SCID Postn*^{-/-} mice were compared with *NOD.SCID Postn*^{+/+} and *NOD.SCID Postn*^{+/-} mice. (A) Neuropathy incidence curve shows the onset of clinical symptoms. Dotted line represents the time point at which mice were used in experiments (10 weeks after AT). (B) Representative CMAP traces 10 weeks after AT. The CMAP of the *NOD.SCID Postn*^{-/-} nerve had a smaller amplitude and was more dispersed than that of the *NOD.SCID Postn*^{+/+} nerve (note the difference in the y-axis scale: 2 vs. 20 mV). (C) Peak amplitude, (D) conduction velocity, and (E) duration of CMAPs for mice in A. Each dot represents an individual mouse. (F) Representative images of semithin sections of sciatic nerves from *NOD.SCID Postn*^{+/+} (*n* = 8) and *NOD.SCID Postn*^{-/-} (*n* = 3) recipients of *NOD.Aire*^{GW/+} activated splenocytes. Original magnification, $\times 100$. (G) The number of myelinated axons/1,000 μm^2 was counted in cross sections of tibial nerves from *NOD.SCID Postn*^{+/+} and *NOD.SCID Postn*^{-/-} AT recipients. (H) EM images. Demyelinated axons (indicated by asterisks) were observed in the *NOD.SCID Postn*^{+/+} nerve (*n* = 8), whereas the *NOD.SCID Postn*^{-/-} (*n* = 3) nerve looked normal. Scale bar: 2 μm . (I) H&E staining of sciatic nerves. The *NOD.SCID Postn*^{+/+} nerve was heavily infiltrated by hematoxylin-positive nuclei compared with the *NOD.SCID Postn*^{-/-} nerve. Scale bar: 12 μm . (J) Infiltration scores were assigned as follows: 0 = no infiltration; 1 = 1%–25% of the nerve was infiltrated; 2 = 26%–50% of the nerve was infiltrated; 3 = 51%–75% of the nerve was infiltrated; 4 = 76%–100% of the nerve was infiltrated. Each dot represents an individual mouse. **P* < 0.05 and ***P* < 0.005, by log-rank test (A), 2-tailed, unpaired *t* test with Welch's correction (C–E and G), or Fisher's exact test (J).

between *POSTN* and *S100B*, indicating that Schwann cells are the source of *POSTN* in human CIDP patients as well as in murine SAPP. As a complementary approach, we sought to determine whether a HSC line can be induced to express *POSTN*. It has been reported that Neuregulin 1 (*NRG1*) and *TGF- β* can induce *Postn* expression in cultured rat Schwann cells (35). Further, *Tgfb* is highly expressed in the sciatic nerve of SAPP mice (Supplemental Figure 7), suggesting its presence at the site of inflammation. Moreover, infiltrating CD4^+ T cells express high levels of *Tgfb* (data not shown). Given these data, we cultured immortalized HSCs in the presence of *NRG1*, *TGF- β* , or both *NRG1* and *TGF- β* , and

measured *POSTN* expression by qRT-PCR (Figure 2H). *POSTN* expression was increased by 3-fold in HSCs treated with *TGF- β* or *TGF- β* and *NRG1*, but not in HSCs treated with *NRG1* alone. These data indicate that *TGF- β* induces *POSTN* expression in HSCs and support the notion that Schwann cells are the source of increased *POSTN* expression in CIDP.

Postn deficiency delays the onset of neuropathy. Mice homozygous for the *Postn lacZ* reporter allele also lack functional *Postn* expression, because the β -gal cassette replaces exons 4–10 of the *Postn* gene (45). Thus, *NOD.Postn*^{lacZ/lacZ} mice are effectively *Postn* knockouts (hereafter referred to as *NOD.Postn*^{-/-}). Although

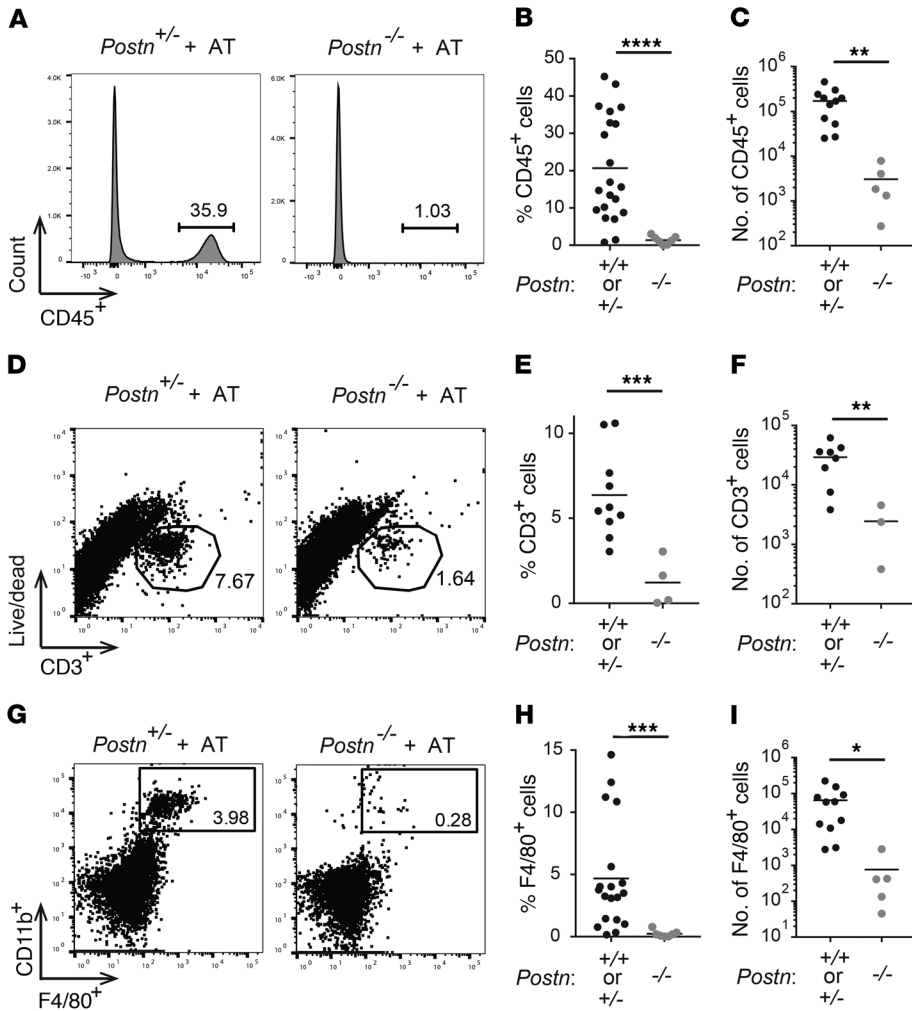

Figure 4. *Postn*-deficient mice have fewer infiltrating T cells and macrophages.

Flow cytometry was used to evaluate the immune cell infiltrate of sciatic nerves from *NOD.SCID Postn*^{+/+}, *NOD.SCID Postn*^{-/-}, and *NOD.SCID Postn*^{-/-} mice 10 weeks after AT with *NOD.Aire*^{GW/+} activated splenocytes. (A) Representative histograms of CD45 staining. (B) Frequency and (C) total number of CD45⁺ cells. (D) Representative dot plots of CD3⁺ versus live/dead staining. (E) Frequency and (F) total number of CD3⁺ cells. (G) Representative flow plots of F4/80⁺ versus CD11b⁺ staining. (H) Frequency and (I) total number of F4/80⁺CD11b⁺ cells. Each dot represents an individual mouse. **P* < 0.05, ***P* < 0.005, ****P* < 0.0005, and *****P* < 0.0001, by 2-tailed, unpaired *t* test with Welch's correction.

Postn is expressed in the PNS during embryonic development, it has been reported that *Postn*-deficient mice have normal PNS function (35) demonstrating that *Postn* is dispensable for PNS development. Consistent with this, we saw no overt signs of PNS impairment in *NOD.Postn*^{-/-} mice when assessed clinically (Supplemental Figure 8A), electrophysiologically (Supplemental Figure 8, B-E), or anatomically (Supplemental Figure 8, F-H). Thus, genetic *Postn* deficiency in mice does not alter PNS structure or function or preclude the use of *Postn*-deficient mice to probe the role of *Postn* in PNS autoimmunity.

To undertake these studies, we used the AT model of inflammatory neuropathy, in which splenocytes from *Postn*-sufficient, neuropathic *NOD.Aire*^{GW/+} mice were transferred into *Postn*-deficient *NOD.SCID* recipients (*NOD.SCID Postn*^{-/-}). Reconstituted recipient mice were *Postn* deficient in non-T and -B cell types (including Schwann cells), since *NOD.SCID Postn*^{-/-} recipient mice lack T and B cells. Splenocyte transfer provoked neuropathy in more than 90% of *Postn*-sufficient (*NOD.SCID Postn*^{+/+} or *NOD.SCID Postn*^{+/-}) recipient mice by 12 weeks after transfer (Figure 3A). The incidence of neuropathy was not different between *Postn* WT (*NOD.SCID Postn*^{+/+}) and heterozygous (*NOD.SCID Postn*^{+/-}) recipient mice (Supplemental Figure 9), suggesting that heterozygosity for the mutant *Postn* allele does not have a functional con-

sequence. In contrast, we found that *NOD.SCID Postn*^{-/-} recipient mice were protected from neuropathy, since splenocyte transfer provoked neuropathy in only 40% of *NOD.SCID Postn*^{-/-} recipients by 12 weeks after transfer (Figure 3A). Thus, *Postn* deficiency in non-T and -B cells ameliorates clinical neuropathy.

To further characterize PNS disease in these mice, we performed electromyography (EMG) on recipients 10 weeks after AT, or earlier, if moderate or severe neuropathy (clinical score of 3) was noted. The 10-week time point was chosen, because most *Postn*-sufficient recipient mice develop neuropathy by this time. EMG revealed that *Postn*-sufficient recipients had significantly reduced compound muscle action potential (CMAP) peak amplitudes (Figure 3, B and C), slower conduction velocities (Figure 3D), and increased CMAP duration (Figure 3, B and E) compared with *NOD.SCID Postn*^{-/-} recipient mice 10 weeks after AT. The combination of increased CMAP durations and reduced conduction velocities suggested that more axons were demyelinated in the *Postn*-sufficient recipient mice. To investigate this point, we examined sciatic nerves by light microscopy (semithin sections) and EM (thin sections) and found larger regions of demyelinated axons in *Postn*-sufficient recipients compared with *Postn*-deficient recipients (Figure 3, F and H). In order to quantify demyelination, we compared the density of myelinated axons in tibial

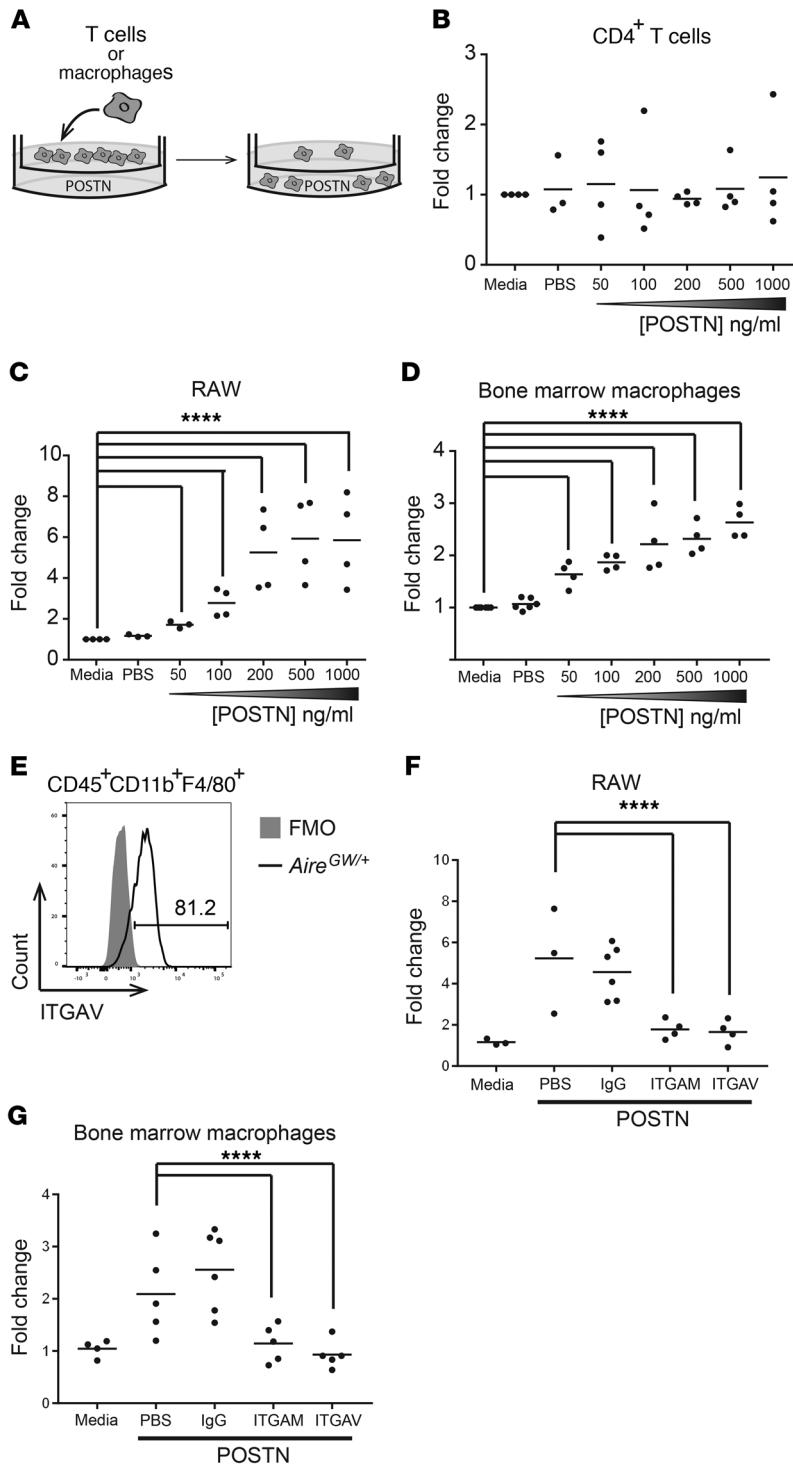

Figure 5. POSTN promotes macrophage chemotaxis via AM and AV integrins. (A) Transwell migration assay diagram. T cells or macrophages were placed in the upper chamber of a Transwell, and POSTN was placed in the lower chamber. Following a 4-hour (T cells) or 18-hour (macrophages) culture, the number of cells in the bottom chamber was enumerated. The concentration of POSTN was varied from 50 to 1,000 ng/ml. (B) CD4⁺ T cells isolated from the spleens of neuropathic *NOD.Aire^{GW/+}* mice were used in a Transwell migration assay as outlined in A. Each dot represents an individual mouse. (C) RAW macrophages were used in a Transwell migration assay. Each dot represents an individual well. (D) Bone marrow was isolated from *NOD.Aire^{GW/+}* neuropathic mice and grown in the presence of GM-CSF for 5 days to generate bone marrow-derived macrophages, which were used in a Transwell migration assay. Each dot represents an individual mouse. (E) Sciatic nerves from neuropathic *NOD.Aire^{GW/+}* mice were digested and stained for flow cytometry. A representative histogram of ITGAV expression on CD45⁺CD11b⁺F4/80⁺ macrophages is shown. ITGAV expression was compared with a fluorescence-minus-one (FMO) control. The number represents the frequency of events within the gate. RAW cells (F) or bone marrow-derived macrophages (G) were used in a Transwell migration assay with 100 ng/ml POSTN. IgG isotype control, anti-ITGAM (CD11b), or anti-ITGAV antibodies were included in the top chamber of the Transwell. All values are represented as the fold change compared with media alone. *****P* < 0.0001. Statistical analysis was performed in R using the *lm()* function, where parameters were fit to each mouse as well as the difference in treatment. *P* values were calculated by comparing the fit of the full model to a model without a term for the difference in treatment and adjusted using Bonferroni's correction.

nerve cross sections. As expected, the number of myelinated axons/1,000 μm² was significantly lower in *Postn*-sufficient AT recipient mice than in *Postn*-deficient mice (Figure 3G). In addition to demyelination, other factors such as edema and immune cell infiltration may contribute to the decreased myelinated nerve density observed in neuropathic animals. Indeed, the regions of demyelinated axons contained many cells that were not surrounded by a basal lamina and had the ultrastructural features of macrophages and lymphocytes. To investigate this issue further, we stained paraffin sections of sciatic nerves with H&E

and observed decreased cellular infiltration of the sciatic nerve in *NOD.SCID Postn^{-/-}* recipients compared with *Postn*-sufficient recipients (Figure 3, I and J).

We next used flow cytometry to determine the cellular composition of sciatic nerves in reconstituted *Postn*-sufficient versus *Postn*-deficient recipient mice. We found decreased frequency and fewer absolute numbers of infiltrating CD45⁺ hematopoietic cells in sciatic nerves of *NOD.SCID Postn^{-/-}* recipients compared with *Postn*-sufficient recipients (Figure 4, A–C), confirming decreased immune cell infiltration with *Postn* deficiency. To deter-

Figure 6. Macrophages promote peripheral neuropathy. (A–E) RNA was isolated from the sciatic nerves of *NOD.WT* (WT) mice and from CD3⁺CD11b⁺ enriched macrophages from the sciatic nerves of *NOD.Aire*^{GW/+} neuropathic mice. *Cxcl9* (A), *Cxcl10* (B), *Tnfa* (C), *Arg* (D), and *Tgfb* (E) expression relative to cyclophilin was measured by qRT-PCR. (F–H) Sciatic nerves from *NOD* or *NOD.Aire*^{GW/+} neuropathic mice were digested and stained for flow cytometric analysis. Representative histograms showing CD80⁺ (F), CD86⁺ (G), and MHCII⁺ (H) expression on macrophages and nonmacrophages from *NOD* or *NOD.Aire*^{GW/+} neuropathic mice. (I) Macrophages were skewed toward an M1 or M2 phenotype prior to inclusion in a Transwell migration assay; 100 ng/ml POSTN was used in the bottom chamber. All values are represented as the fold change compared with media alone. (J–N) *NOD.SCID* recipients of *NOD.Aire*^{GW/+} splenocytes were treated with vehicle or clodronate-containing liposomes weekly starting 5 weeks (arrow) after AT; nerve conduction was done at 10 weeks (dotted line in J). (J) Neuropathy incidence curve shows that fewer clodronate-treated mice developed neuropathy. (K) Representative EMG CMAPs from untreated *NOD.SCID* mice as well as post-AT *NOD.SCID* mice treated with vehicle or clodronate liposomes (note the difference in the scale of the y axis: 5 vs. 20 mV). Compared with vehicle, clodronate significantly reduced the CMAP peak amplitudes (L), CMAP durations (M), and conduction velocities (N). Each dot represents an individual mouse. **P* < 0.05, ***P* < 0.005, ****P* < 0.0005, and *****P* < 0.0001, by 2-tailed *t* test with Welch's correction (A–E), log-rank test (J), or ordinary 1-way ANOVA with Tukey's post hoc test for multiple comparisons (L–N). max, maximum.

mine whether *Postn* deficiency alters the cellular composition of immune cell infiltration, we compared the frequencies of CD3⁺ T cells and F4/80⁺ macrophages within the nerves. We previously reported that T cells and macrophages account for the majority of infiltrating cells in neuropathic *NOD.Aire*^{GW/+} mice (7). Likewise,

immunohistochemical staining of sciatic nerve sections from reconstituted, neuropathic *NOD.SCID* recipients of transferred *NOD.Aire*^{GW/+} splenocytes showed increased CD3⁺ T cells and F4/80⁺ macrophages (Supplemental Figure 10). The frequency and absolute numbers of both CD3⁺ T cells (Figure 4, D–F) and

CD11b⁺F4/80⁺ macrophages (Figure 4, G–I) were reduced in reconstituted *NOD.SCID Postn*^{-/-} recipient mice compared with their *Postn*-sufficient counterparts. Thus, we conclude that neuropathy resistance in *Postn*-deficient recipient mice is associated with less demyelination and decreased immune cell infiltration.

POSTN promotes macrophage chemotaxis. Reduced T cell and macrophage numbers in the sciatic nerve of *Postn*-deficient AT recipient mice could be the result of reduced proliferation, reduced T cell activation, or increased cell death. If *Postn* deficiency impacts T cell or macrophage proliferation or death, one would expect to see fewer T cells and macrophages in the spleens of *Postn*-deficient mice. However, we observed no difference in the frequency or total number of CD3⁺, CD4⁺, or CD8⁺ T cells or CD11b⁺ macrophages (Supplemental Figure 11). Additionally, the frequency and number of Ki67⁺ T cells (Supplemental Figure 12, A–C) and macrophages (Supplemental Figure 12, D–F) were similar in *NOD.Postn*^{+/+} and *NOD.Postn*^{-/-} mice, suggesting that *Postn* deficiency does not affect T cell or macrophage proliferation. Likewise, we observed no difference in the frequency or number of effector/memory (CD44⁺CD62L⁻) CD4⁺ T cells in *Postn*-deficient mice compared with *Postn*-sufficient mice (Supplemental Figure 12, G–K). Finally, we detected no difference in the expression of the apoptotic regulator *Bcl2* in macrophages treated in vitro with POSTN (Supplemental Figure 13). Taken together, these data suggest that reduced numbers of T cells and macrophages in the sciatic nerves of *Postn*-deficient AT recipients cannot be explained by altered immune cell proliferation, activation, or death.

Another possible explanation for decreased T cell and macrophage nerve infiltration in *Postn*-deficient mice is that POSTN normally promotes the migration of these immune cell types into the PNS. We used a Transwell system (Figure 5A) to test the ability of CD4⁺ T cells or macrophages to migrate toward increasing concentrations of POSTN protein. POSTN failed to induce the migration of CD4⁺ T cells that were isolated from the spleens of neuropathic *NOD.Aire*^{GW/+} mice, regardless of the concentration of POSTN (Figure 5B). However, the migration of RAW cells, a macrophage-derived cell line, was increased in response to POSTN in a dose-dependent manner (Figure 5C). We observed similar results when *NOD.Aire*^{GW/+} bone marrow-derived macrophages were used in place of RAW cells (Figure 5D). Known POSTN receptors include the integrins ITGAV (42) and ITGAM (CD11b) (41), which have been implicated in mediating various POSTN-dependent effects, and macrophages in infiltrated sciatic nerves express both CD11b (also known as ITGAM) (Figure 4G) and ITGAV (Figure 5E). Inclusion of blocking antibodies specific to CD11b/ITGAM or ITGAV in the upper chamber of the Transwell prevented RAW cells and *NOD.Aire*^{GW/+} bone marrow-derived macrophages from migrating across the membrane, whereas IgG isotype control antibodies did not (Figure 5, F and G). These data demonstrate that POSTN is directly chemotactic to macrophages but not T cells and that this response requires ITGAV and ITGAM.

Macrophages promote the development of PNS autoimmunity. While macrophages are a predominant cell type in the immune cell infiltrate of neuropathic nerves, their role in the development of autoimmune peripheral neuropathy is unclear. To address this question, we first assessed the expression of M1- and M2-associated markers. We isolated macrophages from the sciatic

nerves of neuropathic *NOD.Aire*^{GW/+} mice and measured the expression of M1- and M2-associated markers by qRT-PCR. Since *NOD.WT* sciatic nerves have few resident macrophages, we used whole *NOD.WT* nerve tissue as a comparison. No significant difference was seen in the expression of the M1-associated markers *Il12*, *iNos*, or *Cd86* or the M2-associated markers *Il10*, *Fizz*, *Mrc*, or *Ym1* (Supplemental Figure 14); however, we detected a significant increase in the M1-associated markers *Cxcl9*, *Cxcl10*, and *Tnfa* and the M2-associated markers *Arg* and *Tgfb* (Figure 6, A–E). Additionally, we used flow cytometry to measure the activation markers CD80, CD86, and MHCII on nerve-infiltrating CD11b⁺F4/80⁺ macrophages from the sciatic nerves of neuropathic *NOD.Aire*^{GW/+} mice. Compared with CD11b⁻F4/80⁻ nonmacrophage cells, CD11b⁺F4/80⁺ macrophages expressed more CD80, CD86, and MHCII (Figure 6, F–H). CD11b⁻F4/80⁻ nonmacrophage cells from sciatic nerves of *NOD.Aire*^{GW/+} mice expressed an intermediate amount of MHCII (Figure 6H), which may reflect an upregulation of MHCII expression by other cell types such as Schwann cells (51–53). These data suggest that nerve-infiltrating macrophages are heterogeneous, expressing both M1- and M2-associated markers, and express markers of activation.

Since nerve-infiltrating macrophages express both M1- and M2-associated markers, we wondered whether POSTN attracts macrophages of a specific phenotype. POSTN has been suggested to recruit M2 antiinflammatory macrophages (54), but whether POSTN also recruits the M1 macrophage subtype is unclear. To test this, macrophages were skewed toward an M1 or M2 phenotype prior to inclusion in a Transwell migration assay. Unskewed, and M1- and M2-skewed macrophages all migrated to a similar degree in response to POSTN (Figure 6I), indicating that POSTN is a chemotactic factor for both M1 and M2 macrophages. It has also been reported that POSTN can regulate the expression of markers of M1 and M2 polarization (54). To determine whether POSTN alters macrophage polarization, we skewed macrophages toward an M1 or M2 phenotype in the presence or absence of POSTN and measured the expression of M1 and M2 markers by qRT-PCR. POSTN did not change the expression of the M1-associated markers *Tnfa* and *iNos* or the M2-associated marker *Arg* (Supplemental Figure 15). Thus, POSTN does not impact macrophage polarization in vitro.

Next, to determine whether macrophages contribute to SAPP, we treated *NOD.Aire*^{GW/+} mice between 7 and 14 weeks of age with clodronate liposomes to deplete phagocytic cells. Uptake of clodronate liposomes by phagocytes induces their apoptosis, and clodronate liposomes have previously been used to deplete macrophages in autoimmune mouse models (55–58). As expected, fewer F4/80⁺CD11b⁺ macrophages were noted in the spleens of mice 3 days after treatment with clodronate compared with vehicle control liposome numbers (Supplemental Figure 16). Clodronate treatment was associated with a significant delay in the onset of peripheral neuropathy in *NOD.Aire*^{GW/+} mice compared with vehicle liposome treatment (Supplemental Figure 17A). Flow cytometric analysis of sciatic nerves from 21-week-old *NOD.Aire*^{GW/+} mice demonstrated decreased frequency and absolute numbers of CD11b⁺F4/80⁺ macrophages in the sciatic nerves of clodronate liposome-treated mice. Thus, clodronate treatment protects

against SAPP through macrophage depletion (Supplemental Figure 17, B and C). In parallel, we investigated whether macrophage depletion was similarly protective in the AT model of inflammatory neuropathy. We administered clodronate or vehicle liposomes to reconstituted *NOD.SCID* recipients from 5 weeks after transfer until the mice developed neuropathy or were used in further experiments. The onset of clinical neuropathy in reconstituted recipients was significantly delayed with clodronate compared with vehicle liposome treatment (Figure 6J). Moreover, nerve conduction performed 5 weeks after administering clodronate (10 weeks after administration of splenocytes) (Figure 6, K–N) showed increased CMAP peak amplitudes (Figure 6L), decreased CMAP durations (Figure 6M), and faster nerve conduction velocities (Figure 6N) with clodronate treatment. Thus, in the AT model, clodronate-mediated depletion of macrophages protects against the development of demyelinating neuropathy, which suggests a pathogenic role for macrophages in inflammatory neuropathy.

Discussion

The development of tissue-specific autoimmunity involves a complex interplay between autoreactive immune cells and the target tissue. Whether the PNS regulates disease progression in autoimmune neuropathies, however, has not been documented. We show here that Schwann cells participate in the immune response by upregulating the ECM protein POSTN. *Postn* expression was increased in multiple mouse models of CIDP, suggesting that this may be a generalizable finding in inflammatory neuropathies. The absence of *Postn* delayed the onset of disease and reduced the severity of neuropathy. *Postn* deficiency also resulted in improved nerve function by EMG and reduced immune cell infiltration into nerves. Together, these findings suggest that Schwann cell-derived POSTN promotes PNS autoimmunity by enhancing immune cell infiltration (Supplemental Figure 18).

Postn is upregulated in various diseases and injuries (59) including cancer (60), myocardial infarction (61), asthma (62), skin inflammation (21), glomerulonephritis (22), and colitis (43). TGF- β or neuregulin/ERBB3 signaling (35, 63) can induce *Postn* expression in Schwann cells during development; additionally, *Postn* expression can also be induced by IL-4 and IL-13 in keratinocytes during allergic skin inflammation (21) and by TNF- α and IL-17 during liver fibrosis (64). POSTN signals through ITGAV/B3 (21, 42), ITGAV/B5 (42), and ITGAM (eosinophils) (41) and results in the phosphorylation of focal adhesion kinase (FAK) (65) and AKT (65) in neurons and the activation of NF- κ B (21, 43) in keratinocytes and colon. POSTN regulates various cytokines and chemokines including TNF- α in skin inflammation and following spinal cord injury (21, 23); IL-1A, granulocyte-macrophage-CSF (GM-CSF), and the chemokine ligand CCL17 in allergic skin inflammation and glioblastoma (21, 54); RANTES (CCL5) in kidney and nasal epithelia (22, 66); and CCL2, CCL4, CCL7, and CXCL2 in pulmonary fibrosis (20). Additionally, POSTN has been shown to promote immune cell recruitment to sites of inflammation in spinal cord injury and glioblastoma (20, 23, 54). We observed a similar effect of POSTN on the recruitment of immune cells to the sciatic nerve during SAPP.

While both T cell and macrophage numbers were reduced in peripheral nerves of *Postn*-deficient mice, only macrophages

responded to POSTN in an in vitro Transwell migration assay. This finding suggests that POSTN primarily promotes macrophage chemotaxis and does not directly promote T cell chemotaxis. Instead, POSTN may promote T cell influx indirectly through the recruitment of macrophages that in turn express T cell chemoattractants. This notion is consistent with our observation (Figure 6, A and B) that nerve-infiltrating macrophages express the T cell chemoattractants *Cxcl9* and *Cxcl10*. Additionally, POSTN has been reported to regulate other T cell chemoattractants including RANTES (22, 66), which is secreted by macrophages during EAN (9), and the chemokine ligand CCL17 (21). Thus, we propose that a positive feedback loop exists between T cells and macrophages. This cycle is probably initiated by PNS-specific CD4⁺ T cells, given our data that CD4⁺ T cells are sufficient to incite SAPP in immunodeficient mice (7). These early infiltrating T cells produce TGF- β , which induces Schwann cells to express *Postn*. By binding to ITGAM and ITGAV on macrophages, POSTN attracts macrophages into the endoneurium. This amplifies a positive feedback loop between macrophages and T cells through increased macrophage expression of the T cell chemoattractants *Cxcl9* and *Cxcl10* (Supplemental Figure 18).

In mouse and rat models of nerve injury, macrophages are recruited 3–5 days after injury (67). In this setting, macrophages are important in clearing myelin debris and participate in nerve regeneration by secreting growth-promoting factors and cytokines that act upon Schwann cells and neurites (68). Given this reparative role for macrophages during axotomy, the promotion by *Postn* of macrophage infiltration may have both proinflammatory and reparative effects. Further, it is also possible that *Postn*-dependent macrophage infiltration may even be antiinflammatory, since nerve-infiltrating macrophages express some immunosuppressive M2-associated markers, and data from our group and others show that *Postn* can promote M2 macrophage chemotaxis (54). Our results indicate that macrophages overall were proinflammatory during PNS autoimmunity, since macrophage depletion delayed the onset of disease. Nevertheless, it is important to acknowledge that the macrophage population is likely to be heterogeneous (69), since both M1- and M2-associated markers were expressed (Figure 6, A–E), and that a subset of PNS-infiltrating macrophages may ameliorate disease. Further delineation of macrophage subsets and their function in SAPP will be the subject of future studies.

In addition to SAPP and axotomy, other disease states, including some hereditary neuropathies, are also associated with macrophage infiltration into the PNS (70). At present, it is not clear whether the same chemotactic factors mediate macrophage influx in each of these conditions. Multiple factors, such as CCR2–CCL2 interactions, have been implicated in macrophage recruitment after nerve injury (71). CCR2 is expressed on infiltrating macrophages, and CCL2 (also known as MCP) secretion by Schwann cells recruits macrophages into the injured nerve (72–74). Additionally, MIP1A and IL-1 β also play important roles in macrophage chemotaxis with axotomy (72). Whether POSTN also plays a role in macrophage infiltration with hereditary neuropathies and whether CCR2–CCL2, MIP1A, and IL-1 β might promote macrophage infiltration during autoimmune peripheral neuropathy await further investigation.

In the CNS, *Postn* is expressed by several glial cell types including astrocytes (65) and pericytes (23) following injury. *Postn*

promotes scar formation, regulates blood-brain barrier permeability, and induces proinflammatory molecules such as MMP9, leading to impaired functional recovery following spinal cord injury (23) and increased pathology following subarachnoid hemorrhage (75). In contrast to the CNS, we did not observe increased *Postn* expression following PNS injury. The regenerative capacity of the PNS is markedly better than that of the CNS; however, the underlying reasons for this difference in regenerative capacity are poorly understood. Since *Postn* deficiency improves recovery following CNS injury, we speculate that a lack of *Postn* upregulation following PNS injury may partially account for the improved ability of the PNS to repair itself.

In preclinical trials, POSTN inhibitors have shown promise as cancer therapeutics, and both antibody-based and aptamer POSTN inhibitors are actively being pursued (76, 77). Our finding that POSTN is induced in mouse models of inflammatory neuropathy and required for macrophage-mediated disease acceleration suggests that POSTN inhibition may be a potential immunotherapeutic strategy for inflammatory neuropathies. Since POSTN recruits macrophages to the PNS through interaction with ITGAV, targeting ITGAV is another potential strategy implicated by our results. Currently, several antibody and small-molecule inhibitors of ITGAV are in phase I and phase II clinical trials for the treatment of cancer (78, 79). Our results provide a basis for the development of these molecules as novel therapeutics for inflammatory neuropathies.

Methods

Animals

Strains and housing. Mice were housed in a specific pathogen-free facility at the UNC-CH. *NOD.Aire^{GW/+}* and myelin protein zero T cell receptor-Tg (*NOD.POT*) mice were generated as previously described (44, 80). *NOD.POT Tcr-Tg* mice were a gift of Jeffrey Bluestone (UCSF, San Francisco, California, USA). *NOD.SCID* mice were purchased from The Jackson Laboratory. *B6.Postn^{lacZ/+}* mice (45) were purchased from The Jackson Laboratory and were backcrossed onto the nonobese diabetic (*NOD*) background for 8 generations using speed congenics (80). Genome scanning to select breeders of highest *NOD* strain origin was performed by JAX services using a 150 SNP panel that was polymorphic between *NOD* and *C57BL/6*. *NOD.Postn^{lacZ/+}* were then crossed with *NOD.SCID* mice to generate *NOD.Postn^{lacZ/+} SCID* and *NOD.Postn^{lacZ/lacZ} SCID* (also referred to as *NOD.Postn^{-/-} SCID*) mice.

AT model. Forty-eight-well plates were coated with anti-CD3 (eBioscience, clone 145-2C11; 1 μ g/ml in PBS) and anti-CD28 (BD Pharmingen, clone 37.51; 1 μ g/ml in PBS) overnight at 4°C or for at least 2 hours at 37°C and washed with PBS. Splenocytes from neuropathic *NOD.Aire^{GW/+}* or *NOD.POT* mice were plated at a density of 10^6 (*NOD.Aire^{GW/+}*) or 5×10^5 (*POT*) cells/well and cultured for 96 to 120 hours in DMEM supplemented with 10% FBS, 10 mM HEPES buffer (*NOD.POT* mice only), penicillin-streptomycin (100 U/ml, Gibco, Thermo Fisher Scientific), and 2-mercaptoethanol (55 μ M). Activated splenocytes (1×10^6) were harvested, washed once with sterile PBS, and adoptively transferred in sterile PBS using retro-orbital injection into immunodeficient *NOD.SCID* recipients sedated with 2% isoflurane in oxygen.

Evaluation of SAPP. Mice were evaluated weekly (spontaneous model) or every other day (AT model) for clinical signs of neuropathy,

which was scored as follows: 0 = no signs of neuropathy present; 1 = mild hind limb weakness; 2 = pronounced bilateral hind limb weakness; 3 = reduced or absent ability to grip cage grating; and 4 = moribund. For the neuropathy incidence curve, mice were considered neuropathic when they reached a score of 2 in order to limit the effect of false positives. SAPP was confirmed by electromyography, which was performed as previously described (81, 82).

Surgery. Mice were anesthetized with isoflurane and 100 mg/kg ketamine/10 mg/kg xylazine or 250 mg/kg avertin. Fur was removed from the surgical area with depilatory cream and cleaned with alcohol wipes. The sciatic nerve was exposed and transected at the sciatic notch. The contralateral nerve was exposed but left intact (mock). The wound was sealed with surgical glue. Meloxicam (10 mg/kg) was administered at the time of surgery, and 2 mg/kg meloxicam was administered daily following surgery for pain management. Three days after nerve transection surgery, nerves were harvested, frozen in liquid nitrogen, and stored at -80°C until use. RNA was extracted from transected and mock nerves, and *Postn* levels were measured by qRT-PCR.

Flow cytometry

Nerve digestion. Nerves were chopped into segments with a razor blade and digested in PBS containing 1 mg/ml collagenase and 1% FBS at 37°C for 30 minutes with periodic agitation. Part way through the digestion, the sample was triturated with a 20-gauge needle to aid in tissue disruption. Dissociated nerves were filtered through a 40- μ m mesh and washed prior to use in experiments.

Antibodies. CD3 (clone 145-2C11), CD4 (clone RM4-5), CD8 (clone 53-6.7), F4/80 (clone BM8), and CD45 (clone 30F11) antibodies were purchased from eBioscience. CD11b (clone M1/70) was purchased from BioLegend. Live/Dead Fixable Yellow Dye (Life Technologies, Thermo Fisher Scientific) was used to exclude dead cells. Rabbit anti-p75 (1:500) was purchased from Abcam, and DyLight 488-conjugated goat anti-rabbit IgG (1:500) was purchased from Thermo Fisher Scientific.

Staining. Single-cell suspensions were washed twice with FACS buffer. Fc receptors were blocked by incubating cells with supernatant from a 2.4G2 hybridoma for 10 minutes. Cells were stained for 30 minutes on ice and washed prior to analysis.

Analysis. Samples were run on a Beckman Coulter CyAn ADP or BD LSR II flow cytometer and analyzed using FlowJo software. A BD FACSAria II was used for sorted samples.

Immunostaining

Mouse tissues. Nerves from *NOD.Aire^{GW/+}* and *NOD.WT* mice were embedded in OCT and frozen at -20°C for 2 hours prior to storage at -80°C. Sciatic nerve cross sections or longitudinal sections (6- μ m) were fixed with cold acetone, blocked with 2.5% goat serum, and stained with 10 μ g/ml anti-periostin (Abcam), anti-F4/80 (eBioscience), and anti-CD3 (BioLegend) for 2 hours. After washing with PBS containing 0.1% Tween (PBST), sections were incubated with anti-rat-HRP or anti-rabbit-HRP (VECTOR Laboratories) antibody for 30 minutes and developed in DAB solution until the desired stain intensity was achieved. All sections were processed in parallel, including the same length of time in the DAB solution. Samples were imaged on a Nikon Eclipse 80i wide-field microscope.

Humantissues. Slide-mounted cryosections of sciatic nerves from deidentified CIDP patients were air dried and fixed with 2% paraformaldehyde (PFA), washed in PBS, and permeabilized with 0.2% Triton

X-100. After blocking with 5% goat serum, sections were washed in PBS and incubated with 1:50 rabbit polyclonal anti-human POSTN (Abcam, catalog ab14041) and 1:200 mouse monoclonal anti-human S100B (Atlas, catalog AMAb91038, clone CL2720) for 18 hours at 4°C. Sections were washed with PBS and incubated with 1:200 Alexa Fluor 594-labeled goat polyclonal anti-rabbit secondary antibody (Invitrogen, Thermo Fisher Scientific, catalog A11037) and 1:200 Alexa Fluor 488-labeled goat polyclonal anti-mouse secondary antibody (Invitrogen, catalog A11001) at room temperature for 1 hour. After incubation with a secondary antibody, slides were washed with PBS and coverslipped using antifade medium containing 4',6-diamidino-2-phenylindole (Prolong Gold, Invitrogen, Thermo Fisher Scientific, catalog P36931) and photographed using a Zeiss 800 confocal microscope.

Transwell migration assay

T cells. Chemotaxis was measured using Transwell assays as described previously (83). Migration of CD4⁺ T cells was measured using a 24-well Transwell plate (Corning Life Sciences) with 6.5-mm polycarbonate filters and 5- μ m pores. CD4⁺ T cells from neuropathic *NOD.Aire^{GW/+}* spleens were purified using the Magnisort CD4⁺ T cell Enrichment Kit (Invitrogen, Thermo Fisher Scientific). Two million CD4⁺ T cells were resuspended in Transwell media (100 μ l RPMI 1640 medium with 0.1% fatty acid-free BSA [Sigma-Aldrich], 100 U/ml penicillin G, 2 mM L-glutamine, and 25 mM HEPES buffer). Cells were placed on the Transwell inserts. Media (600 μ l), media plus PBS, or media plus 50–1,000 ng/ml POSTN (R&D Systems) were added to the lower chambers. Migration was performed for 4 hours at 37°C and 5% CO₂. Migrated cells were counted with a hemocytometer.

Macrophages. Bone marrow was flushed out of the femurs and tibiae of *NOD.Aire^{GW/+}* mice using PBS and then cultured in DMEM containing 10% FBS, penicillin-streptomycin, and 10% L cell supernatant for 5 days prior to use. RAW 264.7 cells or *NOD.Aire^{GW/+}* bone marrow-derived macrophages were cultured in DMEM with 10% FBS in a 24-well plate. Cells were washed 3 times with PBS, resuspended in DMEM without FBS, and seeded at 1 \times 10⁶ cells/ml into the upper chamber in a total volume of 250 μ l. Transwell inserts with 8- μ m pores (Corning) were used. Recombinant POSTN (R&D Systems) was added to the lower chamber at 50, 100, 200, 500, and 1,000 ng/ml in DMEM with 5% FBS. Anti-CD11b (Thermo Fisher Scientific) and anti-CD51 (ITGAV) (BD) antibodies were added into the upper chamber at a concentration of 10 μ g/ml. For experiments comparing M1 and M2 macrophages, 200,000 bone marrow-derived macrophages were seeded in the upper chamber of the Transwell in a total volume of 350 μ l. Macrophages were incubated with or without macrophage-skewing conditions for 24 hours, and then the upper chamber was changed to serum-free DMEM culture medium, and the lower chamber was changed to DMEM with 5% FBS, with or without 100 ng/ml POSTN. Cells were allowed to migrate through the Transwell insert membrane for 24 hours. The inserts were removed, fixed in cold methanol, and stained with methanol containing 1% crystal violet. The inside of the Transwell was swabbed thoroughly with cotton swabs and air dried at room temperature overnight. The number of migrated raw cells and macrophages was counted by bright-field microscopy at \times 40. Four bright-field images were analyzed per well. Values from each well were averaged and normalized to the media control. At least 3 mice were used per condition in at least 2 separate experiments.

Macrophage skewing

Bone marrow-derived macrophages were seeded at 250,000 cells/well in 24-well plates in DMEM medium containing 10% FBS and 1% penicillin-streptomycin. LPS (100 ng/ml) and IFN- γ (25 ng/ml) were added to the media for M1 differentiation, and IL-4 (25 ng/ml) was added to the media for M2 differentiation. After 24 hours in skewing conditions, 100 ng/ml POSTN was added to some of the cultures, and the macrophages were cultured for another 24 hours. Total RNA was extracted from the macrophages and used in qRT-PCR analyses. *Cxcl9*, *Cxcl10*, *Cd86*, *iNos*, *Il12*, and *Tnfa* were used as M1 markers, and *Il10*, *Ym1*, *Arg1*, *Fizz*, and *Mrc* were used as M2 markers.

HSC culture and stimulation

Immortalized HSCs were cultured as described previously (84). HSCs were grown to 80% confluence and seeded into 12-well plates at a density of 250,000 cells in 2 ml growth media per well. After 24 hours at 37°C in a humidified 5% CO₂ incubator, serum-free media were used and cells were treated with 1 ng/ml TGF- β (STEMCELL Technologies), 10 ng/ml NRG1 (Thermo Fisher Scientific), or both for 24 hours at 37°C with 5% CO₂. *Postn* expression was measured by qRT-PCR.

Macrophage depletion

AT model. Mice were treated with 200 μ l clodronate or vehicle control liposomes 5 weeks after AT. Each following week, mice received 100 μ l clodronate or control liposomes until neuropathy developed. For the *Aire^{GW/+}* spontaneous model, mice were treated weekly for 7 weeks with 200 μ l clodronate or vehicle control liposomes starting at 7 weeks of age. Treatment was discontinued after 7 weeks of treatment because of the development of ascites. Clodronate and control liposomes were purchased from Encapsula NanoSciences.

X-gal staining of sciatic nerves and EM

Mice were euthanized and perfused with 0.1 M phosphate buffer (PB) followed by cold 0.5% glutaraldehyde (Sigma-Aldrich) in 0.1 M PB. Sciatic nerves were fixed in 0.5% glutaraldehyde in 0.1 M PB for 3 hours at 4°C. Nerves were washed twice with 0.1 M PB and then twice with 2 MgCl₂ in 0.1 M PB. Samples were incubated overnight at 37°C in the following X-gal working solution: 2.0 mM MgCl₂ (Sigma-Aldrich), 4.0 mM K₄Fe(CN)₆ (Sigma-Aldrich), 4.0 mM K₃Fe(CN)₆ (Sigma-Aldrich), and 1.0 mg/ml X-gal (5-bromo-4-chloro-3-indolyl- β -D-galactopyranoside) (Sigma-Aldrich) in 0.1 M PB. Nerves were washed twice in 0.1 M PB, post-fixed in 4% glutaraldehyde (Sigma-Aldrich) overnight at 4°C, rinsed in 0.1 M PB, transferred to a 2% OsO₄ in 0.1 M PB for 1 hour, and then processed for embedment in Epon. Semithin sections were stained with 1% paraphenylenediamine or alkaline toluidine blue and visualized by light microscopy (Leica DMR) using interactive software (Leica Application Suite). Thin sections were stained with lead citrate and imaged in a Jeol-1010 transmission electron microscope. Selected images were processed with Adobe Photoshop to generate the figures.

Quantitation of demyelination

Semithin sections of tibial nerve stained with 1% paraphenylenediamine were analyzed using Fiji software (ImageJ, NIH). The area of each tibial nerve was determined on the basis of the inner edge of the perineurium. The total number of myelinated axons in each cross section was counted manually using Fiji software to mark each myelinated axon. The following formula was used to determine the number of

myelinated axons per 1,000 μm^2 : (number of total axons in the tibial nerve/total area of the tibial nerve) \times 1,000.

qRT-PCR

Primers. The following primers were used: *Arg* (Mm00475988_m1), *Cd86* (Mm00444543_m1), *Fizz* (Mm00445109_m1), *iNos* (Mm00440502_m1), *Mrc* (Mm01329362_m1), *Lama2* (Mm00550083_m1), *Lama4* (Mm01193660_m1), *Lama5* (Mm01222029_m1), *Lamb1* (Mm00801853_m1), *Postn* (Mm01284919_m1), *POSTN* (Hs01566750_m1), *Thbs2* (Mm01279240_m1), *Tnfa* (Mm00443258_m1), and *Ym1* (Mm00657889_mH). The primer probe set for cyclophilin A (82) or *GAPDH* (Hs02758991_g1) was used as an internal control.

Whole sciatic nerves were homogenized by mortar and pestle followed by use of the QIAshredder (QIAGEN). RNA was isolated from whole nerves using the RNeasy Plus Mini Kit or Zymo RNA MicroPrep Kit (QIAGEN). The Agilent Absolutely RNA Nanoprep Kit was used to isolate RNA for samples with fewer than 10^4 cells. QIAGEN's RNeasy Plus Micro Kit was used for samples with between 10^4 and 5×10^5 cells. SuperScript II Reverse Transcriptase (Invitrogen, Thermo Fisher Scientific) was used for cDNA synthesis. TaqMan Universal PCR Master Mix (Applied Biosystems) was used for PCR. The Applied Biosystems QuantStudio 6 Flex Real Time PCR System and QuantStudio 6 and 7 software were used for data acquisition and analysis, respectively.

Western blot analysis

Whole sciatic nerves were homogenized in Laemmli buffer. Proteins were separated by SDS-PAGE and Novex NUPAGE 4%–12% Bis-Tris Gel (Life Technologies, Thermo Fisher Scientific) and transferred onto methanol-activated PVDF membranes (Thermo Fisher Scientific). The blot was blocked with 5% nonfat dry milk in TBS for 1 hour at room temperature and subsequently incubated overnight at 4°C with polyclonal anti-POSTN (Abcam) diluted to 1:5,000 in TBS with 0.01% TBS Tween-20 (TBST) and 5% nonfat dry milk. Blots were washed, incubated with 1:10,000 HRP-conjugated goat anti-rabbit antibody (Abcam) in blocking buffer for 1 hour at room temperature, and washed again. Blots were developed by SuperSignal West Femto Maximum Sensitivity Substrate and exposed to x-ray film. GAPDH was used as a loading control. After 3 washes for 10 minutes with TBST and 1 wash for 5 minutes in TBS, the blot was incubated with HRP-conjugated mouse anti GAPDH antibody (Thermo scientific) diluted to 1:1,000 for 1 hour at room temperature. The blot was washed and developed by SuperSignal West Femto Maximum Sensitivity Substrate and exposed to x-ray film or imaged with a Bio-Rad ChemiDoc.

Statistics

Statistics were performed with GraphPad Prism software or R. For neuropathy incidence curves, a log-rank (Mantel-Cox) test was used. An unpaired, 2-tailed *t* test was used when comparing 2 groups with continuous values. Welch's correction was applied when the standard deviation was different for each group. For discrete data, Fisher's exact test was performed in R. ANOVA with multiple comparisons was used when comparing 3 or more groups. A paired *t* test was used when experimental and control samples were obtained from the

same animal, as in the nerve transection surgery. For the macrophage chemotaxis assay, statistics were performed in R using the *lm()* function, in which parameters were fit to each mouse as well as the difference in treatment. *P* values were calculated by comparing the fit of the full model to a model without a term for the difference in treatment. *P* values were adjusted using Bonferroni's correction. A *P* value of less than 0.05 was considered significant. Unless otherwise noted, data are presented as individual values with means.

Study approval

All animal experiments were approved by the IACUC of UNC-CH and performed in compliance with the Animal Welfare Act and NIH guidelines for the ethical care and use of animals in research.

Author contributions

DEA and MAS designed the study. DEA, YW, CJS, JFH, AH, SSS, and MAS analyzed the data. DEA, YW, JLL, BC, EWX, DS, CK, RN, CJS, EK, XLZ, and JFH performed experiments. DEA, YW, and JS performed the statistical analyses. DEA, SSS, and MAS wrote the manuscript.

Acknowledgments

Research reported in this publication was supported by the National Institute of Neurological Disorders and Stroke (RO1NS079683, MAS, principal investigator, and RO1NS107851, MAS and SSS, principal investigators); the GBS/CIDP Foundation (MAS, principal investigator); a National Institute of Allergy and Infectious Diseases (NIAID) Ruth L. Kirschstein National Research Service Award (NRSA) Institutional Research Training Grant (T32 AI 007273; J.P. Ting, principal investigator); and a National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) Ruth L. Kirschstein NRSA Institutional Research Training Grant (T32 DK 007750; R.J. Falk, principal investigator). All flow cytometric experiments were carried out with the support of the UNC Flow Cytometry Core Facility. The UNC Flow Cytometry Core Facility is supported in part by a Cancer Center Core Support Grant (P30 CA016086, to the UNC Lineberger Comprehensive Cancer Center); in part by a North Carolina Biotech Center Institutional Support Grant (2012-IDG-1006); and by the Office of the Director of UNC-CH. Confocal and wide-field microscopy for murine samples was performed at the UNC Neuroscience Center Microscopy Core Facility, which is supported in part by funding from the National Institute of Neurological Disorders and Stroke (NINDS) (P30 NS045892) and a National Institute of Child Health and Human Development Intellectual and Developmental Disabilities Research Center Support Grant (U54 HD079124). The content is solely the responsibility of the authors and does not necessarily represent the official views of the NIH.
