# ABSTRACT OF THE DISSERTATION

Breastfeeding Interventions for Women with a History of Substance Use

by

Kate Mitchell

Doctor of Nursing Practice

University of California, Los Angeles, 2023

Professor Wei-Ti Chen, Chair

Pregnancy serves as a significant motivating factor for many pregnant people to reduce or abstain from substance use. However, many women relapse during the postpartum period. Additionally, in the United States, substance-use related deaths are a leading cause of maternal mortality.

One potential targeted intervention is development of a lactation support program designed for patients with a history of substance use. Providing supported lactation services to this higher risk population may extend abstinence motivation from pregnancy to the postpartum period, reducing postpartum relapse rates and improving lactation rates. In addition to increasing contact during the postpartum period, targeted breastfeeding support may deter against substance use during an emotionally challenging period fraught with relapse triggers.

The quality improvement project aim is to increase support for vulnerable patients through a pilot lactation program. The project lead evaluates the effectiveness of the pilot to impact breastfeeding rates, postpartum substance use, and maternal satisfaction. By pairing patients with a Certified Nurse-Midwife Internationally Board-Certified Lactation Consultant who focuses on patients with a history of substance use, obstetric practices may impact rates of breastfeeding and postpartum substance use while also achieving high levels of maternal satisfaction.

Few studies focus on the unique needs of people with a history of substance use. As rates of substance use increase in the United States, focused research is needed to determine how to best support this population.

The dissertation of Kate Mitchell is approved.

## CURRICULUM VITAE

Kate Mitchell

### Education

2023	Doctorate of Nursing Practice(c), University of California- Los Angeles
2021	Certificate Lactation Consultant, University of California- San Diego
2016	MS Nursing, Nurse-Midwifery, University of California- San Francisco
2014	Diploma Nursing, University of California- San Francisco
2011	BA International Studies, University of San Francisco

### Nurse-Midwifery Experience

2018 - present	Los Angeles County Department of Health Services
2017 – 2018	Indian Health Service

### Professional Activities

2022 – 2023	Alliance for Innovation in Maternal Health (AIM): OB Emergency Toolkit Committee
2018	American College of Nurse-Midwives (ACNM): Thacher Community Grant

## **Breastfeeding Interventions for Women with a History of Substance Use**

Substance use (SU) during the perinatal period affects fetal, neonatal, and maternal health outcomes, leading to increased risk of preterm birth, intrauterine growth restriction, postpartum depression, and fatal overdose (Chomchai et al., 2019). Despite the negative impact on maternal and fetal health, approximately 5% of pregnant women consume illicit drugs (National Institute on Drug Abuse, 2020), 10% drink alcohol (Denny et al., 2020), and 10% use tobacco (Hansen et al., 2018). Pregnancy serves as a significant motivating factor for many women to reduce or abstain from substance use (Frazer et al., 2019). While many women successfully decrease substance use or abstain from use during pregnancy, rates of postpartum relapse are high: Forray et al. (2015) estimate that 80% of women relapse on one or more substances in the first three months postpartum. On average, relapse occurs within 110 days of delivery for tobacco, 127 days for alcohol, 138 days for marijuana, and 287 days for cocaine products (Forray et al., 2015).

According to the Centers for Disease Control and Prevention (CDC), substance-use related deaths are a leading cause of maternal mortality from 2007 to 2016 (CDC, 2018). In this subset of women, the risk of death or disability secondary to relapse is highest in the postpartum period. In California between 2010 and 2012, 18% of postpartum deaths were attributed to illicit substance use and suicide (Goldman-Mellor & Margerison, 2019). Beyond personal risks associated with maternal relapse, there is an increased risk of neglect, abuse, and/or chemical exposure to the infant and older children in the home when caregivers relapse (Goldberg & Blaauw, 2019). In addition, this population has an increased risk of postpartum depression (Pentecost et al., 2021), further impacting physical health and mother-child bonding. According to Alexander (2013), dual diagnosis increases relapse risk, especially for women with low

socioeconomic status (SES), further highlighting the importance of targeted, interprofessional interventions to improve postpartum care. One potential targeted intervention is development of a breastfeeding support program designed for women with a history of SU. In addition to increasing medical surveillance during the vulnerable postpartum period, Cook and Larson (2019) suggest that breastfeeding may serve as a deterrent against substance use during a period fraught with relapse triggers.

Patients with a history of SU in pregnancy have complex medical and social needs during the postpartum period. One controversial aspect of postpartum care in this population is whether or not they should breastfeed their infant. Current national guidelines from American Pediatric Association (APA) suggest women who use substances can safely breastfeed in certain circumstances; additionally, APA offers nuanced recommendations for shared decision-making with patients after reviewing risks and benefits of lactation (Eidelman et al., 2019). Research suggests lactation is most successful when breastfeeding mothers receive approval from their families, antepartum education from their obstetric provider, practical support from postpartum nurses while inpatient, and ongoing professional lactation support after discharge (Bartick et al., 2017; Blixt et al., 2019; Brown, 2017; Chiang et al., 2021; McGuinness et al., 2020; Rollins et al., 2016; Walters et al., 2019). As multiple studies suggest, evidence-based lactation care requires long-term, professional support. For women with a history of SU, ensuring access to competent and compassionate team-based lactation support is essential for increasing historically low breastfeeding rates (Bartholomew & Lee, 2019).

Supported breastfeeding may be an underutilized intervention in this medically and socially high-risk population. By providing individualized breastfeeding support, providers may increase rates of safe breastfeeding and extend sobriety motivation from pregnancy to the

postpartum period, ultimately decreasing relapse rates in postpartum women. The project provides the education and support needed for successful breastfeeding in a high-risk population through one-to-one counseling with a Certified Nurse-Midwife (CNM)/Internationally Board-Certified Lactation Consultant (IBCLC).

### **Problem statement**

Women with a history of substance use are at elevated risk of relapse in the postpartum period (Forray et al., 2015; Wu et al., 2020). Additionally, they are less likely to initiate breastfeeding (Bartholomew & Lee, 2019). At this urban, safety net hospital, CNMs serve many socially high-risk patients with a history of SU prior to pregnancy or during pregnancy. Owing to the midwife-led prenatal care program, midwives are often the primary care providers for substance-using women during their pregnancies. This model of midwifery care for substance-using women is unique as many practices consider SU an indicator of a high-risk pregnancy and a factor that may preclude patients from midwifery care (Ranchoff & Declercq, 2020). However, CNMs are well equipped to provide care to this vulnerable population as midwives improve obstetric health outcomes through therapeutic, relationship-based care that decreases stigma (Shogren, 2020) and increases maternal self-sufficiency (Reid & McStay, 2018). Furthermore, patients with a history of substance use benefit from the midwifery model of continuity care during the antepartum, intrapartum, and postpartum periods (Whitehead et al., 2019). This project harnesses the power of the established midwife-patient relationship to promote postpartum sobriety/substance harm reduction and lactation.

### **Current practice**

The current standard-of-care for postpartum patients at this safety net hospital includes one phone call at postpartum day twenty-one to postpartum day fifty-six. The CNM initiates the

phone call and typically focuses on the adult patient's physical recovery from birth and her current mental wellbeing. CNMs routinely ask the patient what her chosen feeding method is for the baby and if she is experiencing issues with feeding; if patients report feeding difficulty, CNMs refer the patient to community Women Infants and Children (WIC) centers. If the CNM determines a physical examination is indicated, the CNM will schedule the patient for an in-person evaluation. If the CNM determines there is an acute breastfeeding issue such as mastitis, she will refer the patient to obstetric triage immediately. Prior to the postpartum phone call, many breastfeeding patients seek assistance with breastfeeding issues in the community at non-affiliated centers.

### **Population, Intervention, Comparison, Outcome, and Time (PICOT)**

In women with a history of substance use (P), how does enrollment in a midwife-led breastfeeding program (I) compared to standard care [one postpartum telehealth visit at six weeks postpartum] (C) affect patient breastfeeding rates (O1), self-reported substance use (O2), or maternal satisfaction (O3) in the immediate postpartum period [day one until week six] (T)?

### **Theoretical framework**

The therapeutic patient-midwife relationship is central to effective intervention. Engaging substance-using patients in care involves significant relationship building and demonstration of genuine empathy (Page, 2016). Mary Koloroutis developed the Relationship-Based Care (RBC) Model to guide health care practitioners in compassionate relationships that ultimately improve health outcomes. Koloroutis (2004) identifies the foundation of RBC as the recognition that relationships with patients and their families are “a sacred, privileged trust” (p. 134). The first component of the RBC framework, the patient-provider relationship, complements the midwifery model because it centers patients and emphasizes the importance of connection (Butts & Rich,

2018; Koloroutis, 2004). According to Koloroutis, the RBC framework maintains the patient and family as the central focus and demonstrates “unwavering respect and personal concern for the patient” (p. 15). In addition, RBC emphasizes the importance of engaging patients in their self-care, an aspect that the breastfeeding intervention achieves by providing mothers with practical skills for self-sufficiency. The positive relationships formed by RBC may diminish the chronic psychosocial stress experienced by women with a history of SU (Gavin et al., 2012). Utilizing the RBC framework may impact measurable outcomes, such as breastfeeding frequency or self-reported substance use rates, because it lays the foundation for therapeutic recovery beyond the postpartum period.

### **Literature Search**

The benefits of breastfeeding to maternal and neonatal health are well documented in medical literature (Bernardo et al., 2013; Brown, 2017; Chowdhury et al., 2015); however, literature on practical interventions to increase breastfeeding initiation and continuation rates is less robust. Furthermore, interventions to increase breastfeeding rates among special populations, including women with a history of SU, are rarer still. Multiple searches were performed using two electronic article databases, Cumulative Index to Nursing and Allied Health Literature (CINAHL) Complete and PubMed via the University of Los Angeles, California (UCLA) library. Limiting findings to peer-reviewed articles published in English between 2018 to 2022, a search was conducted on PubMed using the search terms ("breast feed\*" OR "breastfed" OR "lactation") AND ("substance abuse" OR "drug use") AND ("support" OR "intervention"), yielding 180,456 results. Inclusion of Boolean terms like OR and AND improved article relevance. Using the same search refinement criteria, the terms ("substance abuse or substance use or drug abuse or drug addiction or drug use") AND ("breastfeed or breast feed or

breastfeeding” OR “lactation”) AND (“support”) were entered in CINAHL, yielding 1,933 results. Articles were further refined by relevance and ultimately 200+ articles were reviewed in the development of this DNP QI proposal. Of those articles, ten articles were selected for literature review (Appendix A).

Titles and abstracts were reviewed for relevance to the population and applicability to the primary care setting. The ten articles included in the literature review inspired the development of this DNP proposal and the structure of the pilot intervention. Ultimately seven key studies were selected for appraisal based on their subject relevance, reliability, and applicability to the intended population. The seven key articles are included in the Table of Evidence (see Table 1).

### **Literature Review**

Louis-Jacques et al. (2020) explored the impact of a quality improvement (QI) project focused on maternal knowledge of substance use during lactation. In the QI project, study organizers conducted pre-tests of maternal knowledge, provided one hour of education about the effects of substances during breastfeeding, and then collected post-tests of knowledge; additionally, organizers collected information about participants breastfeeding behavior during the postpartum period. The QI project included 121 pregnant women recruited from prenatal clinics in Hillsborough County, Florida. Louis-Jacques et al. (2020) determined that although maternal knowledge about substance use during lactation increased following the education intervention, overall women using medications postpartum were less likely to exclusively breastfeed than those not taking medications (adjusted OR at 2–4 weeks = 3.150 (95% CI: 1.292–7.684) and adjusted OR at 6–8 weeks = 4.305 (95% CI: 1.076–17.225) regardless of medication type. While this study suggests educational sessions may increase baseline knowledge, it also reveals many patients are incorrectly instructed to discontinue breastfeeding

regardless of the pharmacologic safety profile of their prescriptions. While this QI project did not enroll a large number of women with illicit substance use, it reveals the need for increased provider education regarding lactation, substance use, and harm reduction for providers serving target population.

Harris et al. (2020) examined the correlation between substance use identified by urine toxicology screening in the antepartum period with ongoing substance use identified by urine toxicology in the postpartum period. The study enrolled 503 women receiving care at Boston Medical Center (BMC). The purpose of this retrospective cohort study was to determine best practices for lactation support; the established practice at the investigation site was to discourage women from breastfeeding if they have a positive urine toxicology screening during the third trimester of pregnancy. Harris et al. (2020) utilized student's t-test for continuous variables and Pearson's Chi-squared test for categorical variables; researchers then used 2×2 tables to calculate sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) of non-prescribed use prenatally at: 90-31 days prior to delivery, 30 days prior to delivery, at the time of delivery hospitalization, and by trimester. Researchers determined that positive urine toxicology at delivery was associated with the highest odds of postpartum substance use (odds ratio (OR) 4.51 [95% confidence interval (CI) 2.57-7.91]). However, Harris et al. (2020) also determined the positive predictive value of a urine toxicology screening is lower than negative predictive value, resulting in women at little risk of postpartum substance use being discouraged by their health care team from breastfeeding. Findings from Harris et al. (2020) suggest widespread use of urine toxicology screening should not be used as a guiding metric for determining safety of lactation in the target population. This study highlights the complexity of

lactation counseling for women with a history of substance use and suggests recommendations should not be based on a single data point.

Yonke et al. (2019) investigated the difference between breastfeeding intention in women enrolled in medication-assisted therapy (MAT) compared with rates of breastfeeding at the time of hospital discharge and at two months postpartum. This longitudinal retrospective cohort study enrolled six women from the Milagro Prenatal Program at the University of New Mexico (UNM). Researchers conducted chart reviews to determine the participants' infant feeding plan as stated during their prenatal care; researchers then compared breastfeeding intention with documented breastfeeding during the hospital admission and at various time intervals following hospital discharge. Yonke et al. (2019) examined these differences using Pearson chi-square tests. Researchers determined 84% of participants intended to breastfeed; of those 84%, 76% of participants on methadone therapy breastfed at discharge compared to 100% on buprenorphine therapy. However, at two months postpartum, only 12% on methadone therapy and 11% on buprenorphine therapy breastfed exclusively. This study recognizes the high desire of patients to breastfeed and documents the high breastfeeding success rate achieved with intensive, inpatient lactation support. These findings suggest that intensive, longer-term breastfeeding support may build off the success of short-term, inpatient lactation support to increase breastfeeding duration in the target population.

Cook and Larson (2019) designed a qualitative descriptive study exploring how substance use disorder influences maternal breastfeeding practices. The researchers enrolled six Caucasian women receiving treatment at a North Carolina drug rehabilitation therapy program and conducted interviews focused on the participants' breastfeeding experiences. The researchers employed a two-reviewer content analysis with identification of patterns and code words to

identify key themes. Cook and Larson (2019) categorized the discussions into three themes: The Battle (i.e., relapse), The Lockdown (i.e., consequences), and The Best Shot (i.e., bonding with their baby). The research, while limited by the small, racially homogenous sample size, reveals breastfeeding as an opportunity to reduce Neonatal Opioid Withdrawal Syndrome (NOWS) severity, increase mother-child bonding, and promote maternal self-confidence. Cook and Larson's (2019) suggest women in recovery desire breastfeeding and successful breastfeeding may positively impact their self-image, making specialized lactation support in this population a worthwhile intervention.

Young-Wolff et al. (2020) examined the rates of completed SU screening and patient demographic data. This study was a retrospective descriptive study involving 70,031 women at Kaiser Permanente Northern California prenatal clinics. Of the 70,031 women screened, 11,926 women screened positive via substance use questionnaires and/or urine screening tests for ethanol, cannabis, and illicit substances, such as cocaine, amphetamine, and opioids (Young-Wolff et al., 2020). Young-Wolff et al. (2020) determined that 83% of women who screened positive accepted and participated in a 1-hour counseling intervention session. After correlating demographic data, Young-Wolff et al. (2020) found women who participated in the counseling intervention session were younger, more likely to be African American or Hispanic, from neighborhoods with lower income, and had lower education levels. Of note, women who screened positive for alcohol use in pregnancy were less likely to participate compared to women who screened positive for drug use in pregnancy. This study suggests that most women who use substances in pregnancy accepted the counseling intervention. It also suggests that screening and counseling interventions are acceptable to the most medically vulnerable demographic groups. While participation was high for patients using drugs, this study highlights the need for a more

tailored approach to women using alcohol in pregnancy. Young-Wolff et al. (2020) contributes to this QI project as it suggests the perinatal period is an impressionable period in which patients may be more likely to accept substance use interventions.

MacVicar et al. (2018) conducted a mixed methods research study examining the feasibility and impact of a breastfeeding support intervention tailored for substance-exposed mothers and babies. The study examined how 1:1 inpatient education covering practical breastfeeding and neonatal self-consolation techniques, along with frequent encouragement, impacted breastfeeding rates and neonatal health outcomes. The target population included adult patients who intended to breastfeed, were enrolled in medical assisted therapy (MAT) during pregnancy, and delivered at term. The study enrolled 14 women and randomly assigned them to either the intervention group or the standard-care group (i.e. received general lactation education and support). While the study was quite small and focused only on inpatient interventions, the authors found a significant improvement in breastfeeding rates at hospital discharge: 100% (7 of 7) of the intervention group breastfed at discharge compared with 57% of control participants. MacVicar et al. (2018) suggests targeted, 1:1 lactation support is an effective intervention in the target population.

Dagla et al. (2020) implemented a retrospective cohort study to determine how a 12-month long midwife-led program providing antepartum education, breastfeeding care, and psychosocial support impacted initiation, exclusivity, and duration of breastfeeding. The study was conducted in Greece and included 1080 women. While the study excluded women with significant mental health issues and/or substance use, the study suggests long-term, interprofessional education and psychosocial support positively impacts breastfeeding rates: intervention participants who completed the full program initiated breastfeeding at higher rates

(96.3% vs. 94%) and continued breastfeeding longer (44.3% at 6 months postpartum vs. 0.78%). The study, while not focused solely on socially high-risk women, presents interesting future research questions examining breastfeeding not as a single decision but within the psychosocial context of women's lives. Dagla et al. (2020) presents interesting questions on whether or not CNMs can expand the success of long-term lactation support from the general population to the target population.

McGuinness et al. (2020) studied the impact of a Midwife/Internationally Board-Certified Lactation Consultant (IBCLC) led, hospital-based breastfeeding clinic on breastfeeding duration and patient satisfaction. The study, conducted in Ireland, enrolled ninety-nine women who delivered at an urban, obstetric hospital and attended the breastfeeding clinic via self-referral. The breastfeeding clinic intervention involved group education, 1:1 assessment by the clinical Midwife/IBCLC, development of a care plan, and weekly follow up. While 76% of the hospital's patients initiated breastfeeding, the target intervention group boasted high initiation rates and impressive breastfeeding duration: 99% breastfeeding at six weeks, 92% at three months, and 77% at six months. Although these rates are significantly higher than national averages in the United States and in Ireland, the study authors did not differentiate between rates of exclusive breastfeeding and any breastfeeding, which may exaggerate impact. Additionally, study authors did not document breastfeeding rates at six weeks, three months, and six months for non-attendees so true comparisons between participants and a control group are not possible. While this study lacks quantitative rigor, the qualitative data demonstrates attendees were highly satisfied with the intervention: interviews revealed participants felt empowered and attributed breastfeeding success to the support of their Midwife/IBCLCs. This study contributes to the extensive existing research on the need for professional lactation support for increasing

breastfeeding initiation and duration. Additionally, the article is valuable to this DNP QI proposal as it focuses specifically on the role of Midwife/IBCLCs to lead breastfeeding interventions within an obstetric hospital clinic.

Pezley et al. (2022) conducted a randomized pilot trial investigating how two web-based educational series affect perinatal depression rates and/or breastfeeding rates in the postpartum period. One educational series focused on strategies for mood management in the perinatal period while the other series included perinatal mood content with additional lactation content. The study recruited nationally and included 22 participants who identified as Black or African American, intended to breastfeed, and self-reported mild to moderate depressive symptoms based on a Patient Health Questionnaire (PHQ 8) score. The study enrolled participants at 20 to 28 weeks of pregnancy and followed participants until they were 12 weeks postpartum. The results of the interventions were compared by computing means and standard deviations for continuous variables and frequencies for categorical variables. While breastfeeding rates were high overall, higher rates of breastfeeding were observed in the lactation intervention group: 100% of lactation participants breastfed in any amount (i.e. breastfed and supplemented with infant formula) and 91% exclusively breastfed at six weeks compared to the mood management group in which 86% breastfed in any amount and 57% exclusively breastfed at six weeks postpartum. Pezley et al. (2022) informs this QI proposal because it shows that breastfeeding educational interventions offered during the antepartum period and continued during the postpartum period impact breastfeeding rates even in populations that historically have lower rates of breastfeeding. However, due to the small sample size and the exclusion of participants with a diagnosis of a mental health disorder, including substance use disorder, the applicability of this intervention to the target population of substance using women is unknown.

Samawi et al. (2021) synthesized published research on interventions to decrease alcohol consumption in the antepartum and postpartum periods in a systematic review of eleven articles. The systematic review included randomized controlled trials and quasi-experimental studies that compared specific interventions to control groups. These studies focused on pregnant and postpartum women who consumed alcohol in pregnancy or during the postpartum period. While each study differed on how it defined alcohol use (i.e. any alcohol consumption versus diagnosed alcohol use disorder), all studies sought to affect rates of alcohol use through 1:1 verbal interventions, such as Motivational Interviewing or Cognitive-Behavioral Therapy, within health care settings such as clinics or hospitals. Of the eleven studies, six studies found decreased alcohol consumption in all participants without a statistically significant difference in consumption for the intervention group compared to the control group. Of the five studies finding significant decreases in alcohol consumption in the intervention group compared to the control group, three were structured to provide an initial intervention with frequent, scheduled follow up interventions. This systematic review is limited by the small number of studies reviewed but suggests continuity and ongoing evaluation may be key to amplifying intervention impact for pregnant and postpartum women who use substances. Such findings influence the QI proposal by structuring the intervention to include provider-participant continuity and weekly follow up with participants.

### **Literature Synthesis**

The literature search revealed consensus on best practice guidelines for lactation support and postpartum care (Dagla et al., 2020; McGuinness et al., 2020; Pezley et al., 2022). While the literature search demonstrates high desire for breastfeeding amongst women with a history of SU (Cook & Larson, 2019; MacVicar et al., 2018; Yonke et al., 2019), it also reveals the need for

additional research exploring best practice postpartum and lactation interventions for women with a history of SU (Harris et al., 2020; Samawi et al., 2021; Young-Wolff et al., 2020). The literature suggests professional lactation support improves breastfeeding initiation, exclusivity, and continuation rates in the general population (Dagla et al., 2020; McGuinness et al., 2020) but does not reveal if these results can be replicated in populations with a history of SU in the long term. These gaps in knowledge highlight the need for the proposed intervention and the need for additional, multidisciplinary research investigating other strategies for perinatal health improvement in substance-using populations.

## **Methodology**

### **Ethical Considerations**

As a quality improvement project implementing best practices for lactation support, this pilot received an Internal Review Board (IRB) waiver from the University of California, Los Angeles and a waiver from the institutional setting.

Guidelines set by the Health Insurance Portability and Accountability Act of 1996 (HIPAA) protecting participants' private health information will be followed. Anonymizing patient information and maintaining patients' information within secure Electronic Medical Record networks will ensure compliance with HIPPA privacy and security rules.

As the target population faces many complex social issues, including poverty, substance dependency, new motherhood, and possible social welfare involvement, that make them uniquely vulnerable, their participation in this pilot must be without coercion. As the pilot occurs within a safety-net hospital setting, most patients will classify as low-income and have publicly funded health insurance plans, such as Medi-Cal or LA Care, or presumptive Medi-Cal. Research shows that socioeconomic status (SES), specifically personally experiencing poverty and living in an

impoverished area, may affect maternal health outcomes more than genetic predisposition (Graham, 2016). This pilot project recognizes the ethical obligation of medical providers to acknowledge these social determinants of health and develop targeted interventions to counteract the negative impact of poverty.

### **Project Design**

This intervention is a quasi-experimental quality improvement (QI) project that utilizes the Plan Do Study Act (PDSA) methodology to determine the impact of enrolling pregnant women with a history of substance use (broadly defined to include tobacco, alcohol use, marijuana, and illicit drugs) in a pilot breastfeeding support program. The aim of this evidence-based QI project was to improve the standard of care that women with a history of substance use receive during the postpartum period.

### **Setting**

The intervention setting was in a large, urban hospital. The intervention occurred within the women's health clinic, the inpatient postpartum unit, and via telehealth visits.

### **Sampling**

The intervention sample included pregnant women with a history of substance use who desire to breastfeed and who receive their antepartum/postpartum care with the midwifery practice. Inclusion criteria were as follows: pregnant patients who are 18 years old+, who have a history of substance use or current substance use in pregnancy, who desire to breastfeed, and who are English-speaking. For the purposes of this QI project, substance use is broadly defined to include tobacco, alcohol use, marijuana, and/or other illicit drugs. Exclusion criteria included patients who decline breastfeeding or who have a medical contraindication to breastfeeding, such as human immunodeficiency virus (HIV) with a detectable viral load or infant galactosemia

(Davanzo, 2018). The comparison group consisted of women who met criteria for inclusion in the intervention group but who were recruited after delivery.

### **Recruitment**

CNM IBCLCs, staff CNMS, the perinatal social worker (SW), and public health nurse (PHN) referred potential participants to the project lead based on the pilot's established eligibility criteria. Recruiters explained the pilot breastfeeding support program and referred interested parties to the project lead for additional counseling. The project lead conducted informed consent prior to enrollment in the QI project.

### **Plan for Implementation**

The project committee implemented the pilot intervention in Summer 2023 (see Appendix B). As the proposal was a pilot conducted by existing CNM IBCLC staff, no additional hiring was necessary. In May 2023, the project committee met to discuss project structure, the intervention bundle, and implementation. The project committee consisted of current employees, including the project lead, staff CNMs, the perinatal SW, and PHN. The project lead's main responsibilities were to coordinate the pilot, ensure adequate recruitment, communicate with implementers, collect pilot data, and analyze results. The project lead provided direct patient care, including antepartum education, in-person postpartum evaluation, and telehealth follow-up.

### **Data Collection**

The Project Lead collected demographic information about participants using the Demographic Survey (Appendix C). Assisted by the CNM IBCLC, the participant completed the Breastfeeding Attrition Prediction Tool (BAPT) prior to delivery (Appendix D). During the in-person evaluation, the CNM IBCLC provided standard breastfeeding support, including

completion of a LATCH assessment (Appendix E). Pilot questionnaires measured rates of participant breastfeeding at hospital discharge, weekly rates of any breastfeeding at one to six weeks, weekly rates of exclusive breastfeeding at one to six weeks, weekly rates of any self-reported substance use, and the number of participants completing the program (Appendix F). Data regarding rates of breastfeeding at hospital discharge were collected from chart review correlated with participants' reports of feeding mode. Data regarding rates of breastfeeding and substance use were collected from participant reports during the telehealth appointment. Qualitative measurements included post-intervention interviews to evaluate participants' satisfaction with the program, self-reported challenges with breastfeeding, and self-reported motivating factors for breastfeeding (Appendix F). Additionally, enrollees answered questions about postpartum substance use (PPSU), including questions about postpartum substance use behavior, relapse triggers, and sobriety/substance use reduction motivators. The qualitative interviews occurred after completion of the program or after withdrawal from the program. Lastly, patients completed General Anxiety Disorder-7 (GAD-7) and Patient Health Questionnaire-9 (PHQ-9) surveys to assess anxiety and depression levels (Appendix G). CNMs referred patients with elevated GAD-7 (score  $\geq 5$ ) and PHQ-9 (score  $\geq 5$ ) to the clinic perinatal social worker, as is standard practice for any patient with abnormal mental health screening results.

### **Intervention Bundle**

The program paired the woman with the CNM IBCLC who provided interventions in three stages: 1) Antepartum, 2) Immediately Postpartum, and 3) Postpartum (Appendix H).

### **Stage One: Antepartum**

In stage one, the CNM met with the participant after enrollment and while the participant was still pregnant. During stage one, the CNM built rapport with the participant while providing in-person, 1:1 breastfeeding education, including information about substances in breast milk and harm reduction techniques for safe breastfeeding after potential relapse (i.e. the option of pumping breast milk and discarding milk until substance sobriety is re-established). Stage one data collection included 1) demographic survey, 2) BAPT survey, and 3) chart review of PHQ-9 and GAD-7.

### **Stage Two: Immediately Postpartum**

In stage two, the CNM met with the participant at the hospital within the first 24-48 hours of delivery. During this visit, the CNM provided social support, reviewed breastfeeding education, and assessed the breastfeeding dyad using the LATCH score. During this visit, the CNM continued rapport building using the RBC model. Stage two data collection included: 1) the LATCH score.

### **Stage Three: Weekly Postpartum**

In stage three, the CNM met with the participant via telephone call weekly for six weeks. During stage three, the CNM continued providing social support while also evaluating breastfeeding using questionnaire #1. If the CNM determined in-person evaluation was warranted, the CNM scheduled an in-person lactation visit. At the final six-week telehealth visit, the CNM collected questionnaire #2. Data collection during stage three included: 1) weekly questionnaire #1, 2) one-time questionnaire #2 at final visit, and 3) chart review of PHQ-9 and GAD-7.

## **Analysis**

Quantitative data regarding breastfeeding rates and substance use rates were analyzed using independent samples T-test to determine possible relationships between breastfeeding rates and postpartum substance use rates. Demographic data was analyzed with frequency distributions. Survey responses were also analyzed with frequency distributions.

## **Demographics**

Six women enrolled in the pilot and four women served as the comparison group. In total, five (50%) identified as Hispanic, one (10%) as Asian, one (10%) as African American, and three (30%) as “Other”; none identified as Caucasian (Table 1). Participant and control group ages ranged from 22-39 years old (Table 2). All participants enrolled in the third trimester of their pregnancy, with a range of 33 weeks to 36 weeks of gestation. One participant in the pilot group reported a previous birth; no one in the control group reported a previous birth. In both groups, the reported substances used included five women endorsing (50%) marijuana, seven (70%) endorsing alcohol, two (20%) endorsing methamphetamine, and one (10%) endorsing tobacco use (Table 3). No one endorsed active substance use at the time of enrollment. In total, five (50%) had a known mental health diagnosis; of those, 3 were diagnosed with anxiety, 3 were diagnosed with depression, 1 was diagnosed with schizophrenia, and 2 were diagnosed with bipolar disorder (Table 4).

## **Outcomes**

Of the six women who participated in the pilot, five women continued the pilot after delivery. Of those five women, 100% (N=5) reported breastfeeding or feeding expressed breastmilk at six weeks postpartum, compared to 50% (N=4) of the comparison group at six weeks postpartum (Table 5). At six weeks, 100% (N=5) of the participants and 100% (N=4) of

the comparison group denied substance use (Table 6). Of the five women who completed the pilot, 100% (N=5) reported the breastfeeding program was “very helpful” or “helpful”; none reported the program as “not helpful” (Table 7).

An independent samples T-test with an alpha level of .05 was conducted on group responses related to breastfeeding behavior (“In the past 7 days, have you breastfed the baby or fed the baby breast milk?”). “Yes” responses were coded as “1” and “No” responses were coded as “0”. This analysis revealed no statistically significant difference between the breastfeeding behaviors of the participant group and the comparison group (p-value = 0.31) (Appendix M).

### **Discussion**

The purpose of this pilot was to improve breastfeeding support for socially high-risk patients who may not initiate breastfeeding and/or may be at risk of substance use during the postpartum period. Organizers anticipated an increased rate of breastfeeding in the intervention group and projected possible decreased rates of postpartum substance use; however, no difference was noted in breastfeeding behavior or postpartum substance use behavior between the participants and the control group. While MacVicar et al. (2018) found greater likelihood of breastfeeding amongst substance using women who received tailored breastfeeding support compared to routine care, their study focused on women enrolled in substance abuse programs. Like Yonke et al. (2019) and Cooke & Larson (2019), this pilot revealed high intention to breastfeed in patients with a history of substance use in pregnancy. While Dagla et al. (2020) showed that midwife-led lactation support can lead to increased breastfeeding rates, the duration of this pilot (six weeks) was brief compared to the twelve-month intervention initiated by Dagla et al.. Similar to the population studied by Harris et al. (2020), postpartum substance use rates

were low overall; however, it is unclear how the pilot impacted postpartum substance use behavior compared to routine care.

This pilot did not demonstrate a statistically significant difference in breastfeeding behavior or postpartum substance use between the intervention and comparison groups. The impact of the pilot may be modest due to the small sample size and lack of population diversity. Additionally, the pilot did not control for dual diagnosis of substance use and mental health disorders in the cohorts, which may have affected results. Although general increases in breastfeeding rates and general decreases in PPSU rates were expected, the degree of impact may also be limited by competing health priorities during the postpartum period. Overall, the pilot presented low instances of PPSU in the target population, regardless of participating status on in the assigned group. The overall low rate of substance use may not be representative of general postpartum substance use rates as the pilot concluded data collection at six weeks postpartum versus twelve weeks postpartum. As suggested by Forray et al. (2015), most substance use resumes by twelve weeks postpartum. Had the pilot extended the timeframe beyond six weeks, pilot coordinators may have observed a difference in substance use rates between the intervention group and comparison group. Additionally, the pilot did not control for patients who self-identified recreational use versus self-identified problematic use or addiction. This expansive inclusion criteria allowed greater enrollment in the pilot but may have resulted in inclusion of patients at low risk of relapse. Finally, the impact on substance use rates also may have been obscured as the pilot relied on subjective patient report versus objective toxicology reports, unlike the study by Young-Wolff et al. (2020).

In future study, researchers should consider surveying women at twelve weeks postpartum to determine if breastfeeding behavior and sobriety are sustained at similar rates.

Researchers should develop additional qualitative surveys to understand reasons why this population may wean and/or reasons why they resume substance use.

While organizers anticipated high patient interest in intervention participation, recruitment proved difficult due to a couple of factors. Potential recruits expressed concern that the time commitment of participation was excessive. Additionally, some patients expressed confidentiality concerns and were hesitant to answer detailed questions about substance use in pregnancy. Other potential recruits declined participation because they felt they received adequate breastfeeding education already. In future recruitment, researchers should consider offering enrollment incentives, such as breastfeeding-themed literature, stickers, charms, or water bottles. Additionally, organizers will consider additional survey questions to reveal satisfaction rates for routine breastfeeding education and support in the comparison group.

### **Limitations**

Numerous possible confounders may affect data reliability. The generalizability of this QI project is limited by the small intervention group and comparison group. Another significant confound may be that women who are intrinsically motivated to breastfeed may be more likely to enroll in this time-intensive intervention. Higher breastfeeding rates among enrollees may be related to intrinsic motivation versus the intervention. Additionally, self-reported SU may not be a reliable indicator of the intervention's success at decreasing PPSU as patients may be inclined to under-report PPSU if they fear judgement or other possible ramifications. Furthermore, decreased PPSU rates may be due to increased interpersonal support received during antepartum care and not due to breastfeeding behavior.

## **Implications for Clinical Practice & Research**

While numerous studies investigate best practices for lactation support in the general population, fewer studies focus on the unique needs of women with a history of SU in pregnancy (Haase et al., 2019; van Dellen et al., 2019). As substance use rates increase among pregnant women in the United States (Denny et al., 2020; Haight et al., 2018), focused research is needed to determine how to best support postpartum women in recovery from SU.

In line with research conducted by Cook & Larson (2019), MacVicar et al. (2018), Yonke et al., (2019), this pilot revealed high maternal desire for breastfeeding amongst women with histories of substance use. While this small pilot did not demonstrate differences in breastfeeding behavior or postpartum substance use between the participant group and the comparison group, patients found the intervention helpful (Table 8). The high levels of maternal satisfaction support continuation of the pilot and further evaluation of the intervention bundle.

One potential implication for future research is how such an intervention impacts adherence to the postpartum care schedule. Patients with low socioeconomic status (SES) and/or a history of SU have lower rates of appointment adherence (Arpey et al., 2017; Simmons & Austin, 2022). Overall, research demonstrates attendance for postpartum care is lower compared to prenatal care attendance across patient demographics (de Bocanegra et al., 2017) but rates are improved when postpartum care follows a more holistic model that includes lactation services (Sacks et al., 2022).

Another potential implication for clinical practice and further research is the impact of breastfeeding on long-term health outcomes for people exposed to substances in-utero. Beyond the potential relapse protection, the project may also positively impact child health by increasing safe breastfeeding rates within a population at elevated risk of childhood illness.

Furthermore, additional research could explore the option for breast milk testing of relative substance dose; such an inquiry would fall within the harm reduction framework to improve individual risk/benefit counseling and informed consent. While such testing is not widely available for illicit substances, alcohol test strips for breast milk are available over the counter in the United States. In a future study, testing for commonly used substances such as marijuana could determine if such tests influence patient breastfeeding behavior.

Lastly, additional potential models of care could be examined, such as integrating IBCLCs or lactation counselors within women's recovery programs. In the field of perinatal health, Doctorate of Nursing Practice (DNP) CNMs hold a unique space as expert clinicians and quality improvement (QI) champions, allowing them to develop important research questions and implement QI projects. This QI initiative addresses multiple American Association of Colleges of Nursing (AACN) DNP Essentials, including Essential II: Organizational and Systems Leadership for Quality Improvement and Systems Thinking; Essential VII: Clinical Prevention and Population Health for Improving the Nation's Health; and Essential VIII: Advanced Nursing Practice (AACN, 2006). The proposal meets the DNP Essential of leadership by addressing health disparities in a target population (i.e. women using substances during the perinatal period) through development of a new care model based on contemporary scientific literature. Additionally, the proposal addresses the DNP Essential of population health by promoting human milk feeding, an intervention proven to positively impact public health outcomes, and while also decreasing illicit substance exposure. Lastly, the proposal utilizes the expertise of CNMs within their specialization to impact health outcomes, thereby meeting the DNP Essential of advanced practice nursing. DNPs are well equipped to lead such

interprofessional investigations because they possess the medical and population health knowledge needed for answering complex questions.

### **Conclusion**

Evidence suggests that timely access to professional lactation support increases breastfeeding success over time (Bartick et al., 2017; Chiang et al., 2021; Jiang, 2021; Rollins et al., 2016; Walters et al., 2019), may reduce maternal distress (Chrzan-Dętkoś et al., 2021; Dagla et al., 2021; McGuinness et al., 2020), and may reduce postpartum substance use rates (Cook & Larson, 2020; Orton et al., 2018). Considering the public health benefit and significant future cost avoidance, inquiries into breastfeeding interventions focused on women with a history of SU are needed. Beyond individual-level interventions such as this QI project, robust policy analysis is needed to determine how social policies such as universal paid family leave and/or universal basic income could also impact breastfeeding rates, perinatal mental illness, and postpartum substance use.

### **Funding**

The project lead did not acquire funding from any public or private entities.

26. I am confident I can breastfeed.	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	

## Appendix E

### LATCH Assessment Tool

#### LATCH Assessment Tool

- The LATCH system assigns a numerical score of 0, 1, or 2 to five key components of breastfeeding for a possible total score of 10 points.
- Ideally, the quality of the infant's latch should be assessed twice over a 24 hour period by two different healthcare providers and documented. (For example, the nurse can review the LATCH scores from the previous shift and see that there has been improvement related to the "hold" attribute, with the mother able to position without help. However, the nurse may see that the "comfort" characteristic has worsened over time and therefore needs follow-up. This collaborative approach provides a consistent measure of the progress of breastfeeding.)
- Make copies of this tool to use in your practice.

	0	1	2	Score
<b>L</b> Latch	Too sleepy No sustained latch or suck	Repeated attempts for latch or suck Hold nipple in mouth	Grasps breast Tongue down Lips flanged Rhythmical sucking	
<b>A</b> Audible swallowing	None	A few with stimulation	Spontaneous and intermittent (<24 hrs)	
<b>T</b> Type of nipple	Inverted	Flat	Everted (after stimulation)	
<b>C</b> Comfort	Engorged Cracked, bleeding, large blisters, or bruises	Filling Reddened, small blisters or bruises	Soft Non-tender	
<b>H</b> Hold	Full assist (staff holds infant at breast)	Minimal assist (staff holds, then mother takes over)	No assist from staff Mother able to position and hold infant	
				<b>TOTAL:</b>

## Appendix F

### Pilot Questionnaires [Assessment]

#### Breastfeeding Interventions for Women with a History of Substance Use

##### Pilot Questionnaire 1

Before leaving the hospital, were you breastfeeding the baby?

yes	no
-----	----

In the past 7 days, have you breastfed the baby or fed the baby breast milk?

yes	no
-----	----

In the past 7 days, have you fed the baby breast milk only?

yes	no
-----	----

In the past 7 days, have you used any substances, including tobacco, alcohol, drugs, or prescription drugs that were not prescribed?

yes	no
-----	----

If yes, what substances did you use? *Formal or street name is fine*

##### Pilot Questionnaire 2

1. On the following scale, note your experience of breastfeeding.

- |                       |                        |
|-----------------------|------------------------|
| 1. Very easy          | 4. Very difficult      |
| 2. Easy               | 5. Extremely difficult |
| 3. Somewhat difficult |                        |

2. What makes you want to breastfeed?

3. Have you felt like using substances since you delivered?

yes	no
-----	----

a. If yes, what triggered the feeling?

b. What makes you not want to use substances?

4. Did you find the breastfeeding program helpful?

- |                     |                |
|---------------------|----------------|
| 1. Very helpful     | 4. Not helpful |
| 2. Helpful          |                |
| 3. Somewhat helpful |                |

## Appendix G

### GAD-7 and PHQ-9

#### Patient Health Questionnaire and General Anxiety Disorder (PHQ-9 and GAD-7)

Date \_\_\_\_\_ Patient Name: \_\_\_\_\_ Date of Birth: \_\_\_\_\_

**Over the last 2 weeks, how often have you been bothered by any of the following problems?  
Please circle your answers.**

<b>PHQ-9</b>	<b>Not at all</b>	<b>Several days</b>	<b>More than half the days</b>	<b>Nearly every day</b>
1. Little interest or pleasure in doing things.	0	1	2	3
2. Feeling down, depressed, or hopeless.	0	1	2	3
3. Trouble falling or staying asleep, or sleeping too much.	0	1	2	3
4. Feeling tired or having little energy.	0	1	2	3
5. Poor appetite or overeating.	0	1	2	3
6. Feeling bad about yourself – or that you are a failure or have let yourself or your family down.	0	1	2	3
7. Trouble concentrating on things, such as reading the newspaper or watching television.	0	1	2	3
8. Moving or speaking so slowly that other people could have noticed. Or the opposite – being so fidgety or restless that you have been moving around a lot more than usual.	0	1	2	3
9. Thoughts that you would be better off dead, or of hurting yourself in some way.	0	1	2	3
<b>Add the score for each column</b>				

**Total Score (add your column scores):** \_\_\_\_\_

If you checked off any problems, how difficult have these made it for you to do your work, take care of things at home, or get along with other people? (Circle one)

Not difficult at all
Somewhat difficult
Very Difficult
Extremely Difficult

**Over the last 2 weeks, how often have you been bothered by any of the following problems?  
Please circle your answers.**

<b>GAD-7</b>	<b>Not at all sure</b>	<b>Several days</b>	<b>Over half the days</b>	<b>Nearly every day</b>
1. Feeling nervous, anxious, or on edge.	0	1	2	3
2. Not being able to stop or control worrying.	0	1	2	3
3. Worrying too much about different things.	0	1	2	3
4. Trouble relaxing.	0	1	2	3
5. Being so restless that it's hard to sit still.	0	1	2	3
6. Becoming easily annoyed or irritable.	0	1	2	3
7. Feeling afraid as if something awful might happen.	0	1	2	3
<b>Add the score for each column</b>				

**Total Score (add your column scores):** \_\_\_\_\_

If you checked off any problems, how difficult have these made it for you to do your work, take care of things at home, or get along with other people? (Circle one)

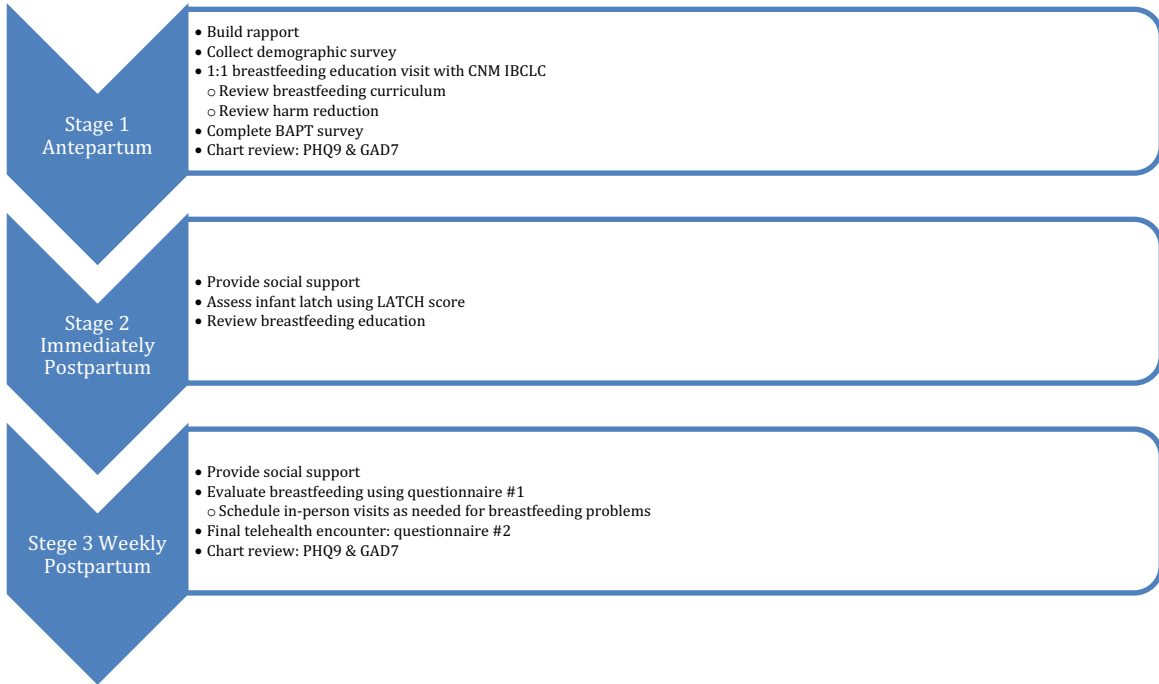

Not difficult at all
Somewhat difficult
Very Difficult
Extremely Difficult
