 $^{1}\,\mbox{FARNHAM}$ 95 compares cyclotron frequency of trapped electrons with that of a single trapped $^{12}\text{C}^{+6}$ Ion. The result is $m_e=0.0005485799111(12)$ u, where the figure in parenthesis is the $^{1}\sigma$ uncertainty in the last digit. The uncertainty after conversion to MeV is dominated by the uncertainty in the electron charge.

² COHEN 87 (1986 CODATA) value in atomic mass units is 0.000548579903(13). See footnote on FARNHAM 95.

22 This DOHMEN 93 limit assumes a glant resonance excitation of the daughter Ca nucleus (mean energy and width both 20 MeV).

23 This DOHMEN 93 limit assumes the daughter Ca nucleus is left in the ground state. However, the probability of this is unknown.

²⁴ Assuming a giant-resonance-excitation model.

LIMIT ON MUONIUM -> ANTIMUONIUM CONVERSION

Forbidden by lepton family number conservation.

$R_{\rm g} = G_{\rm C} / G_{\rm F}$

The effective Lagrangian for the $\mu^+e^-
ightarrow \mu^-e^+$ conversion is assumed to be

$$\mathcal{L} = 2^{-1/2} \; \textit{G}_{\textit{C}} \; [\overline{\psi}_{\mu} \gamma_{\lambda} \; (1 \, - \, \gamma_{5}) \; \psi_{e}] \; [\overline{\psi}_{\mu} \gamma_{\lambda} \; (1 \, - \, \gamma_{5}) \; \psi_{e}] \; + \; \text{h.c.}$$

The experimental result is then an upper limit on $G_{\mathcal{C}}/G_{\mathcal{F}}$, where $G_{\mathcal{F}}$ is the Fermi coupling constant.

MUON DECAY PARAMETERS

Revised October 1997 by W. Fetscher and H.-J. Gerber (ETH Zürich).

Introduction: All measurements in direct muon decay, $\mu^- \to e^- + 2$ neutrals, and its inverse, $\nu_\mu + e^- \to \mu^- + \text{neutral}$, are successfully described by the "V-A interaction", which is a particular case of a local, derivative-free, lepton-number-conserving, four fermion interaction [1]. As shown below, within this framework, the Standard Model assumptions, such as the V-A form and the nature of the neutrals $(\nu_\mu \text{ and } \bar{\nu}_e)$, and hence the doublet assignments $(\nu_e \ e^-)_L$ and $(\nu_\mu \ \mu^-)_L$, have been determined from experiments [2,3]. All considerations on muon decay are valid for the leptonic tau decays $\tau \to \ell + \nu_\tau + \bar{\nu}_e$ with the replacements $m_\mu \to m_\tau$, $m_e \to m_\ell$.

Parameters: The differential decay probability to obtain an e^{\pm} with (reduced) energy between x and x+dx, emitted in the direction \widehat{z} at an angle between ϑ and $\vartheta+d\vartheta$ with respect to the muon polarization vector \vec{P}_{μ} , and with its spin pointing in the arbitrary direction $\widehat{\zeta}$, neglecting radiative corrections, is given by

$$\begin{split} \frac{d^2\Gamma}{dx\ d\cos\vartheta} &= \frac{m_\mu}{4\pi^3} \ W_{e\mu}^4 \ G_F^2 \ \sqrt{x^2 - x_0^2} \\ &\quad \times (F_{IS}(x) \pm P_\mu \cos\vartheta \ F_{AS}(x)) \\ &\quad \times \left[1 + \vec{P}_e(x,\vartheta) \cdot \hat{\zeta} \right] \ . \end{split} \tag{1}$$

Here, $W_{e\mu}=\max(E_e)=(m_{\mu}^2+m_e^2)/2m_{\mu}$ is the maximum e^\pm energy, $x=E_e/W_{e\mu}$ is the reduced energy, $x_0=m_e/W_{e\mu}=9.67\times 10^{-3}$, and $P_{\mu}=|\vec{P}_{\mu}|$ is the degree of muon polarization. $\hat{\zeta}$ is the direction in which a perfect polarization-sensitive electron detector is most sensitive. The isotropic part of the spectrum, $F_{IS}(x)$, the anisotropic part $F_{AS}(x)$ and the electron polarization, $\vec{P}_e(x,\vartheta)$, may be parametrized by the Michel parameters [1,4] ρ , η , ξ , δ , etc. These are bilinear combinations of the coupling constants $g_{\epsilon\mu}^{\gamma}$, which occur in the matrix element (given below).

If the masses of the neutrinos as well as x_0^2 are neglected, the energy and angular distribution of the electron in the rest frame of a muon (μ^{\pm}) measured by a polarization insensitive detector, is given by

$$\begin{split} \frac{d^2\Gamma}{dx\ d\cos\vartheta} \sim x^2 \cdot \left\{ 3(1-x) + \frac{2\rho}{3}(4x-3) + 3\eta\ x_0(1-x)/x \right. \\ \left. \pm P_\mu \cdot \xi \cdot \cos\vartheta \left[1 - x + \frac{2\delta}{3}(4x-3) \right] \right\} \ . \end{split}$$

Here, ϑ is the angle between the electron momentum and the muon spin, and $x\equiv 2E_e/m_\mu$. For the Standard Model coupling, we obtain $\rho=\xi\delta=3/4,\,\xi=1,\,\eta=0$ and the differential decay rate is

$$\frac{d^2 \Gamma}{dx \ d\cos\vartheta} \ = \ \frac{G_F^2 m_\mu^5}{192 \pi^3} \ \left[3 - 2 x \pm P_\mu \cos\vartheta (2x-1) \right] \ x^2 \quad . \label{eq:delta}$$

The coefficient in front of the square bracket is the total decay rate.

If only the neutrino masses are neglected, and if the e^{\pm} polarization is detected, then the functions in Eq. (1) become

$$\begin{split} F_{IS}(x) &= x(1-x) + \frac{2}{9} \, \rho (4x^2 - 3x - x_0^2) + \eta \cdot x_0 (1-x) \\ F_{AS}(x) &= \frac{1}{3} \xi \, \sqrt{x^2 - x_0^2} \\ &\qquad \times \left[1 - x + \frac{2}{3} \delta \left(4x - 3 + \left(\sqrt{1 - x_0^2} - 1 \right) \right) \right] \\ \vec{P}_e(x, \vartheta) &= P_{T_1} \, \hat{x} + P_{T_2} \hat{y} + P_L \, \hat{z} \, . \end{split}$$

Here \hat{x} , \hat{y} , and \hat{z} are orthogonal unit vectors defined as follows:

 \hat{z} is along the e momentum

 $\widehat{y} = [\widehat{z} \times \vec{P_{\mu}}]/|[\widehat{z} \times \vec{P_{\mu}}]|$ is transverse to the e momentum and perpendicular to the "decay plane" $\widehat{x} = \widehat{y} \times \widehat{z}$ is transverse to the e momentum and in the "decay plane."

The components of $\vec{P_e}$ then are given by

$$\begin{split} P_{T_1}(x,\vartheta) &= P_{\mu}\sin\vartheta \; F_{T_1}(x)/\left(F_{IS}(x) \pm P_{\mu}\cos\vartheta \; F_{AS}(x)\right) \\ P_{T_2}(x,\vartheta) &= P_{\mu}\sin\vartheta \; F_{T_2}(x)/\left(F_{IS}(x) \pm P_{\mu}\cos\vartheta \; F_{AS}(x)\right) \\ P_{L}(x,\vartheta) &= \pm F_{IP}(x) + P_{\mu}\cos\vartheta \\ &\qquad \times F_{AP}(x)/\left(F_{IS}(x) \pm P_{\mu}\cos\vartheta \; F_{AS}(x)\right) \; , \end{split}$$

where

$$\begin{split} F_{T_1}(x) &= \frac{1}{12} \left\{ -2 \left[\xi'' + 12(\rho - \frac{3}{4}) \right] (1 - x) x_0 \\ &- 3\eta(x^2 - x_0^2) + \eta''(-3x^2 + 4x - x_0^2) \right\} \\ F_{T_2}(x) &= \frac{1}{3} \sqrt{x^2 - x_0^2} \left\{ 3 \frac{\alpha'}{A} (1 - x) + 2 \frac{\beta'}{A} \sqrt{1 - x_0^2} \right\} \\ F_{IP}(x) &= \frac{1}{54} \sqrt{x^2 - x_0^2} \left\{ 9 \xi' \left(-2x + 2 + \sqrt{1 - x_0^2} \right) \right. \\ &+ 4 \xi (\delta - \frac{3}{4}) (4x - 4 + \sqrt{1 - x_0^2}) \right\} \\ F_{AP}(x) &= \frac{1}{6} \left\{ \xi''(2x^2 - x - x_0^2) + 4(\rho - \frac{3}{4}) \left(4x^2 - 3x - x_0^2 \right) \right. \\ &+ 2 \eta'' (1 - x) x_0 \right\} . \end{split}$$

For the experimental values of the parameters ρ , ξ , ξ' , ξ' , δ , η , η' , α/A , β/A , α'/A , β'/A , which are not all independent, see the Data Listings below. Experiments in the past have also been analyzed using the parameters a, b, c, a', b', c', α/A , β/A , α'/A , β'/A (and $\eta = (\alpha - 2\beta)/2A$), as defined by Kinoshita and Sirlin [5]. They serve as a model-independent summary of all possible measurements on the decay electron (see Listings below). The relations between the two sets of parameters are

$$\begin{split} \rho - \frac{3}{4} &= \frac{3}{4}(-a+2c)/A \;, \\ \eta &= (\alpha - 2\beta)/A \;, \\ \eta'' &= (3\alpha + 2\beta)/A \;, \\ \delta - \frac{3}{4} &= \frac{9}{4} \;\cdot \; \frac{(a'-2c')/A}{1 - [a+3a'+4(b+b')+6c-14c']/A} \;, \\ 1 - \xi \frac{\delta}{\rho} &= 4 \; \frac{[(b+b')+2(c-c')]/A}{1 - (a-2c)/A} \;, \\ 1 - \xi' &= \; [(a+a')+4(b+b')+6(c+c')]/A \;, \\ 1 - \xi'' &= \; (-2a+20c)/A \;, \end{split}$$

where

$$A = a + 4b + 6c.$$

The differential decay probability to obtain a *left-handed* ν_e with (reduced) energy between y and y + dy, neglecting radiative corrections as well as the masses of the electron and of the neutrinos, is given by [6]

$$\frac{d\Gamma}{dy} \; = \; \frac{m_{\mu}^5 \; G_F}{16\pi^3} \; \cdot \; Q_L^{\nu_e} \; \cdot y^2 \Big\{ (1-y) - \omega_L \cdot (y-\tfrac{3}{4}) \Big\} \; .$$

Here, y=2 E_{ν_e}/m_{μ} . $Q_L^{\nu_e}$ and ω_L are parameters. ω_L is the neutrino analog of the spectral shape parameter ρ of Michel. Since in the Standard Model, $Q_L^{\nu_e}=1$, $\omega_L=0$, the measurement of $d\Gamma/dy$ has allowed a null-test of the Standard Model (see Listings below).

Matrix element: All results in direct muon decay (energy spectra of the electron and of the neutrinos, polarizations, and angular distributions) and in inverse muon decay (the reaction cross section) at energies well below $m_W c^2$ may be parametrized in terms of amplitudes $g_{e\mu}^{\gamma}$ and the Fermi coupling constant G_F , using the matrix element

$$\frac{4G_F}{\sqrt{2}} \sum_{\substack{\gamma = S, V, T\\ e, \mu = R, L}} g_{\varepsilon\mu}^{\gamma} \langle \bar{e}_{\varepsilon} | \Gamma^{\gamma} | (\nu_e)_n \rangle \langle \bar{\nu}_{\mu})_m | \Gamma_{\gamma} | \mu_{\mu} \rangle. \tag{2}$$

We use the notation of Fetscher et al. [2], who in turn use the sign conventions and definitions of Scheck [7]. Here, $\gamma=S,V,T$ indicates a scalar, vector, or tensor interaction; and $\varepsilon,\mu=R,L$ indicate a right- or left-handed chirality of the electron or muon. The chiralities n and m of the ν_e and $\bar{\nu}_\mu$ are then determined by the values of γ, ε and μ . The particles are represented by fields of definite chirality [8].

As shown by Langacker and London [9], explicit lepton-number nonconservation still leads to a matrix element equivalent to Eq. (2). They conclude that it is not possible, even in principle, to test lepton-number conservation in (leptonic) muon decay if the final neutrinos are massless and are not observed.

The ten complex amplitudes $g_{\varepsilon\mu}^{\gamma}$ (g_{RR}^{T} and g_{LL}^{T} are identically zero) and G_{F} constitute 19 independent (real) parameters to be determined by experiment. The Standard Model interaction corresponds to one single amplitude g_{LL}^{V} being unity and all the others being zero.

The (direct) muon decay experiments are compatible with an arbitrary mix of the scalar and vector amplitudes g_{LL}^S and g_{LL}^V – in the extreme even with purely scalar $g_{LL}^S = 2$, $g_{LL}^V = 0$. The decision in favour of the Standard Model comes from the quantitative observation of inverse muon decay, which would be forbidden for pure g_{LL}^S [2].

Experimental determination of V-A: In order to determine the amplitudes $g_{\varepsilon\mu}^{\gamma}$ uniquely from experiment, the following set of equations, where the left-hand sides represent experimental results, has to be solved.

$$\begin{split} a &= 16(|g_{RL}^V|^2 + |g_{LR}^V|^2) + |g_{RL}^S + 6g_{RL}^T|^2 + |g_{LR}^S + 6g_{LR}^T|^2 \\ a' &= 16(|g_{RL}^V|^2 - |g_{LR}^V|^2) + |g_{RL}^S + 6g_{RL}^T|^2 - |g_{LR}^S + 6g_{LR}^T|^2 \\ \alpha &= 8\text{Re}\left\{g_{RL}^V(g_{LR}^{S*} + 6g_{LR}^{T*}) + g_{LR}^V(g_{RL}^{S*} + 6g_{RL}^{T*})\right\} \\ \alpha' &= 8\text{Im}\left\{g_{LR}^V(g_{RL}^{S*} + 6g_{RL}^{T*}) - g_{RL}^V(g_{LR}^{S*} + 6g_{LR}^{T*})\right\} \\ b' &= 4(|g_{RR}^V|^2 + |g_{LL}^V|^2) + |g_{RR}^S|^2 + |g_{LL}^S|^2 \\ b' &= 4(|g_{RR}^V|^2 - |g_{LL}^V|^2) + |g_{RR}^S|^2 - |g_{LL}^S|^2 \\ \beta &= -4\text{Re}\left\{g_{RR}^Vg_{LL}^{S*} + g_{LL}^Vg_{RR}^{S*}\right\} \\ \beta' &= 4\text{Im}\left\{g_{RR}^Vg_{LL}^{S*} - g_{LL}^Vg_{RR}^{S*}\right\} \\ c &= \frac{1}{2}\left\{|g_{RL}^S - 2g_{RL}^T|^2 + |g_{LR}^S - 2g_{LR}^T|^2\right\} \\ c' &= \frac{1}{2}\left\{|g_{RL}^S - 2g_{RL}^T|^2 - |g_{LR}^S - 2g_{LR}^T|^2\right\} \\ \text{ad} \\ Q_L^{\nu e} &= 1 - \left\{\frac{1}{4}|g_{LR}^S|^2 + \frac{1}{4}|g_{LL}^S|^2 + |g_{RR}^V|^2 + |g_{RL}^V|^2 + 3|g_{LR}^T|^2\right\} \end{split}$$

$$\begin{split} Q_L^{\nu_e} &= 1 - \left\{ \frac{1}{4} |g_{LR}^S|^2 + \frac{1}{4} |g_{LL}^S|^2 + |g_{RR}^V|^2 + |g_{RL}^V|^2 + 3|g_{LR}^T|^2 \right\} \\ \omega_L &= \frac{3}{4} \, \frac{\{|g_{RR}^S|^2 + 4|g_{LR}^V|^2 + |g_{RL}^S + 2g_{RL}^T|^2\}}{|g_{RL}^S|^2 + |g_{RR}^S|^2 + 4|g_{LL}^V|^2 + 4|g_{LR}^V|^2 + 12|g_{RL}^T|^2\}} \;. \end{split}$$

It has been noted earlier by C. Jarlskog [10], that certain experiments observing the decay electron are especially informative if the yield the V-A values. The complete solution is now found as follows. Fetscher et al. [2] introduced four probabilities $Q_{\varepsilon\mu}(\varepsilon,\mu=R,L)$ for the decay of a μ -handed muon into an ε -handed electron and showed that there exist upper bounds on Q_{RR} , Q_{LR} , and Q_{RL} , and a lower bound on Q_{LL} . These probabilities are given in terms of the $g_{\tau\mu}^{2}$'s by

$$Q_{\varepsilon\mu} = \frac{1}{4}|g_{\varepsilon\mu}^S|^2 + |g_{\varepsilon\mu}^V|^2 + 3(1 - \delta_{\varepsilon\mu})|g_{\varepsilon\mu}^T|^2 , \qquad (3)$$

where $\delta_{\varepsilon\mu}=1$ for $\varepsilon=\mu$, and $\delta_{\varepsilon\mu}=0$ for $\varepsilon\neq\mu$. They are related to the parameters $a,\ b,\ c,\ a',b',$ and c' by

$$egin{aligned} Q_{RR} &= 2(b+b')/A \;, \ Q_{LR} &= [(a-a')+6(c-c')]/2A \;, \ Q_{RL} &= [(a+a')+6(c+c')]/2A \;, \ Q_{LL} &= 2(b-b')/A \;, \end{aligned}$$

with A=16. In the Standard Model, $Q_{LL}=1$ and the others are zero.

Since the upper bounds on Q_{RR} , Q_{LR} , and Q_{RL} are found to be small, and since the helicity of the ν_{μ} in pion decay is known from experiment [11,12] to very high precision to be -1 [13], the cross section S of *inverse* muon decay, normalized to the V-A value, yields [2]

$$|g_{LL}^S|^2 \le 4(1-S) \tag{4}$$

and

$$|g_{LL}^V|^2 = S. (5)$$

Thus the Standard Model assumption of a pure V-A leptonic charged weak interaction of e and μ is derived (within errors)

Lepton Particle Listings

и

from experiments at energies far below mass of the W^{\pm} : Eq. (5) gives a lower limit for V-A, and Eqs. (3) and (4) give upper limits for the other four-fermion interactions. The existence of such upper limits may also be seen from $Q_{RR}+Q_{RL}=(1-\xi')/2$ and $Q_{RR}+Q_{LR}=\frac{1}{2}(1+\xi/3-16\ \xi\delta/9)$. Table 1 gives the current experimental limits on the magnitudes of the $g_{\tau\mu}^{\epsilon}$'s.

Limits on the "charge retention" coordinates, as used in the older literature (e.g., Ref. 16), are given by Burkard et al. [17].

Table 1. Coupling constants $g_{e\mu}^{\gamma}$. Ninety-percent confidence level experimental limits. The limits on $|g_{LL}^{S}|$ and $|g_{LL}^{V}|$ are from Ref. 14, and the others are from Ref. 15. The experimental uncertainty on the muon polarization in pion decay is included.

$\overline{ g_{RR}^S } < 0.066$	$ g_{RR}^V < 0.033$	$ g_{RR}^T \equiv 0$
$ g_{LR}^S <0.125$	$ g_{LR}^V <0.060$	$ g_{LR}^T <0.036$
$\left g_{RL}^S\right <0.424$	$\left g_{RL}^{V}\right <0.110$	$\left g_{RL}^{T}\right <0.122$
$ g_{LL}^S <0.550$	$ g_{LL}^V >0.960$	$ g_{LL}^T \equiv 0$

au discovery paper was PERL 75. $e^+e^- \rightarrow \tau^+\tau^-$ cross-section threshold behavior and magnitude are consistent with pointlike spin-1/2 Dirac particle. BRANDELIK 78 ruled out pointlike spin-0 or spin-1 particle. FELDMAN 78 ruled out J=3/2. KIRKBY 79 also ruled out J=integer, J = 3/2.

 $^{^{17}}$ ACCIARRI 98C limit is on the absolute value of the real part of the weak anomalous magnetic dipole moment.

⁴ BACINO 78B value comes from e^{\pm} X $^{\mp}$ threshold. Published mass 1782 MeV increased by 1 MeV using the high precision $\psi(25)$ mass measurement of ZHOLENTZ 80 to eliminate the absolute SPEAR energy calibration uncertainty.

⁵BAI 92 fit $\sigma(e^+e^- \rightarrow \tau^+\tau^-)$ near threshold using $e\mu$ events.

⁹ SILVERMAN 83 limit is derived from $e^+e^- \rightarrow \tau^+\tau^-$ total cross-section measurements for q^2 up to (37 GeV)².

¹¹ESCRIBANO 97 derive the relationship $|d_{\tau}| = \cot \theta_W |d_{\tau}^W|$ using effective Lagrangian methods, and use a conference result $|d_{\tau}^W| < 5.8 \times 10^{-18}$ ecm at 95% CL (L. Silvestris, ICHEP96) to obtain this result.

 $^{^{12}\,\}mbox{ESCRIBANO}$ 97 use preliminary experimental results.

 $^{^{13}}$ ESCRIBANO 93 limit derived from $\Gamma(Z \to \tau^+ \tau^-)$, and is on the absolute value of the electric dipole moment.

Lepton Family number (LF), Lepton number (L), or Baryon number (B) violating modes (in the modes below, ℓ means a sum over e and μ modes)

L means lepton number violation (e.g. $\tau^- \to e^+\pi^-\pi^-$). Following common usage, LF means lepton family violation and not lepton number violation (e.g. $\tau^- \to e^-\pi^+\pi^-$). B means baryon number violation.

CONSTRAINED FIT INFORMATION

An overall fit to 65 branching ratios uses 141 measurements and one constraint to determine 29 parameters. The overall fit has a $\chi^2=$ 94.2 for 113 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to one.

au BRANCHING FRACTIONS

Revised April 1998 by K.G. Hayes (Hillsdale College).

For the last six years, the rate of publication of new experimental results on the τ lepton has been high. The 30 new experimental papers listed in the τ References for this edition have produced significant changes in the τ Listings. The new results are made possible by the large τ data sets accumulated by the LEP experiments and by CLEO. Measurements of new τ -decay modes with small (< 10^{-3}) branching fractions have been published, and stringent upper limits on other new allowed τ decays have also been published. Significant improvements in branching fraction upper limits for forbidden τ decays have been made including the determination of upper limits for 12 new forbidden decay modes. The great majority of branching fraction upper limits for forbidden modes are now in the range of 10^{-5} to 10^{-6} .

Relatively precise branching fractions for 3-prong exclusive τ -decay modes containing charged kaons have finally been published [1]. This allows the determination of branching fractions for the decay modes $\tau^- \to \pi^- \pi^+ \pi^- \nu_{\tau}$ and $\tau^- \to \pi^- \pi^+ \pi^- \pi^0 \nu_{\tau}$, the last exclusive τ -decay modes with large branching fractions to be measured. The new measurements have resulted in a 30% increase in the number of τ -decay modes in the Listings; 176 decay modes are listed in the current edition, although many are not mutually independent.

There have also been many new measurements of τ -decay parameters. For most parameters, the uncertainty on the world average has decreased by a factor of 2.5 or more. Finally, new experimental limits have been published for the various τ -dipole moments. However, there have been few new measurements of τ -decay modes with large branching fractions, and the world average values for most of these branching fractions have changed little since the last edition.

The constrained fit to \u03c4 branching fractions: The Lepton Summary Table and the List of τ -Decay Modes contain branching fractions for 105 conventional τ -decay modes and upper limits on the branching fractions for 22 other conventional τ -decay modes. Of the 105 modes with branching fractions, 76 are derived from a constrained fit to τ branching fraction data. The goal of the constrained fit is to make optimal use of the experimental data to determine τ branching fractions. For example, the new branching fractions for the decay modes $\tau^- \to \pi^- \pi^+ \pi^- \nu_\tau$ and $\tau^- \to \pi^- \pi^+ \pi^- \pi^0 \nu_\tau$ are determined mostly from experimental measurements of the branching fractions for modes $\tau^- \to h^- h^- h^+ \nu_{\tau}$ and $\tau^- \to h^- h^- h^+ \pi^0 \nu_{\tau}$

and the new measurements of exclusive branching fractions for 3-prong modes containing charged kaons and 0 or 1 π^{0} 's.

Branching fractions from the constrained fit are derived from a set of basis modes. The basis modes form an exclusive set whose branching fractions are constrained to sum exactly to one. The list of 29 basis modes selected for the 1998 fit are listed in Table 1. The only change for the 1996 basis set is that the two modes $\tau \to h^-h^-h^+\nu_{\tau}$ (ex. K^0,ω) and $\tau \to h^- h^- h^+ \pi^0 \nu_{\tau}$ (ex. K^0, ω) have been replaced by the six new modes:

$$\begin{split} \tau &\to \pi^- \pi^+ \pi^- \nu_\tau \ \, (\text{ex.} \ \, K^0, \omega), \\ \tau &\to \pi^- \pi^+ \pi^- \pi^0 \nu_\tau \ \, (\text{ex.} \ \, K^0, \omega), \\ \tau &\to K^- \pi^+ \pi^- \nu_\tau \ \, (\text{ex.} \ \, K^0), \\ \tau &\to K^- \pi^+ \pi^- \pi^0 \nu_\tau \ \, (\text{ex.} \ \, K^0), \\ \tau &\to K^- K^+ \pi^- \nu_\tau, \text{ and } \\ \tau &\to K^- K^+ \pi^- \pi^0 \nu_\tau. \end{split}$$

Table 1: Basis modes for the 1998 fit to τ branching fraction data.

$K^{-}2\pi^{0}\nu_{ au}~({ m ex.}~K^{0})$	$h^-h^-h^+ \geq 3\pi^0 u_ au$
$K^{-}3\pi^{0}\nu_{\tau} \ ({\rm ex.}\ K^{0})$	$3h^-2h^+ u_{ au} \; ({ m ex.} \; K^0)$
$\pi^-\overline{K}^0 u_ au$	$3h^-2h^+\pi^0 u_{ au}~({ m ex.}~K^0)$
$\pi^-\overline{K}^0\pi^0 u_ au$	$h^-\omega u_ au$
$\pi^- K^0 \overline{K}^0 u_ au$	$h^-\omega\pi^0 u_ au$
	$\pi^-\eta\pi^0 u_ au$

In selecting the basis modes, assumptions and choices must be made. Factors pertaining to the selection of the 1996 basis modes are described in the 1996 edition. Additional assumptions have been made in selecting the six new modes for the 1998 basis set. We assume the decays $au^- o \pi^- K^+ \pi^- \ge 0 \pi^0
u_{ au}$ and $au^- o \pi^+ K^- K^- \ge 0 \pi^0
u_{ au}$ have negligible branching fractions. This is consistent with Standard Model predictions for τ decay, although the experimental limits for these branching fractions are not very stringent. The 95% CL upper limits for these branching fractions in the current Listings are B($\tau^- \to \pi^- K^+ \pi^- \ge 0 \pi^0 \nu_{\tau}$) < 0.25% and $B(\pi^+K^-K^- \ge 0\pi^0\nu_{\tau}) < 0.09\%$, values not so different from measured branching fractions for allowed 3-prong modes containing charged kaons. Although our usual goal is to impose as few theoretical constraints as possible so that the world averages and fit results can be used to test the theoretical constraints (i.e., we do not make use of the theoretical constraint from lepton universality on the ratio of the τ -leptonic branching fractions $B(\tau^- \to \mu^- \overline{\nu}_\mu \nu_\tau)/B(\tau^- \to e^- \overline{\nu}_e \nu_\tau) = 0.9728)$, the experimental challenge to identify charged prongs in 3-prong τ decays is sufficiently difficult that experimenters have been forced to make these assumptions when measuring the branching fractions of the allowed decays.

We also assume the branching fraction for the allowed decay $\tau^- \to K^- K^+ K^- \ge 0 \pi^0 \nu_\tau$ is negligible. This decay has limited phase space, and the branching fraction is expected to be very small. The branching fraction upper limit for this decay in the current Listings is $B(\tau^- \to K^- K^+ K^- \ge 0 \pi^0 \nu_\tau) < 0.21\%$ at 95% CL, and the ALEPH Collaboration [1] has determined a much more stringent limit on the branching fraction $B(\tau^- \to K^- K^+ K^- \nu_\tau) < 0.019\%$ at 90% CL.

Recent measurements of several new decay modes having very small branching fractions have raised two other issues regarding the choice of basis modes. The ALEPH Collaboration has recently measured new branching fractions for 1-prong τ decays containing two neutral kaons [2]. The basis set has just one τ -decay mode containing two neutral kaons: $\tau^- \to \pi^- K^0 \overline{K}^0 \nu_{\tau}$. In calculating the contribution of this decay to other measured τ -decay modes, we assume the two neutral kaons decay independently:

$$\begin{split} \mathbf{B}(\tau^- \to \pi^- K_S^0 K_S^0 \nu_\tau) &= \mathbf{B}(\tau^- \to \pi^- K_L^0 K_L^0 \nu_\tau) \\ &= \frac{1}{4} \mathbf{B}(\pi^- K^0 \overline{K}^0 \nu_\tau). \\ \mathbf{B}(\tau^- \to \pi^- K_S^0 K_L^0 \nu_\tau) &= \frac{1}{2} \mathbf{B}(\pi^- K^0 \overline{K}^0 \nu_\tau). \end{split}$$

This assumption may be incorrect. For example, Bose-Einstein correlations between the two neutral kaons can in principle alter these branching fractions. The ratio of the ALEPH measurement of B ($\tau^- \to \pi^- K_S^0 K_L^0 \nu_\tau$) = (0.101 ± 0.023 ± 0.013)% to the average of the CLEO [3] and ALEPH [2] measurements of B($\tau^- \to \pi^- K_S^0 K_S^0 \nu_\tau$) = (0.024 ± 0.005)% is not inconsistent with our assumed value for this ratio of 2. For the sake of simplicity, we retain in this edition the assumption of independent K^0 decay.

There are several newly measured modes with small branching fractions [4] which cannot be expressed in terms of the selected basis modes and are therefore left out of the fit:

$$\begin{split} \mathrm{B}(K^0h^+h^-h^-\nu_\tau) &= (2.3\pm 2.0)\times 10^{-4},\\ \mathrm{B}(\pi^-K_S^0K_L^0\pi^0\nu_\tau) &= (3.1\pm 1.2)\times 10^{-4},\\ \mathrm{B}(\tau^-\to\pi^-\overline{K}^0\pi^0\pi^0\nu_\tau) &= (6\pm 4)\times 10^{-4},\\ \mathrm{plus\ the}\ \eta\to\gamma\gamma\ \mathrm{component\ of\ the\ branching\ fractions}\\ \mathrm{B}(\eta\pi^-\pi^+\pi^-\nu_\tau) &= (3.4\pm 0.8)\times 10^{-4},\\ \mathrm{B}(\eta\pi^-\pi^0\pi^0\nu_\tau) &= (1.4\pm 0.7)\times 10^{-4},\ \mathrm{and}\\ \mathrm{B}(\eta K^-\nu_\tau) &= (2.7\pm 0.6)\times 10^{-4}. \end{split}$$

The sum of these excluded branching fractions is $(0.15\pm0.05)\%$. This is near our goal of 0.1% for the internal consistency of the τ Listings for this edition, and thus for simplicity we do not include these small branching fraction decay modes in the basis set.

The only significant difference between the world average value and the constrained fit value for branching fractions in the 1996 edition was for the 1-prong and 3-prong topological branching fractions. The average values for the topological

branching fractions were dominated by old measurements from the pre-LEP era. Some of these old experiments had significantly underestimated their experimental uncertainties, with the result that, in the period between 1986 and 1990, the uncertainty in the world averages for the 1-prong and 3-prong topological branching fractions were considerably smaller than the uncertainty in the world averages of the very well-measured leptonic branching fractions [5]. Also, several of these old topological branching fraction measurements made the largest contributions the the constrained χ^2 fit. These measurement are now very old and have been retired.

The constrained fit has a χ^2 of 94 for 113 degrees of freedom. The only basis mode branching fraction which shifted more than 1σ from its 1996 value is $B(\tau^- \to \pi^- \nu_\tau)$ which changed from $(11.31 \pm 0.15)\%$ to $(11.08 \pm 0.11)\%$ due mainly to the new measurement of $B(\tau^- \to h^- \nu_\tau)$ by the CLEO Collaboration [6]. The fit and average values for the topological branching fractions are consistent. Table 2 compares the current fit and average values for

$${\rm B_1}\equiv {\rm B(particle}^-\geq 0 \ {\rm neutrals} \ \geq 0 K_L^0 \nu_{\tau}) \ {\rm and} \ {\rm B_3}\equiv {\rm B}(h^-h^-h^+\geq 0 \ {\rm neutrals} \ \nu_{\tau})$$
 with the values from the 1996 edition.

Table 2: Fit and average values for B₁ and B₃.

Branching fraction		1996 Fit	1998 Fit		
B ₁ B ₁	Fit: Ave:	84.96 ± 0.17 85.91 ± 0.30	84.71 ± 0.13 85.1 ± 0.4		
B ₃	Fit:	14.92 ± 0.17 14.01 ± 0.29	15.18 ± 0.13 14.8 ± 0.4		

Another measure of the overall consistency of the τ branching fraction data with the fit constraint is a comparison of the fit and average values for the leptonic branching fractions. Table 3 compares the current fit and average values for $B_e \equiv B(\tau^- \to e^- \overline{\nu}_e \nu_\tau)$ and $B_\mu \equiv B(\tau^- \to \mu^- \overline{\nu}_\mu \nu_\tau)$ with the values from the 1996 edition.

Table 3: Fit and average values for $\tau^- \to e^- \overline{\nu}_e \nu_\tau$ and $\tau^- \to \mu^- \overline{\nu}_\mu \nu_\tau$.

Branching fraction		1996 Fit	1998 Fit
B_e B_e	Fit:	17.83 ± 0.08 17.80 ± 0.08	17.81 ± 0.07 17.78 ± 0.08
B_{μ} B_{μ}	Fit:	17.35 ± 0.10 17.30 ± 0.10	17.37 ± 0.09 17.32 ± 0.09

ı

Conclusions: Many new measurements of τ -lepton properties have been made in the last two years. Experimenters have exploited the availability of large data sets to measure τ decay modes with either small branching fractions or low detection efficiencies. Charged particle identification in 3-prong decays has finally allowed the experimental determination of the branching fraction for the decay modes $\tau^- \to \pi^- \pi^+ \pi^- \nu_{\tau}$ and $\tau^- \to \pi^- \pi^+ \pi^- \pi^0 \nu_{\tau}$, the last exclusive τ -decay modes with large branching fractions to be measured. The basis set of τ -decay modes used in the constrained fit to branching fractions has been expanded to include the new measurements of exclusive 3-prong decays with identified charged prongs and 0 or 1 π^{0} 's. There is no significant evidence of any inconsistency in the branching fraction data used in the constrained fit or to calculate world average values.

τ - BRANCHING RATIOS

 $\begin{array}{l} \Gamma \text{(particle}^- \geq 0 \text{ neutrals } \geq 0 \\ K_0^D \nu_{\tau} \text{("1-prong"))} / \Gamma_{\text{total}} \\ \Gamma_1 / \Gamma = (\Gamma_3 + \Gamma_5 + \Gamma_9 + \Gamma_{10} + \Gamma_{13} + \Gamma_{15} + \Gamma_{19} + \Gamma_{20} + \Gamma_{23} + \Gamma_{24} + \Gamma_{26} + 0.6569 \Gamma_{32} + 0.6569 \Gamma_{36} + 0.6569 \Gamma_{38} + 0.4316 \Gamma_{41} + 0.708 \Gamma_{110} + 0.09 \Gamma_{125} + 0.6569 \Gamma_{36} + 0.6569 \Gamma_{38} + 0.4316 \Gamma_{41} + 0.708 \Gamma_{110} + 0.09 \Gamma_{125} + 0.6569 \Gamma_{36} + 0.6569 \Gamma_{36}$ $0.09\Gamma_{126})/\Gamma$

The charged particle here can be e, μ , or hadron. In many analyses, the sum of the topological branching fractions (1, 3, and 5 prongs) is constrained to be unity. Since the 5-prong fraction is very small, the measured 1-prong and 3-prong fractions are highly correlated and cannot be treated as independent quantities in our overall fit. We arbitrarily choose to use the 3-prong fraction in our fit, and leave the 1-prong fraction out. We do, however, use these 1-prong measurements in our average below The measurements used only for the average are marked "avg," whereas "f&a" marks a result used for the fit and the average.

 103 BARATE 98E obtain this value by adding twice their $R(\pi^- K^0 K^0 L^0)$ value to their

¹⁰³BARATE 98E obtain this value by adding twice their $B(\pi^- K_S^0 K_S^0 \nu_{\tau})$ value to their $B(\pi^- K_S^0 K_L^0 \nu_{\tau})$ value.

104 We multiply the COAN 96 measurement B($h^ K_S^0$ K_S^0 $\nu_{ au}$) = (0.023 \pm 0.005 \pm 0.003)% by 4 to obtain the listed value. This factor of 1/4 is uncertain, and might be as large as 1/2, due to Bose-Einstein correlations and the resonant parentage of this state.

 $\Gamma(\pi^- K_S^0 K_S^0 \nu_T)/\Gamma_{total}$ Bose-Einstein correlations might make the mixing fraction different than 1/4.

Neglecting radiative corrections and terms proportional to m_ℓ^2/m_τ^2 , the energy spectrum of the charged decay lepton ℓ in the τ rest frame is given by

$$\frac{d^2\Gamma_{\tau \to \ell \nu \overline{\nu}}}{d\Omega \, dx} \propto x^2
\times \left\{ 12(1-x) + \rho_{\tau} \left(\frac{32}{3} x - 8 \right) + 24 \eta_{\tau} \, \frac{m_{\ell}}{m_{\tau}} \, \frac{(1-x)}{x} \right.
\left. - P_{\tau} \, \xi_{\tau} \cos \theta \, \left[4(1-x) + \delta_{\tau} \left(\frac{32}{3} x - 8 \right) \right] \right\}.$$
(1)

Here $x=2E_{\ell}/m_{\tau}$ is the scaled lepton energy, P_{τ} is the τ polarization, and θ is the angle between the τ spin and the lepton momentum. With unpolarized τ 's or integrating over the full θ range, the spectrum depends only on ρ_{τ} and η_{τ} . Measurements of the other two Michel parameters, ξ_{τ} and $\delta_{ au}$, require polarized au's. The Standard Model predicitions for $\rho_{\tau}, \, \eta_{\tau}, \, \xi_{\tau}$ and δ_{τ} are $\frac{3}{4}, \, 0, \, 1$ and $\frac{3}{4}$. Where possible, we give separately the parameters for $\tau^- \to e^- \nu_\tau \overline{\nu}_e$ and $\tau^- \to \mu^- \nu_\tau \overline{\nu}_\mu$, to avoid assumptions about universality. Listings labelled "(eor μ)" contain either the results assuming lepton universality if quoted by the experiments or repeat the results from the "e" or " μ " section.

Hadronic two-body decays $\tau \to \nu_{\tau} h$, $h = \pi$, ρ , a_1, \ldots , can under minimal assumptions be written

$$\frac{1}{\Gamma} \frac{d\Gamma}{dz} = f_h(z) + P_\tau \, \xi_h \, g_h(z) \; , \qquad (2)$$

where the kinematic functions f_h , g_h and the definition of the variable z depend on the spin of the hadron h. For the simple case $h = \pi$, one has $z = E_{\pi}/E_{\tau}$, f(z) = 1, and g(z) = 2z - 1. The parameter ξ_h is predicted to be unity and can be identified with twice the negative ν_{τ} helicity. Again ξ_h is listed, when available, separately for each hadron and averaged over all hadronic decays modes.

 ρ^{T} (e or μ) PARAMETER (V-A) theory predicts $\rho = 0.75$.

Heavy Charged Lepton Searches

Charged Heavy Lepton MASS LIMITS

Sequential Charged Heavy Lepton (L±) MASS LIMITS

These experiments assumed that a fourth generation L^\pm decayed to a fourth generation ν_L (or L^0) where ν_L was stable, or that L^\pm decays to a light ν_L via mixing.

See the "Quark and Lepton Compositeness, Searches for" Listings for limits on radiatively decaying excited leptons, i.e. $\ell^* \to \ell \gamma$. See the "WIMPs and other Particle Searches" section for heavy charged particle search limits in which the charged particle could be a lepton.

NEUTRINO MASS

Written February 1998 by B. Kayser (NSF).

While there is no unequivocal evidence for neutrino mass, it is natural to suspect that the neutrinos, like the charged leptons and the quarks, have nonzero masses. Evidence of these masses is being sought through experiments on neutrinos created astrophysically, in the earth's atmosphere, by accelerators, by reactors, and by nuclear decays, and in studies of reactions where neutrinos appear only as virtual particles.

In the decay

$$W^+ \to \ell^+ \nu_{\ell} \tag{1}$$

(SLAC)

of a W boson into a charged lepton of "flavor" $\ell(e, \mu, \text{ or } \tau)$, the accompanying neutrino is referred to as ν_{ℓ} , the neutrino of flavor ℓ . Neutrinos of different flavor are different objects. When an energetic ν_{ℓ} undergoes a charged-current weak interaction, it produces a charged lepton ℓ of the same flavor as the neutrino [1].

If neutrinos have masses, then a neutrino of definite flavor, ν_{ℓ} , need not be a mass eigenstate. Indeed, if leptons behave like quarks, the ν_{ℓ} is a coherent linear superposition of mass eigenstates, given by

$$|\nu_{\ell}\rangle = \sum_{m} U_{\ell m} |\nu_{m}\rangle . \qquad (2)$$

Here, the ν_m are the mass eigenstates, and the coefficients $U_{\ell m}$ form a matrix U known as the leptonic mixing matrix.

There are at least three ν_m , and perhaps more. However, it is usually assumed that no more than three ν_m make significant contributions to Eq. (2). Then U is a 3×3 matrix, and according to the electroweak Standard Model (SM), extended to include neutrino masses, it is unitary.

The relation (2) means that when, for example, a W^+ decays to an e^+ and a neutrino, the neutrino with probability $|U_{e1}|^2$ is a ν_1 , with probability $|U_{e2}|^2$ is a ν_2 , and so on. This behavior is an exact leptonic analogue of what is known to occur when a W^+ decays to quarks.

If each neutrino of definite flavor is a coherent superposition of mass eigenstates, then we will have neutrino oscillation [2]. This is the spontaneous metamorphosis of a neutrino of one flavor into one of another flavor as the neutrino propagates.

To understand neutrino oscillation, let us consider how a neutrino born as the ν_{ℓ} of Eq. (2) evolves in time. First, we apply Schrödinger's equation to the ν_m component of ν_{ℓ} in the rest frame of that component. This tells us that [3]

$$|\nu_m(\tau_m)\rangle = e^{-iM_m\tau_m}|\nu_m(0)\rangle , \qquad (3)$$

where M_m is the mass of ν_m , and τ_m is time in the ν_m frame. In terms of the time t and position L in the laboratory frame, the Lorentz-invariant phase factor in Eq. (3) may be written

$$e^{-iM_m\tau_m} = e^{-i(E_mt - p_mL)} . (4)$$

Here, E_m and p_m are respectively the energy and momentum of ν_m in the laboratory frame. In practice, our neutrino will be extremely relativistic, so we will be interested in evaluating the phase factor of Eq. (4) where $t \approx L$, where it becomes $\exp[-i(E_m - p_m)L]$.

Imagine now that our ν_ℓ has been produced with a definite momentum p, so that all of its mass-eigenstate components have this common momentum. Then the ν_m component has $E_m = \sqrt{p^2 + M_m^2} \approx p + M_m^2/2p$, assuming that all neutrino masses M_m are small compared to the neutrino momentum. The phase factor of Eq. (4) is then approximately

$$e^{-i(M_m^2/2p)L} (5)$$

Alternatively, suppose that our ν_ℓ has been produced with a definite energy E, so that all of its mass-eigenstate components have this common energy [4]. Then the ν_m component has $p_m = \sqrt{E^2 - M_m^2} \approx E - M_m^2/2E$. The phase factor of Eq. (4) is then approximately

$$e^{-i(M_m^2/2E)L} (6)$$

Since highly relativistic neutrinos have $E \approx p$, the phase factors (5) and (6) are approximately equal. Thus, it doesn't matter whether our ν_{ℓ} is created with definite momentum or definite energy.

From Eq. (2) and either Eq. (5) or Eq. (6), it follows that after a neutrino born as a ν_{ℓ} has propagated a distance L, its state vector has become

$$|\nu_{\ell}(L)\rangle \approx \sum_{m} U_{\ell m} e^{-i(M_{m}^{2}/2E)L} |\nu_{m}\rangle$$
 (7)

Neutrinos

Using the unitarity of U to invert Eq. (2), and inserting the result in Eq. (7), we find that

$$|\nu_{\ell}(L)\rangle pprox \sum_{\ell'} \left[\sum_{m} U_{\ell m} e^{-i(M_m^2/2E)L} U_{\ell'm}^* \right] |\nu_{\ell'}\rangle .$$
 (8)

We see that our ν_{ℓ} , in traveling the distance L, has turned into a superposition of all the flavors. The probability that it has flavor ℓ' , $P(\nu_{\ell} \to \nu_{\ell'}; L)$, is obviously given by

$$P(\nu_{\ell} \to \nu_{\ell'}; L) = |\langle \nu_{\ell'} | \nu_{\ell}(L) \rangle|^2 = \left| \sum_{m} U_{\ell m} e^{-i(M_m^2/2E)L} U_{\ell'm}^* \right|^2.$$
(9)

The quantum mechanics of neutrino oscillation leading to the result Eq. (9) is somewhat subtle. It has been analyzed using wave packets [5], treating a propagating neutrino as a virtual particle [6], evaluating the phase acquired by a propagating mass eigenstate in terms of the proper time of propagation [3], requiring that a neutrino's flavor cannot change unless the neutrino travels [4], and taking different neutrino mass eigenstates to have both different momenta and different energies [7]. The subtleties of oscillation are still being explored and discussed.

Frequently, a neutrino oscillation experiment is analyzed assuming that only two neutrino flavors, ν_e and ν_μ for example, mix appreciably. Then the mixing matrix U takes the form

$$U = \begin{pmatrix} \cos \theta_{e\mu} & \sin \theta_{e\mu} \\ -\sin \theta_{e\mu} & \cos \theta_{e\mu} \end{pmatrix} , \qquad (10)$$

where $\theta_{e\mu}$ is the ν_e - ν_μ mixing angle. Inserting this matrix into Eq. (9), we find that

$$P(\nu_e \to \nu_\mu; L) = \sin^2 2\theta_{e\mu} \sin^2 \left(\Delta M_{12}^2 L/4E\right)$$
 (11)

Here, $\Delta M_{12}^2 \equiv M_1^2 - M_2^2$, where ν_1 and ν_2 are the mass eigenstates which make up ν_e and ν_μ . If the omitted factors of \hbar and c are inserted into the argument $\Delta M_{12}^2 L/4E$ of the oscillatory sine function, it becomes 1.27 ΔM_{12}^2 (eV²)L (km)/E (GeV). The probability that a ν_e will retain its original flavor during propagation over a distance L is simply

$$P(\nu_e \to \nu_e; L) = 1 - P(\nu_e \to \nu_\mu; L) . \tag{12}$$

Under some important circumstances, a "two-neutrino" formula virtually identical to that of Eq. (11) accurately describes neutrino oscillation even when all three neutrino flavors mix. One of these circumstances is when all mixing angles are small. That is, each neutrino of definite flavor is dominantly one mass eigenstate, plus only small amounts of the other two. In this circumstance, let us refer to the dominant mass eigenstate component of ν_e as ν_1 , that of ν_μ as ν_2 , and that of ν_τ as ν_3 . Then the mixing matrix U is approximately

$$U \approx \begin{pmatrix} 1 & \theta_{e\mu} & \theta_{e\tau} \\ -\theta_{e\mu} & 1 & \theta_{\mu\tau} \\ -\theta_{e\tau} & -\theta_{\mu\tau} & 1 \end{pmatrix} , \qquad (13)$$

where θ_{ab} is the (small) ν_{ℓ_a} – ν_{ℓ_b} mixing angle. Inserting this mixing matrix in Eq. (9), we find that through second order in the mixing angles,

$$P(\nu_{\ell_a} \to \nu_{\ell_b \neq \ell_a}; L) \approx (2\theta_{ab})^2 \sin^2(\Delta M_{ij}^2 L/4E)$$
 (14)

Here, $\Delta M_{ij}^2 \equiv M_i^2 - M_j^2$, where ν_i and ν_j are, respectively, the dominant mass eigenstate components of ν_{ℓ_a} and ν_{ℓ_b} . We see that when all mixing angles are small, the oscillation between any pair of neutrino flavors is indeed described by a two-neutrino formula just like Eq. (11), but for each pair of flavors, there is a different mixing angle and a different ΔM^2 . In addition, in contrast to Eq. (12), the probability that a neutrino (say, a ν_e) retains its original flavor is now given by

$$P(\nu_e \to \nu_e; L) = 1 - P(\nu_e \to \nu_\mu; L) - P(\nu_e \to \nu_\tau; L)$$
. (15)

Another interesting situation occurs when there is a neutrino mass hierarchy, $M_3 \gg M_2 \gg M_1$, so that $\Delta M_{32}^2 \approx \Delta M_{31}^2 \gg \Delta M_{21}^2$. Then there is a region of L/E in which $\Delta M_{21}^2 L/E$ is negligible compared to unity, but $\Delta M_{32}^2 L/E$ is not. For L/E in this region, it follows from Eq. (9) and the unitarity of U that [8]

$$P(\nu_{\ell_a} \to \nu_{\ell_b \neq \ell_a}; L) \approx |2U_{a3}U_{b3}|^2 \sin^2(\Delta M_{32}^2 L/4E)$$
 (16)

Once again, the oscillation probability has the same form as when just two neutrinos mix. Furthermore, Eq. (16) holds whether the mixing angles are large or small. However, the parameters in Eq. (16) have a different meaning from those in the true two-neutrino formula, Eq. (11). In Eq. (16), the coefficient $|2U_{a3}U_{b3}|^2$ is, in general, $not \sin^2 2\theta_{ab}$, as it would be in the two-neutrino case. (To be sure, $|2U_{a3}U_{b3}|^2$ never exceeds unity, anymore than $\sin^2 2\theta_{ab}$ does.) In addition, in Eq. (16), the mass splitting which appears is always the same one— ΔM_{32}^2 —regardless of which neutrino flavors are being considered.

In a beam of neutrinos born with flavor ℓ_a , neutrino oscillation can be sought in two ways: First, one may seek the appearance in the beam of neutrinos of a different flavor, ℓ_b . Secondly, one may seek a disappearance of some of the original ν_{ℓ_a} flux, or an L-dependence of this flux.

Clearly, no oscillation is expected unless L/E of the experiment is sufficiently large that the phase factors $\exp(-iM_m^2 L/2E)$ in Eq. (9) differ appreciably from one another. Otherwise, $P(\nu_\ell \to \nu_{\ell'}; L) = |\sum_m U_{\ell m} U_{\ell'm}^*|^2 = \delta_{\ell\ell'}$. Now, with omitted factors of \hbar and c inserted, the relative phase of $\exp(-iM_i^2L/2E)$ and $\exp(-iM_j^2L/2E)$ is 2.54 $\Delta M_{ij}^2({\rm eV}^2)$ $L({\rm km})/E({\rm GeV})$. Thus, for example, an experiment in which neutrinos with $E \approx 1$ GeV travel 1 km between production and detection will be sensitive to $\Delta M^2 \gtrsim 1$ eV².

A more direct way than neutrino oscillation experiments to search for neutrino mass is to look for its kinematical effects in decays which produce a neutrino. In the decay $X \to Y\ell^+\nu_\ell$, where X is a hadron and Y is zero or more hadrons, the momenta of ℓ^+ and the particles in Y will obviously be modified if ν_ℓ has a mass. If ν_ℓ is a superposition of mass eigenstates ν_m , then $X \to Y\ell^+\nu_\ell$ is actually the sum of the

Lepton Particle Listings Neutrinos

decays $X \to Y \ell^+ \nu_m$ yielding every ν_m light enough to be emitted. Thus, if, for example, one ν_m is much heavier than the others, the energy spectrum of ℓ^+ may show a threshold rise where the ℓ^+ energy becomes low enough for the heavy ν_m to be emitted [9]. However, if neutrino mixing is small, then the decays $X \to Y \ell^+ \nu_m$ yield almost always the neutrino mass eigenstate which is the dominant component of ν_ℓ . The kinematics of ℓ^+ and Y then reflect the mass of this mass eigenstate.

From kinematical studies of the particles produced in ${}^3{\rm H} \to {}^3{\rm He}\ e^-\overline{\nu}_e, \pi \to \mu\nu_\mu, \ {\rm and}\ \tau \to n\pi\nu_\tau, \ {\rm upper}\ {\rm limits}\ {\rm have}\ {\rm been}\ {\rm derived}\ {\rm for}\ M_1, M_2, \ {\rm and}\ M_3, \ {\rm respectively.}$ Here, we assume mixing to be small, and, as before, call the dominant masseigenstate components of $\nu_e, \nu_\mu, \ {\rm and}\ \nu_\tau, \ {\rm respectively}, \nu_1, \nu_2, \ {\rm and}\ \nu_3.$ In the case of the decay ${}^3{\rm H} \to {}^3{\rm He}\ e^-\overline{\nu}_e, \ {\rm the}\ {\rm upper}\ {\rm bound}\ {\rm on}\ {\rm the}\ {\rm neutrino}\ {\rm mass}\ {\rm is}\ {\rm derived}\ {\rm from}\ {\rm study}\ {\rm of}\ {\rm the}\ e^-\ {\rm energy}\ {\rm spectrum}.$ It should be noted that in several experiments, the theoretical expression used to describe this spectrum does not produce a good fit, either for $M_1=0$ or for $M_1>0$ [10]. Indeed, the best fit is achieved for an unphysical, negative value of M_1^2 . Thus, the quoted limits on M_1 must be interpreted with caution.

Neutrinos carry neither electric charge nor, as far as we know, any other charge-like quantum numbers. To be sure, it may be that the reason an interacting "neutrino" creates an ℓ^- , while an "antineutrino" creates an ℓ^+ , is that neutrinos and antineutrinos carry opposite values of a conserved "lepton number." However, there may be no lepton number. Even then, the fact that "neutrinos" and "antineutrinos" interact differently can be easily understood. One need only note that, in practice, the particles we call "neutrinos" are always left-handed, while the ones we call "antineutrinos" are right-handed. Since the weak interactions are not invariant under parity, it is then possible to attribute the difference between the interactions of "neutrinos" and "antineutrinos" to the fact that these particles are oppositely polarized.

If the neutrino mass eigenstates do not carry any chargelike attributes, they may be their own antiparticles. A neutrino which is its own antiparticle is called a Majorana neutrino, while one which is not is called a Dirac neutrino.

If neutrinos are of Majorana character, we can have neutrinoless double beta-decay $(\beta\beta_{0\nu})$, in which one nucleus decays to another by emitting two electrons and nothing else. This process can be initiated through the emission of two virtual W bosons by the parent nucleus. One of these W bosons then emits an electron and an accompanying virtual "antineutrino." In the Majorana case, this "antineutrino" is no different from a "neutrino," except for its right-handed helicity. If the virtual neutrino has a mass, then (like the e^+ in nuclear β -decay), it is not fully right-handed, but has a small amplitude, proportional to its mass, for being left-handed. Its left-handed component is precisely what we call a "neutrino," and can be absorbed by the second virtual W boson to create the second outgoing

electron. This mechanism yields for $\beta\beta_{0\nu}$ an amplitude proportional to an effective neutrino mass $\langle M \rangle$, given in a common phase convention by [11]

$$\langle M \rangle = \sum_{m} U_{em}^2 M_m \ . \tag{17}$$

Experimental upper bounds on the $\beta\beta_{0\nu}$ rate are used to derive upper bounds on $\langle M \rangle$. Note that, owing to possible phases in the mixing matrix elements U_{em} , the relation between $\langle M \rangle$ and the actual masses M_m of the neutrino mass eigenstates can be somewhat complicated. The process $\beta\beta_{0\nu}$ is discussed further by P. Vogel in this Review.

If neutrinos are their own antiparticles, then their magnetic and electric dipole moments must vanish. To see why, recall that CPT invariance requires that the dipole moments of the electron and its antiparticle be equal and opposite. Similarly, CPT invariance would require that the dipole moments of a neutrino and its antiparticle be equal and opposite. But, if the antiparticle of the neutrino is the neutrino itself, this means that the dipole moments must vanish [12].

If neutrinos are not their own antiparticles, then they can have dipole moments. However, for a Dirac neutrino mass eigenstate ν_m , the magnetic dipole moment μ_m predicted by the Standard Model (extended to include neutrino masses) is only [13]

$$\mu_m = 3.2 \times 10^{-19} M_m (\text{eV}) \mu_B ,$$
 (18)

where μ_B is the Bohr magneton.

Whether neutrinos are their own antiparticles or not, there may be transition magnetic and electric dipole moments. These induce the transitions $\nu_m \to \nu_{m' \neq m} \gamma$.

A Majorana neutrino, being its own antiparticle, obviously consists of just two states: spin up and spin down. In contrast, a Dirac neutrino, together with its antiparticle, consists of four states: the spin-up and spin-down neutrino states, plus the spin-up and spin-down antineutrino states. A four-state Dirac neutrino may be pictured as comprised of two degenerate two-state Majorana neutrinos. Conversely, in the field-theory description of neutrinos, by introducing so-called Majorana mass terms, one can split a Dirac neutrino, D, into two nondegenerate Majorana neutrinos, ν and N. In some extensions of the SM, it is natural for the D, ν , and N masses, M_D , M_{ν} , and M_N , to be related by

$$M_{\nu}M_{N}\approx M_{D}^{2}. \tag{19}$$

In these extensions, it is also natural for M_D to be of the order of $M_{\ell \text{ or } q}$, the mass of a typical charged lepton or quark. Then we have [14]

$$M_{\nu}M_N \sim M_{\ell \, \text{or} \, a}^2 \ . \tag{20}$$

Suppose now that $M_N\gg M_{\ell \text{ or }q}$, so that N is a very heavy neutrino which has not yet been observed. Then relation (20), known as the seesaw relation, implies that $M_\nu\ll M_{\ell \text{ or }q}$. Thus, ν is a candidate for one of the light neutrino mass eigenstates which make up ν_e , ν_μ , and ν_τ . So long as N is heavy, the seesaw

Neutrinos

relation explains, without fine tuning, why a mass eigenstate component of ν_e , ν_{μ} , or ν_{τ} will be light. Interestingly, the picture from which the seesaw relation arises predicts that the mass eigenstate components of ν_e , ν_{μ} , and ν_{τ} are Majorana neutrinos.

In early 1998, there are three observed hints of neutrino oscillation, and thus of neutrino mass. These hints are the behavior of solar neutrinos, the behavior of atmospheric neutrinos, and the results of the LSND experiment.

The flux of solar neutrinos has been detected on earth by several experiments [15] with different neutrino energy thresholds. In every experiment, the flux is found to be below the corresponding prediction of the Standard Solar Model (SSM) [16]. The discrepancies between the observed fluxes and the SSM predictions have proven very difficult to explain by simply modifying the SSM, without invoking neutrino mass [17]. Indeed, we know of no attempt which has succeeded. By contrast, all the existing observations can successfully and elegantly be explained if one does invoke neutrino mass. The most popular explanation of this type is based on the Mikheyev-Smirnov-Wolfenstein (MSW) effect—a matter-enhanced neutrino oscillation [18].

The neutrinos produced by the nuclear processes that power the sun are electron neutrinos ν_e . With some probability, the MSW effect converts a ν_e into a neutrino ν_x of another flavor. Depending on the specific version of the effect, ν_x is a ν_μ , a ν_τ , a ν_μ - ν_τ mixture, or perhaps a sterile neutrino ν_s . Since present solar neutrino detectors are sensitive to a ν_e , but wholly, or at least largely, insensitive to a ν_μ , ν_τ , or ν_s , the flavor conversion accounts for the low observed fluxes.

The MSW $\nu_e \to \nu_x$ conversion results from interaction between neutrinos and solar electrons as the neutrinos travel outward from the solar core, where they were produced. The conversion requires that, somewhere in the sun, the total energy of a ν_e of given momentum, including the energy of its interaction with the solar electrons, equal the total energy of the ν_x of the same momentum, so that we have an energy level crossing. Given the typical density of solar electrons, and the typical momenta of solar neutrinos, the condition that there be a level crossing requires that

$$M_{\nu_{\tau}}^2 - M_{\nu_{e}}^2 \equiv \Delta M_{\nu_{\tau}\nu_{e}}^2 \sim 10^{-5} \text{eV}^2 \,,$$
 (21)

where M_{ν_e} is the mass of the dominant mass eigenstate component of ν_e , and M_{ν_x} is the mass of ν_x .

The solar neutrino observations can also be explained by supposing that on their way from the sun to the earth, the electron neutrinos produced in the solar core undergo vacuum oscillation into neutrinos of another flavor [19]. Assuming that only two neutrino flavors are important to this oscillation, the oscillation probability is described by an expression of the form given by Eq. (11). To explain the observed suppression of the solar ν_e flux to less than half the predicted value at some energies, and to accommodate the observation that the suppression is energy-dependent, the argument $[1.27\Delta M^2(\text{eV}^2)L(\text{km})/E(\text{GeV})]$ of

the oscillatory factor in Eq. (11) must be of order unity when L is the distance from the sun to the earth, and $E \simeq 1$ MeV is the typical energy of a solar neutrino. Perhaps this apparent coincidence makes the vacuum oscillation explanation of the solar neutrino observations less likely than the MSW explanation. To have $[1.27\Delta M^2(\text{eV}^2)L(\text{km})/E(\text{GeV})] \sim 1$, we require that $\Delta M^2 \sim 10^{-10} \text{ eV}^2$.

The solar neutrino experiments, and the comparison between their results and theoretical predictions, are discussed in some detail by K. Nakamura in this *Review*.

Neutrinos created in the earth's atmosphere by cosmic rays result largely from the cosmic-ray-induced production of pions, which then decay via the chain $\pi \to \mu \nu_{\mu}$, $\mu \to e \nu_e \nu_{\mu}$. As we see, this chain produces neutrinos in the ratio $\nu_{\mu}: \nu_e = 2:1$. Since the various neutrinos from the chain have different energy spectra, this 2:1 ratio does not hold at a given neutrino energy, but it is believed that the actual $\nu_{\mu}: \nu_e$ ratio is known to 5% [20]. However, measurements of this ratio in underground detectors yield [21]

$$R \equiv \frac{(\nu_{\mu} : \nu_{e})_{\text{Data}}}{(\nu_{\mu} : \nu_{e})_{\text{MC}}} \approx 0.6 \pm 0.1 , \qquad (22)$$

where $(\nu_{\mu}:\nu_{e})_{\rm MC}$ is the $\nu_{\mu}:\nu_{e}$ ratio expected on the basis of a Monte Carlo simulation. In addition, it is found that the quantity R depends on the direction from which the neutrinos are coming: For upward-going neutrinos, which must have been produced in the atmosphere on the side of the earth opposite to where the detector is located, and then traveled $\sim 10^4$ km, the diameter of the earth, to reach the detector, R has an anomalously low value. But for downward-going neutrinos, which must have been produced in the atmosphere just above the detector and traveled only ~ 10 km to reach it, R is consistent with unity [22].

The atmospheric neutrino results have been interpreted as $\nu_{\mu} \rightarrow \nu_{\tau}$ or $\nu_{\mu} \rightarrow \nu_{e}$ oscillation, described by an expression like that of Eq. (11). To accommodate the fact that the upward-going neutrinos oscillate, making R anomalously low, we must have $[1.27\Delta M^{2}(\mathrm{eV^{2}})L(\mathrm{km})/E(\mathrm{GeV})]\gtrsim 1$ when $L\sim 10^{4}$ km and $E\sim 1$ GeV, a typical energy for the neutrinos studied. This requires $\Delta M^{2}\gtrsim 10^{-4}$ eV². To accommodate the fact that the downward-going neutrinos do not oscillate (since for them R is not anomalous), we must have $[1.27\Delta M^{2}(\mathrm{eV^{2}})L(\mathrm{km})/E(\mathrm{GeV})]\ll 1$ when $L\sim 10$ km and $E\sim 1$ GeV. This requires $\Delta M^{2}\lesssim 10^{-2}$ eV². Thus, the favored ΔM^{2} range is

$$10^{-4} \lesssim \Delta M^2 \lesssim 10^{-2} \text{ eV}^2$$
 (23)

The size of the observed effect implies that the mixing angle is near maximal:

$$\sin^2 2\theta \approx 1. \tag{24}$$

In view of a recent bound on $\nu_e \leftrightarrow \nu_\mu$ oscillation from the CHOOZ reactor experiment [23], the $\nu_\mu \to \nu_\tau$ interpretation of

Lepton Particle Listings Neutrinos

the atmospheric neutrino data is more likely than the $\nu_{\mu} \rightarrow \nu_{e}$ interpretation.

The LSND experiment [24] has studied neutrinos from stopped positively-charged pions, which decay via the chain

$$\pi^{+} \to \mu^{+} \nu_{\mu}$$

$$\longrightarrow e^{+} \nu_{e} \overline{\nu}_{\mu} \tag{25}$$

We note that this chain does not produce $\overline{\nu}_e$, but an excess of $\overline{\nu}_e$ over expected background is reported by the experiment. This excess is interpreted as arising from oscillation of the $\overline{\nu}_{\mu}$ which the chain does produce into $\overline{\nu}_e$. Since the experiment has $L(\mathrm{km})/E(\mathrm{GeV}) \sim 1$, the implied mass splitting is $\Delta M^2 \gtrsim 1 \mathrm{~eV}^2$.

More recently, the same experiment has studied the neutrinos from the decay

$$\pi^+ \to \mu^+ \nu_{\mu} \tag{26}$$

of positively-charged pions in flight. This decay does not produce ν_e , but the experiment reports a ν_e signal above background [25]. This signal is interpreted as coming from $\nu_{\mu} \rightarrow \nu_{e}$ oscillation. The regions of ΔM^2 and $\sin^2 2\theta$ favored by the stopped pion and decay-in-flight data are consistent [25,26].

Suppose we assume that the behavior of the solar, atmospheric, and LSND neutrinos are all to be understood in terms of neutrino oscillation. What neutrino masses are then suggested?

If there are only three neutrinos of definite flavor, ν_e , ν_μ , and ν_τ , made up out of just three neutrinos of definite mass, ν_1 , ν_2 , and ν_3 , then there are only three mass splittings ΔM_{ij}^2 , and they obviously satisfy

$$\Delta M_{12}^2 + \Delta M_{23}^2 + \Delta M_{31}^2 = (M_1^2 - M_2^2) + (M_2^2 - M_3^2) + (M_3^2 - M_1^2) = 0.$$
 (27)

Now, the ΔM^2 required by the MSW explanation of the solar neutrino data is $\sim 10^{-5}$ eV², Eq. (21), and that required by the vacuum oscillation explanation is only 10^{-10} eV². The ΔM^2 required by the vacuum oscillation interpretation of the atmospheric neutrino anomaly is $\sim 10^{-(2-4)} {\rm eV^2}$, Eq. (23). Finally, the ΔM^2 favored by the vacuum oscillation explanation of the LSND data is $\gtrsim 1$ eV². Since the ΔM^2 values required to explain the solar, atmospheric, and LSND effects are of three different orders of magnitude, there is no way these three ΔM^2 values can add up to zero, as demanded by Eq. (27). Thus, it appears that one cannot explain all three of the existing hints of neutrino oscillation without introducing a fourth neutrino. Since this neutrino is known to make no contribution to the width of the Z^0 [27], it must be a neutrino which does not participate in the normal weak interactions—a "sterile" neutrino.

Despite this argument, interesting attempts have been made to make do with just three neutrinos. In one of these [28], there is a neutrino mass hierarchy of the sort described before Eq. (16), with $\Delta M_{32}^2 \approx \Delta M_{31}^2 \gg \Delta M_{21}^2$. The large mass splitting, ΔM_{32}^2 , is taken to be $\sim 0.4~{\rm eV^2}$, and the small one, ΔM_{21}^2 , to be $\sim (3\text{--}10) \times 10^{-5} {\rm eV^2}$. The LSND results are interpreted as $\langle \overline{\nu}_{\mu}^{\rangle} \rightarrow \langle \overline{\nu}_{e}^{\rangle} \rangle$ oscillation governed by the large mass splitting. The solar neutrino observations are explained in terms of an MSW $\nu_{e} \rightarrow \nu_{\mu}$ conversion governed by the small mass splitting. The atmospheric neutrino anomaly, which appears naively to require an intermediate ΔM^2 , is explained as a combination of oscillation effects involving both the large ΔM_{32}^2 and the small ΔM_{21}^2 . This scheme does not quite fit all the data, but it is intriguingly close.

If one assumes that a sterile neutrino cannot be avoided, then all three hints of neutrino oscillation can be accommodated, for example, with the following four neutrinos: A nearly degenerate pair, ν_3 , ν_2 , with $M_3\approx M_2\sim 1$ eV, a lighter neutrino ν_1 , with $M_1\sim 3\times 10^{-3}$ eV, and a sterile neutrino ν_s much lighter than ν_1 [29]. The flavor neutrinos ν_τ and ν_μ are each 50–50 mixtures of ν_3 and ν_2 , in accord with the suggestion from the atmospheric neutrino data that ν_τ and ν_μ are maximally mixed. The ν_e is dominantly ν_1 . The mass splitting $M_3^2-M_2^2$ is chosen to be $\lesssim 10^{-2} {\rm eV}^2$ to facilitate the $\nu_\mu \to \nu_\tau$ oscillation interpretation of the atmospheric anomaly. The splitting $M_1^2-M_s^2\approx M_1^2\sim 10^{-5}~{\rm eV}^2$ allows us to interpret the solar neutrino observations as reflecting MSW conversion of ν_e to the sterile ν_s . The splitting $M_3^2-M_1^2\approx M_2^2-M_1^2\sim 1~{\rm eV}^2$ enables us to explain the $\overline{\nu}_\mu \to \overline{\nu}_e$ oscillation.

The existing hints of neutrino oscillation, and the possible neutrino-mass scenarios which they suggest, will be probed in future neutrino experiments.

In addition to the ν_e , ν_μ , and ν_τ sections, the Review of Particle Physics includes sections on "Number of Light Neutrino Types," "Heavy Lepton Searches," and "Searches for Massive Neutrinos and Lepton Mixing."

- 29. This is a somewhat modified version of a neutrino-mass scenario proposed in D. Caldwell and R. Mohapatra, Phys. Rev. D48, 3259 (1993). In constructing our scenario, we have not assumed that neutrinos are a component of the dark matter in the universe. We thank N. Bahcall for a very enlightening discussion of the mass density of the universe.

 $J = \frac{1}{2}$

Not in general a mass eigenstate. See note on neutrino properties above.

Written April 1996 by D.E. Groom (LBNL).

These limits apply to ν_1 , the primary mass eigenstate in ν_e . They would also apply to any other ν_j which mixes strongly in ν_e and has sufficiently small mass that it can occur in the respective decay. The neutrino mass may be of a Dirac or Majorana type; the former conserves total lepton number while the latter violates it. Either would violate lepton family number, since nothing forces the neutrino mass eigenstates to coincide with the neutrino interaction eigenstates. For limits on a Majorana ν_e mass, see the section on "Searches for Massive Neutrinos and Lepton Mixing," part (C), entitled "Searches for Neutrinoless Double- β Decay."

The square of the neutrino mass $m_{\nu_e}^2$ is measured in tritium beta decay experiments by fitting the shape of the beta spectrum near the endpoint; results are given in one of the tables in this section. In many experiments, it has been found to be significantly negative. In the 1994 edition of this *Review*, it was noted that the combined probability of a positive result was 3.5%. The problem has been exacerbated by the precise and careful experiments reported in two new papers (BELESEV 95 and STOEFFL 95). Both groups conclude that unknown effects cause the accumulation of events in the electron spectrum near its end point. If the fitting hypothesis does not account for this, unphysical values for $m_{\nu_e}^2$ are obtained. BELESEV 95 obtain their value for $m_{\nu_e}^2$ and limit for m_{ν_e} (4.35 eV at 95% CL) under the assumption that a certain narrow region is free of both high-energy and low-energy anomalies. Including the endpoint

accumulation (they find no low-energy anomaly), STOEFFL 95 find a value for $m_{\nu_e}^2$ which is more than 5 standard deviations negative, and report a Bayesian limit of 7 eV for m_{ν_e} which is obtained by setting $m_{\nu_e}^2 = 0$. Given the status of the tritium results, we find no clear way to set a meaningful limit on m_{ν_e} . On the other hand, a mass as large as 10-15 eV would probably cause detectable spectrum distortions near the endpoint.

The spread of arrival times of the neutrinos from SN 1987A, coupled with the measured neutrino energies, should provide a simple time-of-flight limit on m_{ν_e} . This statement, clothed in various degrees of sophistication, has been the basis for a very large number of papers. The LOREDO 89 limit (23 eV) is among the most conservative and involves few assumptions; as such, it is probably a safe limit. We list this limit below as "used," but conclude that a limit about half this size is justified by the tritium decay experiments.

ν_e MASS

Most of the data from which these limits are derived are from β^{-} decay experiments in which a $\overline{
u}_e$ is produced, so that they really apply to $m_{\overline{
u}_1}$ Assuming CPT invariance, a limit on $m_{\overline{\nu}_1}$ is the same as a limit on $m_{\nu_1}^{-1}$. Results from studies of electron capture transitions, given below " m_{ν_1} " $m_{\overline{
u}_1}$ ", give limits on $m_{
u_1}$ itself. OUR EVALUATION of the present status of the tritium decay experiments is discussed in the above minireview.

- ¹ BELESEV 95 (Moscow) use an integral electrostatic spectrometer with adiabatic magnetic collimation and a gaseous tritium sources. A fit to a normal Kurle plot above 18300–18350 eV (to avoid a low-energy anomaly) plus a monochromatic line 7–15 eV below the endpoint yields $m_{\nu}^2=-4.1\pm 10.9 \, {\rm eV}^2$, leading to this Bayesian limit.
- ²CHING 95 quotes results previously given by SUN 93; no experimental details are given. A possible explanation for consistently negative values of m_{ν}^2 is given.
- ³ HIDDEMANN 95 (Munich) experiment uses atomic tritium embedded in a metal-dioxide lattice. Bayesian limit calculated from the weighted mean $m_{\nu}^2 = 221 \pm 4244 \text{ eV}^2$ from he two runs listed below.
- 4 STOEFFL 95 (LLNL) result is the Bayesian limit obtained from the m_{ν}^2 errors given below but with m_{ij}^2 set equal to 0. The anomalous endpoint accumulation leads to a value of m_{ij}^2 which is negative by more than 5 standard deviations.
- 5 The YASUMI 94 (KEK) limit results from their measurement $m_{\nu}{=}110^{+350}_{-110}~{\rm eV}.$
- 6 WEINHEIMER 93 (Mainz) is a measurement of the endpoint of the tritlum β spectrum using an electrostatic spectrometer with a magnetic guiding field. The source is molecular tritium frozen onto an aluminum substrate.
- ⁷ HOLZSCHUH 92B (Zurich) result is obtained from the measurement $m_{\nu}^2 = -24 \pm 48 \pm 61$ (1 σ errors), in eV², using the PDG prescription for conversion to a limit in m_{ν} .
- ⁸ KAWAKAMI 91 (Tokyo) experiment uses tritium-labeled arachidic acid. This result is the Bayesian limit obtained from the $m_{
 u}^2$ limit with the errors combined in quadrature. This was also done in ROBERTSON 91, although the authors report a different procedure.
- 9 ROBERTSON 91 (LANL) experiment uses gaseous molecular tritium. The result is in strong disagreement with the earlier claims by the ITEP group [LUBIMOV 80, BORIS 87 (+ BORIS 88 erratum)] that m_{ν} lies between 17 and 40 eV. However, the probability of a positive m^2 is only 3% if statistical and systematic error are combined in quadrature.
- ¹⁰See also comment in BORIS 87B and erratum in BORIS 88.

v. MASS SQUARED

The tritium experiments actually measure mass squared. A combined limit on mass must therefore be obtained from the weighted average of the results shown here. The recent results are in strong disagreement with the earlier claims by the ITEP group [LUBIMOV 80, BORIS 87 (+ BORIS 88, erratum)] that m_{ν_1} lies between 17 and 40 eV. The BORIS 87 result is excluded because of the controversy over the possibly large unreported systematic errors; see BERGKVIST 85B, BERGKVIST 86, SIMPSON 84, and REDONDO 89. However, the average for the new experiments given below Implies only a 3.5% probability that m^2 is positive. See HOLZSCHUH 92 for a review of the recent direct $m_{
u_1}$ measurements.

11 BELESEV 95 (Moscow) use an integral electrostatic spectrometer with adiabatic magnetic collimation and a gaseous tritium sources. This value comes from a fit to a normal Kurie plot above 18300–18350 eV (to avoid a low-energy anomaly), including the effects of an apparent peak 7-15 eV below the endpoint.

 12 STOEFFL 95 (LLNL) uses a gaseous source of molecular tritium. An anomalous pileup of events at the endpoint leads to the negative value for m_{ν}^2 . The authors acknowledge that "the negative value for the best fit of m_{ν}^2 has no physical meaning" and discuss possible explanations for this effect.

13 SUN 93 uses a tritlated hydrocarbon source. See also CHING 95.

 14 WEINHEIMER 93 (Mainz) is a measurement of the endpoint of the tritium eta spectrum ng an electrostatic spectrometer with a magnetic guiding field. The source is molecular tritium frozen onto an aluminum substrate.

15 HOLZSCHUH 92B (Zurich) source is a monolayer of tritlated hydrocarbon.

16 KAWAKAMI 91 (Tokyo) experiment uses tritium-labeled arachidic acid.

 17 ROBERTSON 91 (LANL) experiment uses gaseous molecular tritium. The result is in strong disagreement with the earlier claims by the ITEP group [LUBIMOV 80, BORIS 87 (+ BORIS 88 erratum)] that m_{ν} lies between 17 and 40 eV. However, the probability of a positive m_{ν}^2 is only 3% if statistical and systematic error are combined in quadrature.

18 HIDDEMANN 95 (Munich) experiment uses atomic tritium embedded in a metal-dioxide lattice. They quote measurements from two data sets.

m_{P1} $-m_{\overline{\nu}_1}$

These are measurement of m_{ν_1} (in contrast to $m_{\overline{\nu}_1}$, given above). The masses can be different for a Dirac neutrino in the absense of CPT invariance. ance. The test is not very strong.

26 RAFFELT 85 limit is from solar x- and γ -ray fluxes. Limit depends on ν flux from pp, now established from GALLEX and SAGE to be > 0.5 of expectation.

²⁷ REINES 74 looked for ν_e of nonzero mass decaying to a neutral of lesser mass + γ . Used liquid scintillator detector near fission reactor. Finds lab lifetime $6. \times 10^7$ s or more. Above value of (mean life)/mass assumes average effective neutrino energy of 0.2 MeV. To obtain the limit 6. \times 10⁷ s REINES 74 assumed that the full $\overline{\nu}_e$ reactor flux could be responsible for yielding decays with photon energies in the interval 0.1 MeV – 0.5 MeV. This represents some overestimate so their lower limit is an over-estimate of the ab lifetime (VOGEL 84). If so, OBERAUER 87 may be comparable or better.

28 BLUDMAN 92 sets additional limits by this method for higher mass ranges. Cosmological

Ilmits are also obtained. 29 Nonobservation of γ' 's in coincidence with ν 's from SN 1987A. 30 KRAKAUER 91 quotes the limit $\tau/m_{\nu_1} > (0.3a^2 + 9.8a + 15.9)$ s/eV, where a is a parameter describing the asymmetry in the neutrino decay defined as $dN_{\gamma}/d\cos\theta =$ $(1/2)(1+a\cos\theta)$ a=0 for a Majorana neutrino, but can vary from -1 to 1 for a Dirac neutrino. The bound given by the authors is the most conservative (which applies for

31 CHUPP 89 should be multiplied by a branching ratio (about 1) and a detection efficiency (about 1/4), and pertains to radiative decay of any neutrino to a lighter or sterile neutrino.

32 Model-dependent theoretical analysis of SN 1987A neutrinos.

33 OBERAUER 87 bounds are from comparison of observed and expected rate of reactor

34 seutrinos. 35 STECKER 80 limit based on UV background; result given is $au>4\times10^{22}$ s at $m_{
u}=20$

$|(v-c)/d|(v \equiv \nu_1 \text{ VELOCITY})$

Expected to be zero for massless neutrino, but tests also whether photons and neutrinos have the same limiting velocity in vacuum.

VALUE (units 10 ⁻⁸)	EVTS	DOCUMENT ID	TECN	COMMENT
<1	17	35 STODOLSKY 88	ASTR	SN 1987A
<0.2				SN 1987A

35 STODOLSKY 88 result based on <10 hr between $\overline{\nu}_e$ detection in IMB and KAMI detectors and beginning of light signal. Inclusion of the problematic 5 neutrino events from FREJ (four hours later) does not change the result.

 $36\,\text{LONGO}$ 87 argues that uncertainty between light and neutrino transit times is $\pm 3\,\text{hr}$, ignoring FREJUS events.

1/2 MAGNETIC MOMENT

Must vanish for Majorana neutrino or purely chiral massless Dirac neutrino. The value of the magnetic moment for the standard SU(2)×U(1) electroweak theory extended to include massive neutrinos (see FUJIKAWA 80) Is $\mu_{\nu} = 3eG_F m_{\nu}/(8\pi^2\sqrt{2}) = (3.20 \times 10^{-19}) m_{\nu} \mu_B$ where m_{ν} is in eV and $\mu_B = e\hbar/2m_e$ is the Bohr magneton. Given the upper bound m_{ν_1} < 7.3 eV, it follows that for the extended standard electroweak theory, $\mu(\nu_1) < 2.3 \times 10^{-18}~\mu_B$. Current experiments are not yet challenging this limit. There is considerable controversy over the validity of many of the claimed upper limits on the magnetic moment from the astrophysical data. For example, VOLOSHIN 90 states that "in connection with the astrophysical limits on $\mu_{\nu_{\tau}}$, ... there is by now a general consensus that contrary to the initial claims (BARBIERI 88, LATTIMER 88, GOLD-MAN 88, NOTZOLD 88), essentially no better than quoted limits (from previous constraints) can be derived from detection of the neutrino flux from the supernova SN1987A." See VOLOSHIN 88 and VOLOSHIN 88C.

38 ELMFORS 97 calculate the rate of depolarization in a plasma for neutrinos with a magnetic moment and use the constraints from a big-bang nucleosynthesis on additional

³⁹ GOVAERTS 96 limit is on $\sqrt{\Sigma \mu \nu_\ell^2}$, based on limits on 2ν decay of ortho-positronium.

 40 GOYAL 95 assume that helicity flip via μ_{ν} would result in faster cooling and hence shorter burst from SN1987A. Limit is based on the assumed presence of a pion condensate or

quark core in the remanant. 41 VIDYAKIN 92 limit is from a $e \overline{\nu}_e$ elastic scattering experiment. No experimental details are given except for the cross section from which this limit is derived. Signal/noise was 1/10. The limit uses $\sin^2 \theta_W = 0.23$ as input.

42 KRAKAUER 90 experiment fully reported in ALLEN 93.

ARAFACET 90 limit applies for a diagonal magnetic moment of a Dirac neutrino, or for a transition magnetic moment of a Majorana neutrino. In the latter case, the same analysis gives $< 1.4 \times 10^{-12}$. Limit at 95%CL obtained from δM_C .

 44 Significant dependence on details of stellar models. 45 A limit of 10^{-13} is obtained with even more model-dependence.

These papers have assumed that the right-handed neutrino is inert; see BARBIERI 888.

47 FUKUGITA 88 find magnetic dipole moments of any two neutrino species are bounded by $\mu < 10^{-16} \, [10^{-9} \, G/B_0]$ where B_0 is the present-day intergalactic field strength.

⁴⁸ Some dependence on details of stellar models.

⁴⁹We obtain above limit from SUTHERLAND 76 using their limit f < 1/3.

NONSTANDARD CONTRIBUTIONS TO NEUTRINO SCATTERING

We report limits on the so-called neutrino charge radius squared in this section. This quantity is not an observable, physical quantity and this is reflected in the fact that it is gauge dependent (see LEE 77C). It is not necessarily positive. A more general interpretation of the experimental results is that they are limits on certain nonstandard contributions to neutrino scattering.

$J = \frac{1}{2}$

Not in general a mass eigenstate. See note on neutrinos in the u_{e} section above.

u_{μ} MASS

Applies to ν_2 , the primary mass eigenstate in ν_μ . Would also apply to any other ν_J which mixes strongly in ν_μ and has sufficiently small mass that it can occur in the respective decays. (This would be nontrivial only for $j\geq 3$, given the ν_e mass limit above.) Results based upon an obselete pion mass are no longer shown; they were in any cass less restrive than ASSAMAGAN 96.

 1 ASSAMAGAN 96 measurement of ρ_μ from $\pi^+\to \mu^+\nu_\mu$ at rest combined with JECK-ELMANN 94 Solution B pion mass yields $m_\nu^2=-0.016\pm0.023$ with corresponding Bayesian limit listed above. If Solution A is used, $m_2=-0.143\pm0.024~{\rm MeV}^2$. Replaces ASSAMAGAN 94.

places ASSAMAGAN 94.

2 DOLGOV 95 removes earlier assumptions (DOLGOV 93) about thermal equilibrium below TQCD for wrong-helicity Dirac neutrinos (ENQVIST 93, FULLER 91) to set more stringent limits.

3 ENQVIST 93 bases limit on the fact that thermalized wrong-helicity Dirac neutrinos would speed up expansion of early universe, thus reducing the primordial abundance. FULLER 91 exploits the same mechanism but in the older calculation obtains a larger production rate for these states, and hence a lower limit. Neutrino lifetime assumed to exceed nucleosynthesis time a.1.5

exceed nucleosynthesis time, ~ 1 s.

*MAYLE 93 recalculates cooling rate enhancement by escape of wrong-helicity Dirac neutrinos using the Livermore Supernova Explosion Code, obtains more restrictive result than the "very conservative" BURROWS 92 limit because of higher core temperature.

⁵ There would be an increased cooling rate if Dirac neutrino mass is included; this does not apply for Majorana neutrinos. Limit is on $\sqrt{m^2_{\nu\mu}+m^2_{\nu\tau}}$, and error becomes very large if ν_{τ} is nonrelativistic, which occurs near the lab limit of 31 MeV. RAJPOOT 93 notes that limit could be evaded with new physics.

8 BURROWS 92 limit for Dirac neutrinos only.

7 Assumes neutrino lifetime 51s. For Dirac neutrinos only.

⁷ Assumes neutrino lifetime >1 s. For Dirac neutrinos only. See also ENQVIST 93.

⁸ NATALE 91 published result multiplied by $\sqrt{8}\sqrt{4}$ at the advice of the author.

9 GRIFOLS 90B estimated error is a factor of 3. 10 GAEMERS 89 published result (< 0.03) corrected via the GANDHI 91 erratum.

11 ANDERHUB 82 kinematics is insensitive to the pion mass.

$m_{\nu_2} - m_{\overline{\nu}_2}$

Test of CPT for a Dirac neutrino. (Not a very strong test.)

 $\nu_{\mu}, \nu_{ au}$

 12 KRAKAUER 91 quotes the limit $\tau/m_{\nu_1}~>~(0.75a^2~+~21.65a~+~26.3)~\text{s/eV},$ where ais a parameter describing the asymmetry in the neutrino decay defined as $dN_{rev}/d\cos\theta$ $\approx (1/2)(1 + a\cos\theta)$ The parameter a=0 for a Majorana neutrino, but can vary from -1 to 1 for a Dirac neutrino. The bound given by the authors is the most conservative (which applies for a=-1).

(which applies for a ≈ -1).

13 BLUDMAN 92 sets additional limits by this method for higher mass ranges. Cosmological limits are also obtained.

14 Nonobservation of γ 's in coincidence with ν 's from SN 1987A. Results should be divided by the $\tau_{\nu} \rightarrow \gamma X$ branching ratio.

15 DODELSON 92 range is for wrong-helicity keV mass Dirac ν 's from the core of neutron star in SN 1987A decaying to v's that would have interacted in KAM2 or IMB detectors.

16 CHUPP 99 should be multiplied by a branching ratio (about 1) and a detection efficiency (about 1/4), and pertains to radiative decay of any neutrino to a lighter or sterile neutrino.

17 Model-dependent theoretical analysis of SN 1987A neutrinos.

 18 Limit applies to ν_{τ} also.

 19 These experiments look for $\nu_{\mu} \to \ \nu_{e} \gamma$ or $\overline{\nu}_{\mu} \to \ \overline{\nu}_{e} \gamma.$

 $^{20}\,\text{HENRY}$ 81 uses UV flux from clusters of galaxies to find $\tau>~1.1\times10^{25}\,\text{s}$ for radiative

²¹ KIMBLE 81 uses extreme UV flux limits to find $\tau > 10^{22}$ – 10^{23} s.

²² REPHAELI 81 consider ν decay γ effect on neutral H in early universe; based on M31 HI concludes $\tau > 10^{24}$ s. ²³ DERUJULA 80 finds $\tau > 3 \times 10^{23}$ s based on CDM neutrino decay contribution to UV

background.

²⁴ STECKER 80 limit based on UV background; result given is $\tau > 4 \times 10^{22}$ s at $m_{\nu} = 20$

$|(v-c)/c| (v \equiv \nu_2 \text{ VELOCITY})$

Expected to be zero for massless neutrino, but also tests whether photons and neutrinos have the same limiting velocity in vacuum.

1/2 MAGNETIC MOMENT

Must vanish for Majorana neutrino or purely chiral massless Dirac neutrino. The value of the magnetic moment for the standard SU(2)×U(1) electroweak theory extended to include massive neutrinos (see FUJIKAWA 80) troweak theory extended to include massive neutrinos (see FUJIKAWA 80) is $\mu_{\nu} = 3 \text{eG}_F m_{\nu} / (8\pi^2 \sqrt{2}) = (3.2 \times 10^{-19}) m_{\nu} \mu_B$ where m_{ν} is in eV and $\mu_B = \text{e}\hbar / 2m_e$ is the Bohr magneton. Given the upper bound $m_{\nu_2} < 0.17$ MeV, it follows that for the extended standard electroweak theory, $\mu(\nu_2) < 0.51 \times 10^{-13} \ \mu_B$.

25 KRAKAUER 90 experiment fully reported in ALLEN 93.

26 ELMFORS 97 calculate the rate of depolarization in a plasma for neutrinos with a magnetic moment and use the constraints from a big-bang nucleosynthesis on additional

²⁷ GOVAERTS 96 limit is on $\sqrt{\Sigma \mu \nu_\ell^2}$, based on limits on 2ν decay of ortho-positronium.

 28 DORENBOSCH 91 corrects an incorrect statement in DORENBOSCH 89 that the ν_2 magnetic moment is $< 1 \times 10^{-9}$ at the 95%CL. DORENBOSCH 89 measures both $\nu_{\mu}e^{-2}$ and $\overline{\nu}_{\mu}$ e elastic scattering and assume $\mu(\nu_{\mu})=\mu(\overline{\nu}_{\mu}).$

 29 RAFFELT 90 limit applies for a diagonal magnetic moment of a Dirac neutrino, or for a transition magnetic moment of a Majorana neutrino. In the latter case, the same analysis gives $<1.4\times10^{-12}$. Limit at 95%CL obtained from $\delta M_{\rm C}$.

30 Significant dependence on details of stellar properties.

 31 if m_{ν_2} < 10 keV.

 32 For $m_{
u_2}=$ 8–200 eV. NUSSINOV 87 examines transition magnetic moments for u_{μ} ightarrow $\nu_{\rm e}$ and obtain < 3 \times 10⁻¹⁵ for $m_{\nu_{\rm 2}}$ > 16 eV and < 6 \times 10⁻¹⁴ for $m_{\nu_{\rm 2}}$ > 4 eV.

 $^{33}\,\text{KIM}$ 74 is a theoretical analysis of $\bar{\nu_{\mu}}$ reaction data.

 34 If m_{ν_2} < 1 keV.

NONSTANDARD CONTRIBUTIONS TO NEUTRING SCATTERING

We report limits on the so-called neutrino charge radius squared in this section. This quantity is not an observable, physical quantity and this is reflected in the fact that it is gauge dependent (see LEE 77C). It is not necessarily positive. A more general interpretation of the experimental results is that they are limits on certain nonstandard contributions to neutrino

Existence indirectly established from au decay data combined with u reaction data. See for example FELDMAN 81. ALBRECHT 92Q rules out J=3/2 by establishing that the ρ^{-} is not in a pure $H_0=-1$ helicity state in $\tau^- \rightarrow \rho^- \nu_\tau$.

Not in general a mass eigenstate. See note on neutrinos in the $\nu_{\rm e}$ section above.

VT MASS

Applies to ν_3 , the primary mass eigenstate in ν_τ . Would also apply to any other ν_f which mixes strongly in ν_τ and has sufficiently small mass that It can occur in the respective decays. (This would be nontrivial only for a hypothetical $j \ge 4$, given the ν_e and ν_μ mass limits above.) See also the Listings in the Neutrino Bounds from Astrophysics and Cosmology section.

- 2 ANASTASSOV 97 derive limit by comparing their m_τ measurement (which depends on m_{ν_τ}) to BAI 96 m_τ threshold measurement.
- 3 FIELDS 97 limit for a Dirac neutrino. For a Majorana neutrino the mass region < 0.93or >31 MeV is excluded. These bounds assume N_{ν} <4 from nucleosynthesis; a wider excluded region occurs with a smaller N_{ν} upper limit.
- ⁴ SWAIN 97 derive their limit from the Standard Model relationships between the tau mass, lifetime, branching fractions for $\tau^- \to e^- \overline{\nu}_e \nu_{ au}, \, \tau^- \to \mu^- \overline{\nu}_{\mu} \nu_{ au}, \, \tau^- \to \pi^- \nu_{ au}$, and $au^- o K^-
 u_{_T}$, and the muon mass and lifetime by assuming lepton universality and using world average values. Limit is reduced to 48 MeV when the CLEO au mass measurement (BALEST 93) is included; see CLEO's more recent $m_{_{V_T}}$ limit (ANASTASSOV 97). Consideration of mixing with a fourth generation heavy neutrino yields $\sin^2 \theta_L < 0.016$
- 5 ALEXANDER 96M bound comes from analyses of $au^- o 3\pi^- 2\pi^+
 u_{ au}$ and $au^- o 1$ $h^-\,h^-\,h^+\,\nu_\tau$ decays.
- ⁶ BOTTINO 96 assumes three generations of neutrinos with mixing, finds consistency with massless neutrinos with no mixing based on 1995 data for masses, lifetimes, and leptonic partial widths.
- THANNESTAD 96C limit is on the mass of a Majorana neutrino. This bound assumes $N_{\nu} < 4$ from nucleosynthesis. A wider excluded region occurs with a smaller N_{ν} upper limit. This paper is the corrected version of HANNESTAD 96; see the erratum:
- 8 SOBIE 96 derive their limit from the Standard Model relationship between the tau mass, lifetime, and leptonic branching fraction, and the muon mass and lifetime, by assuming lepton universality and using world average values.
- ⁹ AKERS 95D bound comes from analysis of $au^- o 3\pi^- 2\pi^+
 u_{ au}$ decay mode.
- 10 BUSKULIC 95H bound comes from a two-dimensional fit of the visible energy and invariant mass distribution of $au o 5\pi(\pi^0)
 u_{ au}$ decays. Replaced by BARATE 98F.
- 11 DOLGOV 95 removes earlier assumptions (DOLGOV 93) about thermal equilibrium below TQCD for wrong-helicity Dirac neutrinos (ENQVIST 93, FULLER 91) to set more strinent limits. DOLGOV 96 argues that a possible window near 20 MeV is excluded.
- 12 SiGL 95 exclude massive Dirac or Majorana neutrinos with lifetimes between 10^{-3} and
- 10⁸ seconds if the decay products are predominantly γ or e^+e^- .

 13 DODELSON 94 calculate constraints on ν_{τ} mass and lifetime from nucleosynthesis for 4 generic decay modes. Limits depend strongly on decay mode. Quoted limit is valid for all decay modes of Majorana neutrinos with lifetime greater than about 300 s. For Dirac neutrinos limits change to < 0.3 or > 33.
- 14 KAWASAKI 94 excluded region is for Majorana neutrino with lifetime >1000 s. Other limits are given as a function of ν_{τ} lifetime for decays of the type $\nu_{\tau} \rightarrow \ \nu_{\mu} \phi$ where ϕ
- is a Nambu-Goldstone boson. 15 PERES 94 used PDG 92 values for parameters to obtain a value consistent with mixing. Reexamination by BOTTINO 96 which included radiative corrections and 1995 PDG parameters resulted in two allowed regions, $m_3 < 70$ MeV and 140 MeV $m_3 < 149$
- 16 BALEST 93 derive limit by comparing their $m_{ au}$ measurement (which depends on $m_{
 u_{ au}}$) to BAI 92 and BACINO 788 m., threshold measurements.
- ¹⁷CINABRO 93 bound comes from analysis of $\tau^- \rightarrow 3\pi^- 2\pi^+ \nu_{\tau}$ and $\tau^- \rightarrow$ $2\pi^-\pi^+2\pi^0\nu_{ au}$ decay modes.
- 18 DOLGOV 93 assumes neutrino lifetime >100 s. For Majorana neutrinos, the low mass limit is 0.5 MeV. KAWANO 92 points out that these bounds can be overcome for a Dirac neutrino if it possesses a magnetic moment. See also DOLGOV 96.
- 19 ENQVIST 93 bases limit on the fact that thermalized wrong-helicity Dirac neutrinos would speed up expansion of early universe, thus reducing the primordial abundance. FULLER 91 exploits the same mechanism but in the older calculation obtains a larger production rate for these states, and hence a lower limit. Neutrino lifetime assumed to exceed nucleosynthesis time, \sim 1 s.

- ²⁰ MAYLE 93 recalculates cooling rate enhancement by escape of wrong-helicity Dirac neutrinos using the Livermore Supernova Explosion Code, obtains more restrictive result than the "very conservative" BURROWS 92 limit because of higher core temperature.
- ²¹ There would be an increased SN 1987A cooling rate if Dirac neutrino mass is included; this does not apply for Majorana neutrinos. Limit is on $\sqrt{m^2_{\ \nu_\mu} + m^2_{\ \nu_\tau}}$, and error becomes very large if ν_τ is nonrelativistic, which occurs near the lab limit of 31 MeV. RAJPOOT 93 notes that limit could be evaded with new physics.
- 22 ALBRECHT 92M reports measurement of a slightly lower au mass, which has the effect of reducing the $u_{ au}$ mass reported in ALBRECHT 88B. Bound is from analysis of $au^-
 ightarrow$ $3\pi^+2\pi^+\nu_{\tau}$ mode.
- 23 BURROWS 92 limit for Dirac neutrinos only.
- 24 Assumes neutrino lifetime >1 s. For Dirac neutrinos. See also ENQVIST 93.
- 25 KOLB 91 exclusion region is for Dirac neutrino with lifetime >1 s; other limits are given.
- $^{26}\,\text{NATALE}$ 91 published result multiplied by $\sqrt{8}\sqrt{4}$ at the advice of the author.
- GRIFOLS 90B estimated error is a factor of 3. ²⁸ GAEMERS 89 published result (< 0.03) corrected via the GANDHI 91 erratum.

以 (MEAN LIFE) / MASS

These limits often apply to $\nu_{\mu}~(\nu_{2})$ also.

- 29 SIGL 95 exclude 1 s $\lesssim \tau \lesssim 10^8$ s for MeV-mass τ nuetrinos from SN 1987A decaying radiatively, and eliminates the lower limit using other published results.
- 30 BLUDMAN 92 sets additional limits by this method for higher mass ranges. Cosmological
- limits are also obtained. 31 Nonobservation of γ 's in coincidence with ν 's from SN 1987A. Results should be divided by the $\tau_{\nu} \rightarrow \ \gamma$ X branching ratio.
- 32 DODELSON 92 range is for wrong-helicity keV mass Dirac u's from the core of neutron star in SN 1987A decaying to u's that would have interacted in KAM2 or IMB detectors.
- 33 GRANEK 91 considers heavy neutrino decays to $\gamma \nu_L$ and $3 \nu_L$, where m_{ν_L} <100 keV. Lifetime is calculated as a function of heavy neutrino mass, branching ratio into $\gamma \nu_L$,
- 34 WALKER 90 uses SN 1987A $_{\gamma}$ flux limits after 289 days to find $m_{_{T}}~>~1.1 \times 10^{15}$ eV s.
- 35 CHUPP 89 should be multiplied by a branching ratio (about 1) and a detection efficiency (about 1/4), and pertains to radiative decay of any neutrino to a lighter or sterile neutrino.
- 36 TERASAWA 88 finds only $10^2 < au < 10^4$ allowed for 30–70 MeV u's from primordal
- 37 KAWASAKI 86 concludes that light elements in primordal nucleosynthesis would be destroyed by radiative decay of neutrinos with 10 MeV < m_{ν} <1 GeV unless $\tau \lesssim 10^4$ s.
- 38 LINDLEY 85 considers destruction of cosmologically-produced light elements, and finds $au < 2 imes 10^3 \, \mathrm{s}$ for 10 MeV $< m_{
 u} <$ 100 MeV. See also LINDLEY 79.
- ³⁹ BINETRUY 84 finds $\tau < 10^8$ s for neutrinos in a radiation-dominated universe. ⁴⁰ SARKAR 84 finds $\tau < 20$ s at $m_{\nu} = 10$ MeV, with higher limits for other m_{ν} , and claims that all masses between 1 MeV and 50 MeV are ruled out.
- ⁴¹ HENRY 81 uses UV flux from clusters of galaxies to find $au > 1.1 imes 10^{25} \, \mathrm{s}$ for radiative
- decay. 42 KIMBLE 81 uses extreme UV flux limits to find $\tau > 10^{22} 10^{23}$ s. 43 REPHAELI 81 consider ν decay γ effect on neutral H in early universe; based on M31 Hi concludes $\tau > 10^{24}$ s. 44 DERUJULA 80 finds $\tau > 3 \times 10^{23}$ s based on CDM neutrino decay contribution to UV
- 45 STECKER 80 limit based on UV background; result given is $au > 4 imes 10^{22}\,\mathrm{s}$ at $m_{
 m p} = 20\,$ eV.

 6 DICUS 78 considers effect of ν decay photons on light-element production, and finds lifetime must be less than "hours." See also DICUS 77.

 7 FALK 78 finds lifetime constraints based on supernova energetics.
- 48 COWSIK 77 considers varity of scenarios. For neutrinos produced in the big bang, present limits on optical photon flux require $\tau>10^{23}\,\mathrm{s}$ for $m_{\nu}\sim 1$ eV. See also COWSIK 79 and GOLDMAN 79.

№ MAGNETIC MOMENT

Must vanish for Majorana neutrino or purely chiral massless Dirac neutrino. The value of the magnetic moment for the standard SU(2)×U(1) electroweak theory extended to include massive neutrinos (see FUJIKAWA 80) is $\mu_{\nu}=3eG_Fm_{\nu}/(8\pi^2\sqrt{2})=(3.20\times 10^{-19})m_{\nu}\mu_B$ where m_{ν} is in eV and $\mu_B=e\hbar/2m_e$ is the Bohr magneton. Given the upper bound $m_{\nu_3}<35$ MeV, it follows that for the extended standard electroweak theory, $\mu(\nu_3)<1.1\times10^{-11}~\mu_B$.

Number of Light Neutrino Types

The neutrinos referred to in this section are those of the Standard SU(2)×U(1) Electroweak Model possibly extended to allow nonzero neutrino masses. Light neutrinos are those with $m_{\nu} < m_{Z}/2$. The limits are on the number of neutrino families or species, including $\nu_{\rm e},\,\nu_{\mu},\,\nu_{\tau}$

THE NUMBER OF LIGHT NEUTRINO TYPES FROM COLLIDER EXPERIMENTS

Revised April 1998 by D. Karlen (Carleton University).

The most precise measurements of the number of light neutrino types, N_{ν} , come from studies of Z production in e^+e^- collisions. At the time of this report, the most recent (preliminary) combined analysis of the four LEP experiments [1] included over 16 million visible Z decays. The invisible partial width, $\Gamma_{\rm inv}$, is determined from these data by subtracting the measured visible partial widths, corresponding to Z decays into quarks and charged leptons, from the total Z width. The invisible width is assumed to be due to N_{ν} light neutrino species each contributing the neutrino partial width Γ_{ν} as given by the Standard Model. In order to reduce the model dependence, the Standard Model value for the ratio of the neutrino to charged leptonic partial widths, $(\Gamma_{\nu}/\Gamma_{\ell})_{\rm SM}=1.991\pm0.001$, is used instead of $(\Gamma_{\nu})_{\rm SM}$ to determine the number of light neutrino types:

$$N_{\nu} = \frac{\Gamma_{\rm inv}}{\Gamma_{\ell}} \left(\frac{\Gamma_{\ell}}{\Gamma_{\nu}}\right)_{\rm SM}$$

The combined LEP result is $N_{\nu} = 2.993 \pm 0.011$.

In the past, when only small samples of Z decays had been recorded by the LEP experiments and by the Mark II at SLC, the uncertainty in N_{ν} was reduced by using Standard Model fits to the measured hadronic cross sections at several center-of-mass energies near the Z resonance. Since this method is much more dependent on the Standard Model, the approach described above is favored.

Before the advent of the SLC and LEP, limits on the number of neutrino generations were placed by experiments at lower-energy e^+e^- colliders by measuring the cross section of the process $e^+e^- \to \nu \bar{\nu} \gamma$. The ASP, CELLO, MAC, MARK J, and VENUS experiments observed a total of 3.9 events above background [2], leading to a 95% CL limit of $N_{\nu} < 4.8$. This process has a much larger cross section at center-of-mass energies near the Z mass and has been measured at LEP by the ALEPH, DELPHI, L3, and OPAL experiments [3]. These experiments have observed several thousand such events, and the combined result is $N_{\nu} = 3.00 \pm 0.09$.

Experiments at $p\overline{p}$ colliders also placed limits on N_{ν} by determining the total Z width from the observed ratio of $W^{\pm} \to \ell^{\pm} \nu$ to $Z \to \ell^{+} \ell^{-}$ events [4]. This involved a calculation that assumed Standard Model values for the total W width and the ratio of W and Z leptonic partial widths, and used an estimate of the ratio of Z to W production cross sections. Now that the Z width is very precisely known from the LEP experiments, the approach is now one of those used to determine the W width.

Massive Neutrinos and Lepton Mixing, Searches for

SEARCHES FOR MASSIVE NEUTRINOS

Revised April 1998 by D.E. Groom (LBNL).

Searches for massive neutral leptons and the effects of nonzero neutrino masses are listed here. These results are divided into the following main sections:

- A. Heavy neutral lepton mass limits;
- B. Sum of neutrino masses;
- C. Searches for neutrinoless double- β decay (see the note by P. Vogel on "Searches for neutrinoless double- β decay" preceding this section);
- D. Other bounds from nuclear and particle decays;
- E. Bounds from particle decays;
- F. Solar ν experiments (see the note on "Solar Neutrinos" by K. Nakamura preceding this section);
- G. Astrophysical neutrino observations;
- H. Reactor $\overline{\nu}_e$ disappearance experiments;
- I. Accelerator neutrino appearance experiments;
- Disappearance experiments with accelerator and radioactive source neutrinos.

Direct searches for masses of dominantly coupled neutrinos are listed in the appropriate section on ν_e , ν_μ , or ν_τ . Searches for massive charged leptons are given elsewhere, and searches for the mixing of (μ^-e^+) and (μ^+e^-) are given in the muon Listings.

Discussion of the current neutrino mass limits and the theory of mixing are given in the note on "Neutrino Mass" by Boris Kayser just before the ν_e Listings.

In many of the following Listings (e.g. neutrino disappearance and appearance experiments), results are presented assuming that mixing occurs only between two neutrino species, such as $\nu_{\tau} \leftrightarrow \nu_{e}$. This assumption is also made for lepton-number violating mixing between two states, such as $\nu_{e} \leftrightarrow \overline{\nu}_{\mu}$ or $\nu_{\mu} \leftrightarrow \overline{\nu}_{\mu}$. As discussed in Kayser's review, the assumption of mixing between only two states is valid if (a) all mixing angles are small or (b) there is a mass hierarchy such that one ΔM_{ij}^{2} ,

e.g. $\Delta M_{21}^2 = M_{\nu_2}^2 - M_{\nu_1}^2$, is small compared with the others, so that there is a region in L/E (the ratio of the distance L that the neutrino travels to its energy E) where $\Delta M_{21}^2 L/E$ is negligible, but $\Delta M_{32}^2 L/E$ is not.

In this case limits or results can be shown as allowed regions on a plot of $|\Delta M^2|$ as a function of $\sin^2 2\theta$. The simplest situation occurs in an "appearance" experiment, where one searches for interactions by neutrinos of a variety not expected in the beam. An example is the search for ν_e interactions in a detector in a ν_μ beam. For oscillation between two states, the probability that the "wrong" state will appear is given by Eq. 11 in Kayser's review, which may be written as

$$P = \sin^2 2\theta \, \sin^2(1.27\Delta M^2 L/E) \,, \tag{1}$$

where $|\Delta M^2|$ is in eV² and L/E is in km/GeV or m/MeV. In a real experiment L and E have some spread, so that one must average P over the distribution of L/E. As an example, let us make the somewhat unrealistic assumption that $b \equiv 1.27L/E$ has a Gaussian distribution with standard deviation σ_b about a central value b_0 . Then:

$$\langle P \rangle = \frac{1}{2} \sin^2 2\theta [1 - \cos(2b_0 \Delta M^2) \exp(-2\sigma_b^2 (\Delta M^2)^2)]$$
 (2)

The value of $\langle P \rangle$ is set by the experiment. For example, if 230 interactions of the expected flavor are detected and none of the wrong flavor are seen, then P=0.010 at the 90% CL. *A superior statistical analysis of confidence limits in the $\sin^2 2\theta - |\Delta M^2|$ plane is given in Ref. 1. We can then solve the above expression for $\sin^2 2\theta$ as a function of $|\Delta M^2|$. This function is shown in Fig. 1. † Curve generated with $\langle P \rangle = 0.005$, $\langle L/E \rangle = 1.11$, and $\sigma_b/b_0 = 0.08$. Note that:

- (a) since the fast oscillations are completely washed out by the resolution for large $|\Delta M^2|$, $\sin^2 2\theta = 2 \langle P \rangle$ in this region;
- (b) the maximum excursion of the curve to the left is to $\sin^2 2\theta = \langle P \rangle$ with good resolution, with smaller excursion for worse resolution. This "bump" occurs at $|\Delta M^2| = \pi/2b_0 \text{ eV}^2$;
- (c) for large $\sin^2 2\theta$, $\Delta M^2 \approx (\langle P \rangle / \sin^2 2\theta)^{1/2}/b_0$; and, consequently,
- (d) the intercept at $\sin^2 2\theta = 1$ is at $\Delta M^2 = \sqrt{\langle P \rangle}/b_0$.

The intercept for large $|\Delta M^2|$ is a measure of running time and backgrounds, while the intercept at $\sin^2 2\theta = 1$ depends also on the mean value of L/E. The wiggles depend on experimental features such as the size of the source, the neutrino energy distribution, and detector and analysis features. Aside from such details, the two intercepts completely describe the exclusion region: For large $|\Delta M^2|$, $\sin^2 2\theta$ is constant and equal to $2\langle P \rangle$, and for large $\sin^2 2\theta$ the slope is known from the intercept. For these reasons, it is (nearly) sufficient to summarize the results of an experiment by stating the two intercepts, as is done in the following tables. The reader is referred to the original papers for the two-dimensional plots expressing the actual limits.

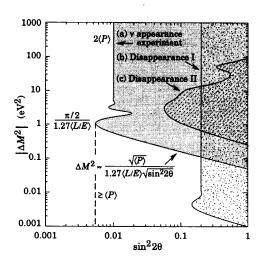

Figure 1: Neutrino oscillation parameter ranges excluded by two hypothetical experiments

(a and b) described by Eq. (2) and one real one (c). Parameters for the first two cases are given in the footnotes. In case (a) one searches for the appearance of neutrinos not expected in the beam. The probability of appearance, in this case 0.5% at some specified CL, is set by the number of right-flavor events observed and/or information about the flux and cross sections. Case (b) represents a disappearance experiment in which the flux is known in the absence of mixing. In case (c), the information comes from measured fluxes at two distances from the target [4].

If a positive effect is claimed, then the excluded region is replaced by an allowed band or allowed regions. This is the case for the LSND experiment [2] and the SuperKamiokande analysis of $R(\mu/e)$ for atmospheric neutrinos [3].

In a "disappearance" experiment, one looks for the attenuation of the beam neutrinos (for example, ν_k) by mixing with at least one other neutrino eigenstate. (We label such experiments as $\nu_k \not\rightarrow \nu_k$.) The probability that a neutrino remains the same neutrino from the production point to detector is given by

$$P(\nu_k \to \nu_k) = 1 - P(\nu_k \to \nu_j) , \qquad (3)$$

where mixing occurs between the kth and jth species with $P(\nu_k \to \nu_j)$ given by Eq. (1) or Eq. (2).

In contrast to the detection of even a few "wrong-flavor" neutrinos establishing mixing in an appearance experiment, the disappearance of a few "right-flavor" neutrinos in a disappearance experiment goes unobserved because of statistical fluctuations. For this reason, disappearance experiments usually cannot establish small-probability (small $\sin^2 2\theta$) mixing.

Disappearance experiments fall into two general classes:

- I. Those in which the beam neutrino flux is known, from theory or from other measurements. Examples are reactor $\overline{\nu}_e$ experiments and certain accelerator experiments. Although such experiments cannot establish very small- $\sin^2 2\theta$ mixing, they can establish small limits on ΔM^2 for large $\sin^2 2\theta$ because L/E can be very large. An example, based on the Chooz reactor measurements [5], is labeled "Disappearance I" in Fig. 1. [†]Curve parameters $\langle P \rangle = 0.1$, $\langle L/E \rangle = 237$, and $\sigma_b/b_0 = 0.5$. For the actual Chooz experiment [5], $\langle L/E \rangle \approx 300$ and the limit on $\langle P \rangle$ is 0.09.
- II. Those in which attenuation or oscillation of the beam neutrino flux is measured in the apparatus itself (two detectors, or a "long" detector). Above some minimum $|\Delta M^2|$ the equilibrium is established upstream, and there is no change in intensity over the length of the apparatus. As a result, sensitivity is lost at high $|\Delta M^2|$, as can be seen by the curve labeled "Disappearance II" in Fig. 1 [4]. Such experiments have not been competititive for a long time. However, a new generation of long-baseline experiments with a "near" detector and a "far" detector with very large L, e.g., MINOS, will be able to use this strategy to advantage.

Finally, there are more complicated cases, such as analyses of solar neutrino data in terms of the MSW parameters [6]. For a variety of physical reasons, an irregular region in the $|\Delta M^2|$ vs $\sin^2 2\theta$ plane is allowed. It is difficult to represent these graphical data adequately within the strictures of our tables.

 $^{^2}$ The decay length of the heavy lepton is assumed to be < 1 cm, limiting the square of the mixing angle $|U_{\ell j}|^2$ to $10^{-12}.$

 16 WENDT 87 is MARK-II search at PEP for heavy u with decay length 1–20 cm (hence

iong-ived). The ADIER 86 is a search for a long-lived penetrating sequential lepton produced in π^- nucleon collisions with lifetimes in the range from 5×10^{-7} – 5×10^{-11} s and decaying into at least two charged particles. U_{ej} and $U_{m,j}$ are mixing angles to ν_e and ν_μ . See also the BADIER 86 entry in the section "Searches for Massive Neutrinos and Lepton Mixing".

23 ENQVIST 89 argue that there is no cosmological upper bound on heavy neutrinos.

(B) Sum of neutrino masses

Revised April 1998 by K.A. Olive (University of Minnesota).

The limits on low mass $(m_{\nu} \lesssim 1 \text{ MeV})$ neutrinos apply to $m_{\rm tot}$ given by

$$m_{
m tot} = \sum_
u (g_
u/2) m_
u$$
 ,

where g_{ν} is the number of spin degrees of freedom for ν plus $\overline{\nu}$: $g_{\nu} = 4$ for neutrinos with Dirac masses; $g_{\nu} = 2$ for Majorana neutrinos. Stable neutrinos in this mass range make a contribution to the total energy density of the Universe which is given by

$$\rho_{\nu} = m_{\text{tot}} n_{\nu} = m_{\text{tot}} (3/11) n_{\gamma} ,$$

where the factor 3/11 is the ratio of (light) neutrinos to photons. Writing $\Omega_{\nu} = \rho_{\nu}/\rho_c$, where ρ_c is the critical energy density of the Universe, and using $n_{\gamma} = 412 \text{ cm}^{-3}$, we have

$$\Omega_{\nu}h^2 = m_{\rm tot}/(94 \text{ eV})$$
.

Therefore, a limit on $\Omega_{\nu}h^2$ such as $\Omega_{\nu}h^2 < 0.25$ gives the limit

$$m_{\mathrm{tot}} < 24 \mathrm{~eV}$$
 .

The limits on high mass $(m_{\nu} > 1 \text{ MeV})$ neutrinos apply separately to each neutrino type.

Limit on Total ν MASS, m_{tot} (Defined in the above note), of effectively stable neutrinos (i.e., those with mean lives greater than or equal to the age of the universe). These papers assumed Dirac neutrinos. When necessary, we have generalized the results reported so they apply to $m_{
m tot}$. For other limits, see SZALAY 76, VYSOTSKY 77, BERNSTEIN 81, FREESE 84. SCHRAMM 84, and COWSIK 85.

VALUE (eV)	DOCUMENT ID		TECN
• • • We do not use the	e following data for average	es, flt	s, Ilmits, etc. • • •

 $^{^3\,\}mathrm{BUSKULIC}$ 96S requires the decay length of the heavy lepton to be < 1 cm, limiting the square of the mixing angle $|U_{\ell j}|^2$ to 10^{-10} .

 $^{^4}$ BUSKULIC 96s ilmit for mixing with au. Mass is > 63.6 GeV for mixing with e or μ .

⁵ BUSKULIC 965 limit for mixing with au. Mass is > 55.2 GeV for mixing with e or μ . 6 ABREU 928 limit is for mixing matrix element pprox 1 for coupling to e or μ . Reduced Somewhat for coupling to τ , increased somewhat for smaller mixing matrix element. Replaces ABREU 91F.

⁷ ADRIANI 921 is a search for isosinglet heavy lepton N_ℓ which might be produced from $Z \to \nu_\ell N_\ell$, then decay via a number of different channels. Limits are weaker for decay lengths longer than about 1 m.

ADEVA 90s limits for the heavy neutrino apply if the mixing with the charged leptons satisfies $|U_1j|^2 + |U_2j|^2 + |U_3j|^2 > 6.2 \times 10^{-8}$ at $m_{L^0} = 20$ GeV and $> 5.1 \times 10^{-10}$ for $m_{L0} = 40$ GeV.

⁹ AKRAWY 90L limits valid if coupling strength is greater than a mass-dependent value, e.g., 4.9×10^{-7} at $m_{L^0} = 20$ GeV, 3.5×10^{-8} at 30 GeV, 4×10^{-9} at 40 GeV.

¹⁰ Limits apply for $\ell=e, \mu$, or τ and for V-A decays of Dirac neutrinos. 11 BURCHAT 90 searched for Z decay to unstable L^0 pairs at SLC. It includes the analyses reported in JUNG 90, ABRAMS 89c, and WENDT 87. 12 For 25 $< m_{L^0} < 42.7$ GeV, DECAMP 90F exclude an L^0 for all values of $|U_{\ell f}|^2$.

 $^{^{13}}$ SHAW 89 also excludes the mass region from 8.0 to 27.2 GeV for Dirac L^0 and from 8.1 to 23.6 GeV for Majorana L^0 with equal full-strength couplings to e and μ . SHAW 89 also gives correlated bounds on lepton mixing.

¹⁴ AKERLOF 88 is PEP e^+e^- experiment at $E_{\rm cm}=$ 29 GeV. The L^0 is assumed to decay via V-A to e or μ or τ plus a virtual W.

¹⁵ MISHRA 87 is Fermilab neutrino experiment looking for either dimuon or double vertex events (hence long-lived).

 $^{^{18}}$ FARGION 95 bound is sensitive to assumed ν concentration in the Galaxy. See also KONOPLICH 94. 19 These results assume that neutrinos make up dark matter in the galactic halo. 20 Limits based on annihilations in the sun and are due to an absence of high energy eutrinos detected in underground experiments.

²¹ MORI 92B results assume that neutrinos make up dark matter in the galactic halo. Limits

based on annihilations in earth are also given. ²² REUSSER 91 uses existing $\beta\beta$ detector (see FISHER 89) to search for CDM Dirac

Limits on MASSES of Light Stable Right-Handed ν (with necessarily suppressed interaction strengths)

VALUE (eV)	DOCUMENT	ID.	TECN	COMMENT

Limits on MASSES of Heavy Stable Right-Handed ν (with necessarily suppressed interaction strengths)

<u> </u>					
• • • We do not use the follo	wing data for avera	ages, fits	s, limits,	etc. • • •	
> 10	²⁵ OLIVE	82	COSM	GR/GF <	0.1
>100	²⁵ OLIVE	82	COSM	GR/GF <	0.01

²⁵ These results apply to heavy Majorana neutrinos and are summarized by the equation: $m_{\nu} > 1.2$ GeV (G_F/G_R) . The bound saturates, and if G_R is too small no mass range is allowed.

(C) Searches for neutrinoless double- β decay

LIMITS FROM NEUTRINOLESS $\beta\beta$ DECAY

Revised 1995 by P. Vogel (Caltech).

Limits on an effective Majorana neutrino mass and a leptonnumber violating current admixture can be obtained from lifetime limits on $0\nu\beta\beta$ nuclear decay. The derived quantities are model-dependent, so the half-life measurements are given first. Where possible we list the references for the matrix elements used in the subsequent analysis. Since rates for the more conventional $2\nu\beta\beta$ decay serve to calibrate the theory, results for this process are also given. As an indication of the spread among different ways of evaluating the matrix elements, we show in Fig. 1 some representative examples for the most popular nuclei. For further calculations, see, e.g., Ref. 1

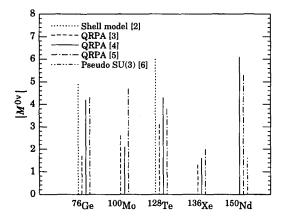

Figure 1: Nuclear matrix elements for $0\nu\beta\beta$ decay calculated by a subset of different methods and different authors for the most popular double-beta decay candidate nuclei. Recalculated from the published half-lives using consistent phase-space factors and $g_A=1.25$. The QRPA [3] value is for $\alpha'=-390$ MeV fm³.

To define the limits on lepton-number violating right-handed current admixtures, we display the relevant part of a phenomenological current-current weak interaction Hamiltonian:

$$\begin{split} H_W = & (G_F/\sqrt{2}) \\ \times & (J_L \cdot j_L^{\dagger} + \kappa J_R \cdot j_L^{\dagger} + \eta J_L \cdot j_R^{\dagger} + \lambda J_R \cdot j_R^{\dagger}) + \text{h.c.} \end{split}$$

where $j_L^\mu = \bar{e}_L \gamma^\mu \nu_{eL}, \ j_R^\mu = \bar{e}_R \gamma^\mu \nu_{eR}$, and J_L^μ and J_R^μ are lefthanded and right-handed hadronic weak currents. Experiments are not sensitive to κ , but quote limits on quantities proportional to η and λ .* In analogy to $\langle m_{\nu} \rangle$ (see Eq. 11 in the "Note on Neutrinos" at the beginning of the Neutrino Particle Listings), the quantities extracted from experiments are $\langle \eta \rangle = \eta \sum U_{1j} V_{1j}$ and $\langle \lambda \rangle = \lambda \sum U_{1j} V_{1j}$, where V_{ij} is a matrix analogous to U_{ij} (see Eq. 2 in the "Note on Neutrinos"), but describing the mixing among right-handed neutrinos. The quantities $\langle \eta \rangle$ and $\langle \lambda \rangle$ therefore vanish for massless or unmixed neutrinos. Also, as in the case of $\langle m_{\nu} \rangle$, cancellations are possible in $\langle \eta \rangle$ and $\langle \lambda \rangle$. The limits on $\langle \eta \rangle$ are of order 10^{-8} while the limits on $\langle \lambda \rangle$ are of order 10^{-6} . The reader is warned that a number of earlier experiments did not distinguish between η and λ . Because of evolving reporting conventions and matrix element calculations, we have not tabulated the admixture parameters for experiments published earlier than 1989.

See the section on Majoron searches for additional limits set by these experiments.

Footnotes and References

- * We have previously used a less accepted but more explicit notation in which $\eta_{RL} \equiv \kappa$, $\eta_{LR} \equiv \eta$, and $\eta_{RR} \equiv \lambda$.

 26 ALSTON-GARNJOST 97 report evidence for $^{2\nu}$ decay of 100 Mo. This decay has been also observed by EJIRI 91, DASSIE 95, and DESILVA 97. 27 BARABASH 97 measure limits for β^+ , EC, and ECEC decay of 92 Mo to the ground and excited states of 92 Ru, respectively. Limits are not competive compared to $\beta^-\beta^$ searches as far as sensitivity to $\langle m_{
u}
angle$ or RHC admixtures is concerned.

28 BAUDIS 97 limit for 0\u03c4 decay of enriched 76 Ge using Ge calorimeters supersedes GUENTHER 97.

GUENT HER 97. 29 DESILVA 97 result for 2ν decay of 100 Mo is in agreement with ALSTON-GARNJOST 97 and DASSIE 95. This measurement has the smallest errors.

30 DESILVA 97 result for 2 ν decay of 150 Nd is in marginal agreement with ARTEMEV 93.

It has smaller errors.

31 DESILVA 97 do not explain whether their efficiency for 0 ν decay of ¹⁵⁰Nd was calculated under the assumption of a $\langle m_{\nu} \rangle$, $\langle \lambda \rangle$, or $\langle \eta \rangle$ driven decay. ³² GUENTHER 97 half-life for the 2 ν decay of ⁷⁶Ge is not in good agreement with the

previous measurements of BALYSH 94, AVIGNONE 91, and MILEY 90.

 33 ALESSANDRELLO 96B experiment can distinguish the 0
u and 2
u modes; it shows that the geochemical observation of ¹³⁰Te decay (BERNATOWICZ 92, KIRSTEN 83,

TAKAOKA 96) is dominanted by the 2 ν decay. Supersedes ALESSANDRELLO 94.

34 ARNOLD 96 measure the 2 ν decay of 116Cd. This result is in agreement with EJIRI 95, but has smaller errors. Supersedes ARNOLD 95.

 35 BALYSH 96 measure the $^{2
u}$ decay of 48 Ca, using a passive source of enriched 48 Ca in

36 EJIRI 96 use energy and angular correlations of the 2 β -rays in efficiency estimate to give limits for the 0ν decay modes associated with $\langle m_{\nu} \rangle$, $\langle \lambda \rangle$, and $\langle \eta \rangle$, respectively. Enriched $^{100}\mathrm{Mo}$ source is used in tracking calorimeter. These are the best limits for

100 Mo. Limit is more stringent than ALSTON-GARNJOST 97.

37 TAKAOKA 96 measure the geochemical half-life of ¹³⁰Te. Their value is in disagreemnt with the quoted values of BERNATOWICZ 92 and KIRSTEN 83; but agrees with several

other unquoted determinations, e.g., MANUEL 91.

38 BARABASH 95 cannot distinguish 0» and 2ν, but it is inferred indirectly that the 0» mode accounts for less than 0.026% of their event sample. They also note that their result disagrees with the previous experiment by the NEMO group (BLUM 92).

 39 BELLOTTI 87 searches for γ rays for 2^+ state decays in corresponding Xe isotopes. Limit for 130 Te case argues for dominant $0^+ \rightarrow 0^+$ transition in known decay of this

40 GEORGADZE 95 result for this and other modes are also give in DANEVICH 95. Result

for 2ν decay omitted because of authors' caveats. ⁴¹ In PIEPKE 94, the studied excited states of 116 Sn have energies above the ground state of 1.2935 MeV for the 2^+ state, 1.7568 MeV for the 0^+_1 state, and 2.0273 for the 0^+_2

state.
42 Limit In the case of a transition induced by a Majorana mass.

43 Limit for lepton-number violating right-handed current-induced (RHC) decay.

44 BERNATOWICZ 92 finds 128 Te/130 Te activity ratio from slope of 128 Xe/132 Xe vs 130Xe/132Xe ratios during extraction, and normalizes to lead-dated ages for the ¹³⁰Te lifetime. The authors state that their results imply that "(a) the double beta decay of ¹²⁸Te has been firmly established and its half-life has been determined ... without any ambiguity due to trapped Xe interferences... (b) Theoretical calculations ... underestimate the [long half-lives of ^{128}Te ^{130}Te] by 1 or 2 orders of magnitude, pointing to a real supression in the $^{2\nu}$ decay rate of these isotopes. (c) Despite [this], most $^{69}\text{-models}$

predict a ratio of 2 ν decay widths ... in fair agreement with observation." Further details of the experiment are given in BERNATOWICZ 93. Our listed half-life has been revised downward from the published value by the authors, on the basis of reevaluated cosmic-ray 128Xe production corrections.

45 AVIGNONE 91 reports confirmation of the MILEY 90 and VASENKO 90 observations of $2\nu\beta\beta$ decay of 76 Ge. Error is 2σ .

 46 BELLOTTI 91 uses difference between natural and enriched 136 Xe runs to obtain etaeta0ulimits, leading to "less stringent, but safer limits."

limits, leading to "less stringent, but safer limits."

47 TURKEVICH 91 observes activity in old U sample. The authors compare their results with theoretical calculations. They state "Using the phase-space factors of Boehm and Vogel (BOEHM 87) leads to matrix element values for the ²³⁸U transition in the same range as deduced for ¹³⁰Te and ⁷⁶Ge. On the other hand, the latest theoretical estimates (STAUDT 90) give an upper limit that is 10 times lower. This large discrepancy implies either a defect in the calculations or the presence of a faster path than the standard wo-neutrino mode in this case." See BOEHM 87 and STAUDT 90.

48 MILEY NO claims only "surgestive evidence" for the decay. Error is 2a.

two-neutrino mode in this case." See BUEHM 87 and STAUDI 30.

48 MILEY 90 claims only "suggestive evidence" for the decay. Error is 2\sigma.

49 KIRSTEN 83 reports "2\sigma" error. References are given to earlier determinations of the 130 Te lifetime.

$\langle m_{ u} \rangle$, The Effective Weighted Sum of Majorana Neutrino Masses Contributing to Neutrinoless Double β Decay

 $\langle m_{\nu} \rangle = |\Sigma| U_{1}^{2} |m_{\nu_{i}}|$, where the sum goes from 1 to n and where n= number of neutrino generations, and ν_j is a Majorana neutrino. Note that U_{1j}^2 , not $|U_{1j}|^2$, occurs in the sum. The possibility of cancellations has been stressed. In the following Listings, only best or comparable limits or lifetimes for each isotope are reported.

⁵⁰ ALSTON-GARNJOST 97 obtain the limit for $\langle m_{\nu} \rangle$ using the matrix elements of ENGEL 88. The limit supersedes ALSTON-GARNJOST 93.

51 BAUDIS 97 limit for $\langle m_{
u}
angle$ is based on the matrix elements of STAUDT 90. This is the most stringent bound on $\langle m_{\nu} \rangle.$ It supersedes the limit of GUENTHER 97.

 52 EJIRI 96 obtain the limit for $\langle m_{
u}
angle$ using the matrix elements of TOMODA 91.

53 DANEVICH 95 is identical to GEORGADZE 95.

55 DANEVICH 99 is identical to GEORGADZE 99.

45 VUILLEUMIER 93 mass range from parameter range in the Caltech calculations (ENGEL 88). On the basis of these calculations, the BALYSH 92 mass range would be <2.2-4.4 eV.

55 BERNATOWICZ 92 finds these majoron mass limits assuming that the measured geochemical decay width is a limit on the 0ν decay width. The range is the range found using matrix elements from HAXTON 84, TOMODA 87, and SUHONEN 91. Further details of the experiment are given in BERNATOWICZ 93.

56 ELLIOTT 92 uses the matrix elements of HAXTON 84.

Limits on Lepton-Number Violating (V+A) Current Admixture

For reasons given in the discussion at the beginning of this section, we list only results from 1989 and later. $\langle \lambda \rangle = \lambda \sum U_{IJ} V_{IJ}$ and $\langle \eta \rangle = \eta \sum U_{IJ} V_{IJ}$, where the sum is over the number of neutrino generations. This sum vanishes for massless or unmixed neutrinos. In the following Listings, only best or comparable limits or lifetimes for each isotope are reported.

 62 BRITTON 92B is from a search for additional peaks in the e^+ spectrum from $\pi^+
ightarrow$ $e^+ \nu_e$ decay at TRIUMF. See also BRITTON 92. 63 BRYMAN 838 obtain upper limits from both direct peak search and analysis of B($\pi \to$

 $e\nu$)/B($\pi \to \mu\nu$). Latter limits are not listed, except for this entry (i.e. — we list the most stringent limits for given mass). ⁶⁴ Analysis of $(\pi^+ \to e^+\nu_e)/(\pi^+ \to \mu^+\nu_\mu)$ and $(K^+ \to e^+\nu_e)/(K^+ \to \mu^+\nu_\mu)$

decay ratios. 65 Analysis of $(K^+ \rightarrow e^+ \nu_e)$ spectrum.

Kink search in nuclear β decay

High-sensitivity follow-up experiments show that indications for a neutrino with mass 17 keV (Simpson, Hime, and others) were not valid. Accordingly, we no longer list the experiments by these authors and some others which made positive claims of 17 keV neutrino emission. Complete listings are given in the 1994 edition (Physical Review **D80** 1173 (1994)). Limits on $|U_{1j}|^2$ as a function of $m_{\nu j}$. See WIETFELDT 96 for a comprehensive review

 $^{66}\,\mathrm{ln}$ the beta spectrum from tritium β decay nonvanishing or mixed $m_{\overline{\nu}_1}$ state in the mass region 0.01–4 keV. For $m_{
u_{ar{j}}}$ <1 keV, their upper limit on $|U_{ar{j}}|^2$ becomes less

⁶⁷BERMAN 93 uses an iron-free intermediate-image magnetic spectrometer to measure 35 S β decay over a large portion of the spectrum. Paper reports (0.01 \pm 0.15)%; above result revised by author on basis of analysis refinements.

68 KALBFLEISCH 93 extends the 17 keV neutrino search of BAHRAN 92, using an improved proportional chamber to which a small amount of $^3\mathrm{H}$ is added. Systematics are significantly reduced, allowing for an improved upper limit. The authors give a 99% confidence limit on $|u_{1j}|^2$ as a function of m_{ν_j} in the range from 13.5 keV to 17.5 keV. Typical upper limits are listed above. They report that this experiment in combination with BAHRAN 92 gives an upper limit of 2.4×10^{-3} at the 99% CL. See also the related papers BAHRAN 93, BAHRAN 93B, and BAHRAN 95 on theoretical aspects of beta spectra and fitting methods for heavy neutrinos.

⁶⁹MORTARA 93 limit is from study using a high-resolution solid-state detector with a superconducting solenoid. The authors note that "The sensitivity to neutrino mass is verified by measurement with a mixed source of $^{35}\mathrm{S}$ and $^{14}\mathrm{C}$, which artificially produces a distortion in the beta spectrum similar to that expected from the massive neutrino."

 $^{70}\,\text{OHSHIMA}$ 93 is the full data analysis from this experiment. The above limit on the mixing strength for a 17 keV neutrino is obtained from the measurement $|U_{1j}|^2 =$ $(-0.11\pm0.33\pm0.30)\times10^{-3}$ by taking zero as the best estimate and ignoring physical boundaries; see discussion in HOLZSCHUH 92B for a comparison of methods. An earlier report of this experiment was given in KAWAKAMI 92.

71 WIETFELDT 93 is an extension of the NORMAN 91 experiment. However, whereas NORMAN 91 reported indications for the emission of a neutrino with mass $m_{\nu j}=$ 21 ± 2 keV and coupling strength = 0.0085 \pm 0.0045, the present experiment states that "We find no evidence for emission of a neutrino in the mass range 5–25 keV. In particular, a 17 keV neutrino with $\sin^2\theta \left(|U_{1j}|^2 \text{ in our notation}\right) = 0.008$ is excluded at the 7σ level." The listed limits can be obtained from the paper's Fig. 4. The authors acknowledge that this conclusion contradicts the one reported in NORMAN 91, based on a smaller data sample. In further tests, WIETFELDT 95 have shown that "the observed distortion was most likely caused by systematic effects... A new measurement with a smaller data sample shows no sign of this distortion."

72 CHEN 92 is a continuation and improvement of the Boehm et al. Caltech iron-free magnetic spectrometer experiment searching for emission of massive neutrinos in 35S decay (MARKEY 85). The upper limit on $|U_{1j}|^2$ for $m_{\nu_i}=17$ keV comes from the measurement $|U_{1j}|^2 = (-0.5 \pm 1.4) \times 10^{-3}$. The authors state that their results "rule out, at the 6σ level, a 17 keV neutrino admixed at 0.85% (i.e. with $|U_{1j}|^2$ 0.85×10^{-2} ," the level claimed by Hime and Jelly in HIME 91. They also state that "our data show no evidence for a heavy neutrino with a mass between 12 and 22 keV" with substantial admixture in the weak admixture in the weak eigenstate ν_{e} ; see their Fig. 4 for a graphical set of measured values of $|U_{1,i}|^2$ for various hypothetical values of

73 KAWAKAMI 92 experiment final results are given in OHSHIMA 93. The upper limit is improved to 0.73×10^{-3} , based on $|U_{1j}|^2 = (-0.11 \pm 0.33 \pm 0.30) \times 10^{-3}$. Ohshima notes that the result is 22σ away from the value $|U_{1j}|^2=1\%$.

 74 BORGE 86 results originally presented as evidence against the SIMPSON 85 claim of a 17 keV antineutrino emitted with $|U_{1J}|^2=0.03$ in $^3\mathrm{H}$ decay.

75 This limit was taken from the figure 3 of APALIKOV 85; the text gives a more restrictive limit of 1.7×10^{-3} at CL = 90%.

76 SCHRECKENBACH 83 is a combined measurement of the β^+ and β^- spectrum.

77 Application of kink search test to tritium β decay Kurie plot.

78 SHROCK 80 was a retroactive analysis of data on several superallowed eta decays to search for kinks in the Kurie plot.

79 Application of test to search for kinks in β decay Kurie plots.

(E) Solar ν Experiments

SOLAR NEUTRINOS

Revised February 1998 by K. Nakamura (KEK, High Energy Accelerator Research Organization, Japan).

The Sun is a main-sequence star at a stage of stable hydrogen burning. It produces an intense flux of electron neutrinos as a consequence of nuclear fusion reactions which generate solar energy, and whose combined effect is

$$4p + 2e^- \rightarrow {}^4\text{He} + 2\nu_e + 26.73 \text{ MeV} - E_{\nu}$$
, (1)

where E_{ν} represents the energy taken away by neutrinos, with an average value being $\langle E_{\nu} \rangle \sim 0.6$ MeV. Each neutrinoproducing reaction, the resulting flux, and contributions to the event rates in chlorine and gallium solar-neutrino experiments predicted by the recent Bahcall and Pinsonneault standard solar model (SSM) calculation [1] are listed in Table 1. This SSM is regarded as the best with helium and heavy-element diffusion. Figure 1 shows the energy spectra of solar neutrinos from these reactions quoted from the SSM calculation by Bahcall and Ulrich [2]. Recently, the SSM has been shown to predict accurately the helioseismological sound velocities with a precision of 0.1% rms throughout essentially the entire Sun, greatly strengthening the confidence in the solar model [3].

Table 1: Neutrino-producing reactions in the Sun (the first column) and their abbreviations (second column). The neutrino fluxes and event rates in chlorine and gallium solar-neutrino expreiments predicted by Bahcall and Pinsonneault [1] are listed in the third, fourth, and fifth columns respectively.

^{* 1} SNU (Solar Neutrino Unit) = 10^{-36} captures per atom per second.

Observation of solar neutrinos directly addresses the SSM and, more generally, the theory of stellar structure and evolution which is the basis of the SSM. The Sun as a well-defined neutrino source also provides extremely important opportunities to investigate nontrivial neutrino properties such as nonzero mass and mixing, because of the wide range of matter density and the very long distance from the Sun to the Earth. In fact, the currently available solar-neutrino data seem to require such neutrino properties, if one tries to understand them consistently.

So far, four solar-neutrino experiments published the results. In addition, a new solar-neutrino experiment (Super-Kamiokande) started observation in 1996. Three of them are radiochemical experiments using ³⁷Cl (Homestake in USA) or ⁷¹Ga (GALLEX at Gran Sasso in Italy and SAGE at Baksan in Russia) to capture neutrinos: $^{37}{\rm Cl}~\nu_e \rightarrow ^{37}{\rm Ar}~e^-$ (threshold 814 keV) or $^{71}{\rm Ga}~\nu_e \rightarrow ^{71}{\rm Ge}~e^-$ (threshold 233 keV). The produced ³⁷Ar and ⁷¹Ge are both radioactive nuclei, with half lives $(\tau_{1/2})$ of 34.8 days and 11.43 days, respectively. After an exposure of the detector for two to three times $\tau_{1/2}$, the reaction products are extracted and introduced into a low-background proportional counter, and are counted for a sufficiently long period to determine the exponentially decaying signal and a

⁹⁶ VILAIN 95C is a search for the decays of heavy isosinglet neutrinos produced by neutral current neutrino interactions. Limits were quoted for masses in the range from 0.3 to 24 GeV. The best limit is listed above.

⁹⁷ BURCHAT 90 includes the analyses reported in JUNG 90, ABRAMS 89c, and WENDT 87. 98 KOPEIKIN 90 find no m_{ν_j} in the interval 1–6.3 MeV at 90%CL for maximal mixing.

⁹⁹ See also limits on $|U_{3j}|$ from WENDT 87.

 $^{^{100}}$ COOPER-SARKAR 85 also give limits based on model-dependent assumptions for ν_{τ} flux. We do not list these. Note that for this bound to be nontrivial, J is not equal to 3, i.e. ν_{j} cannot be the dominant mass eigenstate in ν_{τ} since $m_{\nu_{3}}$ <70 MeV (ALBRECHT 85i). Also, of course, J is not equal to 1 or 2, so a fourth generation would be required for this bound to be nontrivial.

¹⁰² BURCHAT 90 includes the analyses reported in JUNG 90, ABRAMS 89C, and WENDT 87.

Massive Neutrinos and Lepton Mixing

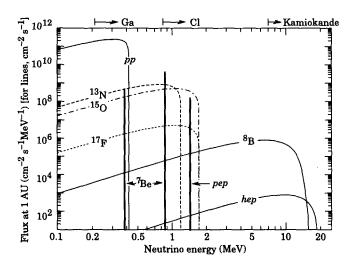

Figure 1: The solar neutrino spectrum predicted by the standard solar model. The neutrino fluxes from continuum sources are given in units of number cm⁻²s⁻¹MeV⁻¹ at one astronomical unit, and the line fluxes are given in number cm⁻²s⁻¹. Spectra for the *pp* chain are shown by solid lines, and those for the CNO chain by dotted or dashed lines. (Courtesy of J.N. Bahcall, 1995.)

constant background. In the chlorine experiment, the dominant contribution comes from ⁸B neutrinos, but ⁷Be, *pep*, ¹³N, and ¹⁵O neutrinos also contribute. At present, the most abundant *pp* neutrinos can be detected only in gallium experiments. Even so, almost half of the capture rate in the gallium experiments is due to other solar neutrinos.

The other experiments are real-time experiments utilizing νe scattering in a large water-Čerenkov detector (Kamiokande and Super-Kamiokande in Japan). These experiments take advantage of the directional correlation between the incoming neutrino and the recoil electron. This feature greatly helps the clear separation of the solar-neutrino signal from the background. Due to the high thresholds (7 MeV in Kamiokande and 6.5 MeV at present in Super-Kamiokande) the experiments observe pure $^8{\rm B}$ solar neutrinos (hep neutrinos contribute negligibly).

Solar neutrinos were first observed in the Homestake chlorine experiment in the late 1960's. From the very beginning, it was recognized that the observed capture rate was significantly smaller than the SSM prediction provided nothing happens to the electron neutrinos after they are created in the solar interior. This deficit has been called "the solar-neutrino problem."

The Kamiokande-II Collaboration started observing the 8 B solar neutrinos at the beginning of 1987. Because of the strong directional correlation of νe scattering, this result gave the

first direct evidence that the Sun emits neutrinos (no directional information is available in radiochemical solar-neutrino experiments.) The observed solar-neutrino flux was also significantly less than the SSM prediction. In addition, Kamiokande-II obtained the energy spectrum of recoil electrons and the fluxes separately measured in the day time and nighttime. The Kamiokande-II experiment came to an end at the beginning of 1995, and a 50-kton second-generation solar-neutrino detector Super-Kamiokande started observation in April, 1996.

GALLEX presented the first evidence of pp solar-neutrino observation in 1992. Here also, the observed capture rate is significantly less than the SSM prediction. SAGE, after the initial confusion which is ascribed to statistics by the group, observed a similar capture rate to that of GALLEX. Both GALLEX and SAGE groups tested the overall detector response with intense man-made 51 Cr neutrino sources, and observed good agreement between the measured 71 Ge production rate and that predicted from the source activity, demonstrating the reliability of these experiments.

The most recent published results on the average capture rates or flux from these experiments are listed in Table 2 and compared to the results from SSM calculations which are taken from "Lepton Particle Listings (E) Solar ν Experiments" in this edition of "Review of Particle Physics." In these calculations, BAHCALL 95B [1] and DAR 96 [9] take into account helium and heavy-element diffusion, but other calculations do not. SSM calculations give essentially the same results for the same input parameters and physics. The BAHCALL 95B [1] model and the TURCK-CHIEZE 93B [10] model differ primarily in that BAHCALL 95B [1] includes element diffusion. DAR 96 [9] model differs significantly from the BAHCALL 95B [1] model mostly due to the use of nonstandard reaction rates, the different treatments of diffusion and the equation of state.

There was a controversy whether the ³⁷Cl capture rate showed possible time variation, anticorrelated with the sunspot numbers which represent the 11-year solar-activity cycle. However, Walther recently argued that the claimed significant anticorrelation is due to a statistical fallacy [7]. Also, eight years of Kamiokande-II solar-neutrino observations covering an entire period of solar cycle 22 [8] does not show evidence for a statistically significant correlation or anticorrelation between the solar-neutrino flux and sunspot number.

All results from the present solar-neutrino experiments indicate significantly less flux than expected from the SSM calculations except DAR 96 [9]. The DAR 96 [9] model predicts the ⁸B solar-neutrino flux which is consistent with the Kamiokande-II result, but even this model predicts ³⁷Cl and ⁷¹Ga capture rates significantly larger than the Homestake, GALLEX, and SAGE results. Is there any possible consistent explanation of all the results of solar-neutrino observations in the framework of the standard solar model? This is difficult because the Homestake result and the Kamiokande result, taken at face value, are mutually inconsistent if one assumes standard neutrino spectra. That is, with the reduction factor of the ⁸B solar-neutrino flux

Table 2: Recent results from the four solar-neutrino experiments and a comparison with theoretical solar-model predictions. Solar model calculations are also presented. The evolution of these results over the years gives some feeling for their robustness as the models have become more sophisticated and complete.

^{* 1} SNU (Solar Neutrino Unit) = 10^{-36} captures per atom per second.

as determined from the Kamiokande result, the Homestake ³⁷Cl capture rate would be oversaturated, and there would be no room to accommodate the ⁷Be solar neutrinos. This makes astrophysical solutions untenable because ⁸B nuclei are produced from ⁷Be nuclei in the Sun.

Several authors made more elaborate analyses using the constraint of observed solar luminosity, and found (see for example, Refs. 18–20)

- that both the comparison of the Kamiokande and gallium results and the comparison of the gallium and chlorine results also indicate strong suppression of the ⁷Be solar-neutrino flux, and
- that not only the SSM but also nonstandard solar models are incompatible with the observed data.

In view of the above situation, it is attractive to invoke nontrivial neutrino properties. Neutrino oscillation in matter (MSW mechanism) is particularly attractive in explaining all the experimental data on the average solar-neutrino flux consistently, without any a priori assumptions or fine tuning. Several authors made extensive MSW analyses using all the existing data and ended up with similar results. For example, Hata and Langacker [19] analyzed the solar-neutrino data as of 1996 in terms of two-flavor oscillations, including the preliminary result from Super-Kamiokande [21]

on the average ⁸B solar-neutrino flux which is consistent with the Kamiokande-II result. They obtained viable solutions for the BAHCALL 95B [1] SSM: the small-mixing solution $(\Delta m^2 \sim 5 \times 10^{-6} \text{ eV}^2 \text{ and } \sin^2 2\theta \sim 8 \times 10^{-3})$ and the large-mixing solution $(\Delta m^2 \sim 1.6 \times 10^{-5} \text{ eV}^2 \text{ and } \sin^2 2\theta \sim 0.6)$. Vacuum oscillations also provide solutions $(\Delta m^2 = (5-8) \times 10^{-11} \text{ eV}^2 \text{ and } \sin^2 2\theta = 0.65 - 1)$.

Assuming that the solution to the solar-neutrino problem be provided by some nontrivial neutrino properties, how can one discriminate various scenarios? The measurements of energy spectrum of the solar neutrinos and the day-night flux difference, and the measurement of solar-neutrino flux by utilizing neutral-current reactions are key issues. The MSW small-mixing solution causes the energy-spectrum distortion, while the MSW large-angle solution causes the day-night flux difference. If the flux measured by neutral-current reactions is consistent with the SSM prediction, and larger than that measured by charged-current reactions, it is a clear indication of neutrino oscillations.

Two high-statistics solar-neutrino experiments, Sudbury Neutrino Observatory (SNO) and Super-Kamiokande are expected to provide such results within a few years. Super-Kamiokande is sensitive to the solar-neutrino spectrum through measurement of recoil electron energy. SNO, which is expected to be completed in 1998, will use 1,000 tons of heavy water (D₂O) to measure solar neutrinos through both inverse beta decay $(\nu_e d \rightarrow e^- pp)$ and neutral current interactions $(\nu_x d \rightarrow \nu_x pn)$. In addition, νe scattering events will also be measured. The Borexino experiment with 300 tons of ultrapure liquid scintillator is approved for the Gran Sasso. The primary purpose of this experiment is the measurement of the ⁷Be solar neutrino flux, whose possible deficit is now a key question, by lowering the detection threshold for the recoil electrons to 250 keV. Also, the vacuum-oscillations cause seasonal variation of the ⁷Be solar neutrino flux. It is hoped that these new experiments will finally provide the key to solving the different solar-neutrino problems raised by the first-generation experiments.

73+18+5 SNU	106 ABDURASHI	94	SAGE	71 Ga \rightarrow 71 Ge			
2.33 ± 0.25 SNU	107 DAVIS	89	HOME	³⁷ Cl radiochemical			

104 FUKUDA 96 results are for a total of 2079 live days with Kamiokandell and Ill from January 1987 through February 1995, covering the entire solar cycle 22, with threshold $\rm E_e > 9.3$ MeV (first 449 days), > 7.5 MeV (middle 794 days), and > 7.0 MeV (last 836 days). These results update the HIRATA 90 result for the average $^8\rm B$ solar-neutrino flux and HIRATA 91 result for the day-night variation in the $^8\rm B$ solar-neutrino flux. The total data sample was also analyzed for short-term variations: within experimental errors, no strong correlation of the solar-neutrino flux with the sunspot numbers was found.

105 HAMPEL 96 reports the combined result for GALLEX I+II+III (53 runs in total), which updates the ANSELMANN 958 result. The GALLEX III result (14 runs) is 53.9 ± 10.6 ± 3.1 SNU, which is "15.8 SNU below but statistically compatible with the new combined result." The total run data, covering the period 14 May 1991 through 4 October 1995, are consistent with a ⁷¹Ge production rate constant in time, but "the confidence with which some kind of periodic or sporadic variability may be excluded has decreased as a result of the statistical departure of GALLEX III." HAMPEL 96 also reports the second calibration run using a strong ⁵¹Cr source. The result combined with the ANSELMANN 95 data was found to be 92 ± 8 for the (measured)/(expected) Cr induced ⁷¹Ge rate.

106 ABDURASHITOV 94 result is for a total of 15 runs from January 1990 through May 1992, using 30 tons of metallic gallium for the first 7 runs, increased to 57 tons for the rest of 8 runs. The first 5 runs in 1990 yielded 40+31+5 SNU which updates the ABAZOV 918 result

ABAZOV 918 result.

107 DAVIS 89 is the average from the ³⁷CL experiment at the Homestake Mine (HOME) from 1970–1988. Earlier averages are given in the references therein.

(F) Astrophysical neutrino observations

Neutrinos and antineutrinos produced in the atmosphere induce μ -like and e-like events in underground detectors. The ratio of the numbers of the two kinds of events is defined as μ/e . It has the advantage that that systematic effects, such as flux uncertainty, tend to cancel, for both experimental and theoretical values of the ratio. The "ratio of the ratios" of experimental to theoretical μ/e , $R(\mu/e)$, or that of experimental to theoretical μ/t total, $R(\mu/t)$ total = $\mu+e$, is reported below. If the actual value is not unity, the value obtained in a given experiment may depend on the experimental conditions.

$R(\mu/e) = (Measured Ratio \mu/e) / (Expected Ratio \mu/e)$

0.0.	113 RECKER ST	928 IMR	Water Cerenkov

 108 ALLISON 97 result is based on an exposure of 1.52 kton yr. ALLISON 97 also studied the background due to interaction of neutrons or photons produced by muon interactions in the rock surrounding the detector. This background is shown not to produce the low values of $R(\mu/e)$.

109 FUKUDA 968 studied neutron background in the atmospheric neutrino sample observed in the Kamlokande detector. No evidence for the background contamination was found.

110 DAUM 95 results are based on an exposure of 2.0 kton yr which includes the data used by BERGER 908. This ratio is for the contained and semicontained events. DAUM 95 also report $R(\mu/e) = 0.99 \pm 0.13 \pm 0.08$ for the total neutrino induced data sample which includes upward going stopping muons and horizontal muons in addition to the contained and semicontained events.

111 FUKUDA 94 result is based on an exposure of 7.7 kton yr and updates the HIRATA 92

111 FUKUDA 94 result is based on an exposure of 7.7 kton yr and updates the HIRATA 92 result. The analyzed data sample consists of fully contained e-like events with 0.1 $< p_e < 1.33 \text{ GeV/}c$ and fully-contained μ -like events with 0.2 $< p_{\mu} < 1.5 \text{ GeV/}c$.

112 FUKUDA 94 analyzed the data sample consisting of fully contained events with visible energy > 1.33 GeV and partially contained μ-like events.

113 BECKER-SZENDY 928 reports the fraction of nonshowering events (mostly muons from atomospheric neutrinos) as $0.36 \pm 0.02 \pm 0.02$, as compared with expected fraction $0.51 \pm 0.01 \pm 0.05$. After cutting the energy range to the Kamiokande limits, BEIER 92 finds $R(\mu/e)$ very close to the Kamiokande value.

$R(\nu_{\mu}) = (Measured Flux of \nu_{\mu}) / (Expected Flux of \nu_{\mu})$

0.95 ± 0.22	117 BOLIEV	81		Baksan
0.62 ± 0.17	CROUCH	78		Case Western/UCI

 114 AHLEN 95 result is for all nadir angles. The lower cutoff on the muon energy is 1 GeV. The errors are statistical / systematic. The Monte Carlo flux error is ± 0.12 .

115 CASPER 91 correlates showering/nonshowering signature of single-ring events with parent atmospheric-neutrino flavor. They find nonshowering ($\approx \nu_{\mu}$ induced) fraction is $0.41 \pm 0.03 \pm 0.02$, as compared with expected 0.51 ± 0.05 (syst).

116 AGLIETTA 89 finds no evidence for any anomaly in the neutrino flux. They define $\rho=$ (measured number of ν_e 's)/(measured number of ν_μ 's). They report ρ (measured)= ρ (expected) = $0.96^{+}0.32^{-}0.28^{+}$

117 From this data BOLIEV 81 obtain the limit $\Delta(m^2) \le 6 \times 10^{-3} \ {\rm eV^2}$ for maximal mixing, $\nu_\mu \not\to \nu_\mu$ type oscillation.

$R(\mu/total) = (Measured Ratio \mu/total) / (Expected Ratio \mu/total)$

					C.

- 149 ACHKAR 95 bound is from data for L=15, 40, and 95 m distance from the Bugey reactor. 150 APOLLONIO 98 search for neutrino oscillations at 1.1 km fixed distance from Chooz
- 151 GREENWOOD 96 search for neutrino oscillations at 18 m and 24 m from the reactor at Savannah River by observing $\overline{v}_e p \to e^+ n$ in a Gd loaded scintillator target. Their region of sensitivity in $\Delta(m^2)$ and $\sin^2 2\theta$ is already excluded by ACHKAR 95.
- 152 The VYRODOV 95 bound is from data for L=15 m distance from the Bugey-5 reactor.
- 153 The VIDYAKIN 94 bound is from data for L=57.0 m, 57.6 m, and 231.4 m from three reactors in the Krasnoyark Reactor complex.
- 154 Several different methods of data analysis are used in AFONIN 88. We quote the most stringent limits. Different upper limits on $\sin^2 2\theta$ apply at intermediate values of $\Delta(m^2)$. Supersedes AFONIN 87, AFONIN 85, and BELENKII 83.
- 155 VIDYAKIN 87 bound is for L = 32.8 and 92.3 m distance from two reactors.

 156 This bound is from data for L = 37.9 m, 45.9 m, and 64.7 m distance from Gosgen reactor. 157 ZACEK 85 gives two sets of bounds depending on what assumptions are used in the data analysis. The bounds in figure 3(a) of ZACEK 85 are progressively poorer for large $\Delta(m^2)$ whereas those of figure 3(b) approach a constant. We list the latter. Both sets of bounds use combination of data from 37.9, 45.9, and 64.7m distance from reactor. ZACEK 85 states "Our experiment excludes this area (the oscillation parameter region allowed by the Bugey data, CAVAIGNAC 84) almost completely, thus disproving the indications of neutrino oscillations of CAVAIGNAC 84 with a high degree of confidence."
- 158 This bound comes from a combination of the VUILLEUMIER 82 data at distance 37.9m from Gosgen reactor and new data at 45.9m.

 159 USHIDA 86C published result is $\sin^2\!2 heta < 0.12$. The quoted result is corrected for a numerical mistake incurred in calculating the expected number of ν_e CC events, normalized to the total number of neutrino interactions (3886) rather than to the total number of u_{μ} CC events (1870).

170 FREEDMAN 93 is a search at LAMPF for $\overline{\nu}_e$ generated from any of the three neutrino types ν_μ , $\overline{\nu}_\mu$, and ν_e which come from the beam stop. The $\overline{\nu}_e$'s would be detected by the reaction $v_e p \rightarrow e^+ n$. FREEDMAN 93 replaces DURKIN 88.

 171 ATHANASSOPOULOS 96 is a search for $\overline{
u}_e$ 30 m from LAMPF beam stop. Neutrinos originate mainly from π^+ decay at rest. $\overline{\nu}_e$ could come from either $\overline{\nu}_\mu \to \overline{\nu}_e$ or $\nu_e \to \overline{\nu}_e$; our entry assumes the first interpretation. They are detected through $\overline{\nu}_e p \to 0$ e⁺n (20 MeV <E_{e+} <60 MeV) in delayed coincidence with $np \rightarrow d\gamma$. Authors observe 51 \pm 20 \pm 8 total excess events over an estimated background 12.5 \pm 2.9. ATHANASSOPOULOS 96B is a shorter version of this paper.

ATHANASSOPOULOS 968 is a shorter version of this paper.

172 ATHANASSOPOULOS 95 error corresponds to the 1.6 σ band in the plot. The expected background is 2.7 ± 0.4 events. Corresponds to an oscillation probability of $(0.34 + 0.20 \pm 0.07)\%$. For a different interpretation, see HILL 95. Replaced by ATHANASSOPOULOS 96.

173 HILL 95 is a report by one member of the LSND Collaboration, reporting a different conclusion from the analysis of the data of this experiment (see ATHANASSOPOULOS 95). Contrary to the rest of the LSND Collaboration, Hill finds no evidence for the neutrino oscillation.

oscillation $\overline{\nu}_{\mu} \rightarrow \ \overline{\nu}_{e}$ and obtains only upper limits.

¹⁷⁴ In reaction $\vec{\nu}_e p \rightarrow e^+ n$.

$\sin^2(2\theta)$ for "Large" $\Delta(m^2)$

 196 BAHCALL 95 analyzed the GALLEX 51 Cr calibration source experiment (ANSELMANN 95). They also gave a 95% CL limit of $<0.19\ eV^2.$

197 BORISOV 96 exclusion curve extrapolated to obtain this value; however, it does not have the right curvature in this region.

$\sin^2(2\theta)$ for "Large" $\Delta(m^2)$

Quark Particle Listings

Quarks

independent of the renormalization scheme used. It is known that the on-shell quark propagator has no infrared divergences in perturbation theory [1], so this provides a perturbative definition of the quark mass. The pole mass cannot be used to arbitrarily high accuracy because of nonperturbative infrared effects in QCD. The full quark propagator has no pole because the quarks are confined, so that the pole mass cannot be defined outside of perturbation theory.

The $\overline{\rm MS}$ running mass $\overline{m}(\mu)$ is defined by regulating the QCD theory using dimensional regularization, and subtracting the divergences using the modified minimal subtraction scheme. The $\overline{\rm MS}$ scheme is particularly convenient for Feynman diagram computations, and is the most commonly used subtraction scheme.

The Georgi-Politzer mass \widehat{m} is defined using the momentum space subtraction scheme at the spacelike point $-p^2 = \widehat{m}^2$ [2]. A generalization of the Georgi-Politzer mass that is often used in computations involving QCD sum rules [3] is $\widehat{m}(\xi)$, defined at the subtraction point $p^2 = -(\xi+1)m_P^2$. QCD sum rules are discussed in more detail in the next section on light quark masses.

Lattice gauge theory calculations can be used to obtain heavy quark masses from ψ and Υ spectroscopy. The quark masses are obtained by comparing a nonperturbative computation of the meson spectrum with the experimental data. The lattice quark mass values can then be converted into quark mass values in the continuum QCD Lagrangian Eq. (1) using lattice perturbation theory at a scale given by the inverse lattice spacing. A recent computation determines the *b*-quark pole mass to be 5.0 ± 0.2 GeV, and the $\overline{\rm MS}$ mass to be 4.0 ± 0.1 GeV [4].

Potential model calculations of the hadron spectrum also involve the heavy quark mass. There is no way to relate the quark mass as defined in a potential model to the quark mass parameter of the QCD Lagrangian, or to the pole mass. Even in the heavy quark limit, the two masses can differ by nonperturbative effects of order $\Lambda_{\rm QCD}$. There is also no reason why the potential model quark mass should be independent of the particular form of the potential used.

Recent work on the heavy quark effective theory [5-9] has provided a definition of the quark mass for a heavy quark that is valid when one includes nonperturbative effects and will be called the HQET mass m_Q . The HQET mass is particularly useful in the analysis of the $1/m_Q$ corrections in HQET. The HQET mass agrees with the pole mass to all orders in perturbation theory when only one quark flavor is present, but differs from the pole mass at order α_s^2 when there are additional flavors [10]. Physical quantities such as hadron masses can in principle be computed in the heavy quark effective theory in terms of the HQET mass m_Q . The computations cannot be done analytically in practice because of nonperturbative effects in QCD, which also prevent a direct extraction of the quark masses from the original QCD Lagrangian, Eq. (1). Nevertheless, for heavy quarks, it is possible to parametrize the nonperturbative effects to a given order in the $1/m_Q$ expansion in terms of a few unknown constants that can be obtained from experiment. For example, the B and D meson masses in the heavy quark effective theory are given in terms of a single nonperturbative parameter $\overline{\Lambda}$,

$$M(B) = m_b + \overline{\Lambda} + \mathcal{O}\left(\frac{\overline{\Lambda}^2}{m_b}\right) ,$$

$$M(D) = m_c + \overline{\Lambda} + \mathcal{O}\left(\frac{\overline{\Lambda}^2}{m_c}\right) . \tag{2}$$

This allows one to determine the mass difference $m_b - m_c =$ M(B) - M(D) = 3.4 GeV up to corrections of order $\overline{\Lambda}^2/m_b$ $\overline{\Lambda}^2/m_c$. The extraction of the individual quark masses m_b and m_c requires some knowledge of $\overline{\Lambda}$. An estimate of $\overline{\Lambda}$ using QCD sum rules gives $\overline{\Lambda} = 0.57 \pm 0.07$ GeV [11]. The HQET masses with this value of $\overline{\Lambda}$ are $m_b = 4.74 \pm 0.14$ GeV and $m_c = 1.4 \pm 0.2$ GeV, where the spin averaged meson masses $(3M(B^*) + M(B))/4$ and $(3M(D^*) + M(D))/4$ have been used to eliminate the spin-dependent $\mathcal{O}(\overline{\Lambda}^2/m_Q)$ correction terms. The errors reflect the uncertainty in $\overline{\Lambda}$ and the unknown spinaveraged $\mathcal{O}(\overline{\Lambda}^2/m_Q)$ correction. The errors do not include any theoretical uncertainty in the QCD sum rules, which could be large. A quark model estimate suggests that $\overline{\Lambda}$ is the constituent quark mass (≈ 350 MeV), which differs significantly from the sum rule estimate. In HQET, the $1/m_Q$ corrections to heavy meson decay form-factors are also given in terms of $\overline{\Lambda}$. Thus an accurate enough measurement of these form-factors could be used to extract $\overline{\Lambda}$ directly from experiment, which then determines the quark masses up to corrections of order

The quark mass m_Q of HQET can be related to other quark mass parameters using QCD perturbation theory at the scale m_Q . The relation between m_Q and $\widehat{m}(\xi)$ at one loop is [12]

$$m_Q = \widehat{m}(\xi) \left[1 + \frac{\widehat{\alpha}_s(\xi)}{\pi} \frac{\xi + 2}{\xi + 1} \log(\xi + 2) \right], \tag{3}$$

where $\widehat{\alpha}_s(\xi)$ is the strong interaction coupling constant in the momentum space subtraction scheme. The relation between m_Q and the $\overline{\text{MS}}$ mass \overline{m} is known to two loops [13],

$$\begin{split} m_Q &= \overline{m}(m_Q) \left[1 + \frac{4\overline{\alpha}_s(m_Q)}{3\pi} \right. \\ &+ \left(16.11 - 1.04 \sum_k \left(1 - \frac{m_{Q_k}}{m_Q} \right) \right) \left(\frac{\overline{\alpha}_s(m_Q)}{\pi} \right)^2 \right] , \quad (4) \end{split}$$

where $\overline{\alpha}_s(\mu)$ is the strong interaction coupling constants in the $\overline{\text{MS}}$ scheme, and the sum on k extends over all flavors Q_k lighter than Q. For the b-quark, Eq. (4) reads

$$m_b = \overline{m}_b (m_b) [1 + 0.09 + 0.06],$$
 (5)

where the contributions from the different orders in α_s are shown explicitly. The two loop correction is comparable in size and has the same sign as the one loop term. There is

presumably an error of order 0.05 in the relation between m_b and $\overline{m}_b(m_b)$ from the uncalculated higher order terms.

D. Light quarks

For light quarks, one can use the techniques of chiral perturbation theory to extract quark mass ratios. The light quark part of the QCD Lagrangian Eq. (1) has a chiral symmetry in the limit that the light quark masses are set to zero, under which left- and right-handed quarks transform independently. The mass term explicitly breaks the chiral symmetry, since it couples the left- and right-handed quarks to each other. A systematic analysis of this explicit chiral symmetry breaking provides some information on the light quark masses.

It is convenient to think of the three light quarks u, d and s as a three component column vector Ψ , and to write the mass term for the light quarks as

$$\overline{\Psi}M\Psi = \overline{\Psi}_L M\Psi_R + \overline{\Psi}_R M\Psi_L, \tag{6}$$

where M is the quark mass matrix M,

$$M = \begin{pmatrix} m_u & 0 & 0 \\ 0 & m_d & 0 \\ 0 & 0 & m_s \end{pmatrix}. \tag{7}$$

The mass term $\overline{\Psi}M\Psi$ is the only term in the QCD Lagrangian that mixes left- and right-handed quarks. In the limit that $M \to 0$, there is an independent SU(3) flavor symmetry for the left- and right-handed quarks. This $G_{\chi} = \mathrm{SU}(3)_L \times \mathrm{SU}(3)_R$ chiral symmetry of the QCD Lagrangian is spontaneously broken, which leads to eight massless Goldstone bosons, the π 's, K's, and η , in the limit $M \to 0$. The symmetry G_{χ} is only an approximate symmetry, since it is explicitly broken by the quark mass matrix M. The Goldstone bosons acquire masses which can be computed in a systematic expansion in M in terms of certain unknown nonperturbative parameters of the theory. For example, to first order in M one finds that [14,15]

$$m_{\pi^0}^2 = B (m_u + m_d) ,$$

$$m_{\pi^{\pm}}^2 = B (m_u + m_d) + \Delta_{em} ,$$

$$m_{K^0}^2 = m_{\overline{K}^0}^2 = B (m_d + m_s) ,$$

$$m_{K^{\pm}}^2 = B (m_u + m_s) + \Delta_{em} ,$$

$$m_{\eta}^2 = \frac{1}{3} B (m_u + m_d + 4m_s) ,$$
(8)

with two unknown parameters B and Δ_{em} , the electromagnetic mass difference. From Eq. (8), one can determine the quark mass ratios [14]

$$\frac{m_u}{m_d} = \frac{2m_{\pi^0}^2 - m_{\pi^+}^2 + m_{K^+}^2 - m_{K^0}^2}{m_{K^0}^2 - m_{K^+}^2 + m_{\pi^+}^2} = 0.56 ,$$

$$\frac{m_s}{m_d} = \frac{m_{K^0}^2 + m_{K^+}^2 - m_{\pi^+}^2}{m_{K^0}^2 + m_{\pi^+}^2 - m_{K^+}^2} = 20.1 ,$$
(9)

to lowest order in chiral perturbation theory. The error on these numbers is the size of the second-order corrections, which are discussed at the end of this section. Chiral perturbation theory cannot determine the overall scale of the quark masses, since it uses only the symmetry properties of M, and any multiple of M has the same G_{χ} transformation law as M. This can be seen from Eq. (8), where all quark masses occur only in the form Bm, so that B and m cannot be determined separately.

The mass parameters in the QCD Lagrangian have a scale dependence due to radiative corrections, and are renormalization scheme dependent. Since the mass ratios extracted using chiral perturbation theory use the symmetry transformation property of M under the chiral symmetry G_{χ} , it is important to use a renormalization scheme for QCD that does not change this transformation law. Any quark mass independent subtraction scheme such as $\overline{\rm MS}$ is suitable. The ratios of quark masses are scale independent in such a scheme.

The absolute normalization of the quark masses can be determined by using methods that go beyond chiral perturbation theory, such as QCD sum rules [3]. Typically, one writes a sum rule for a quantity such as B in terms of a spectral integral over all states with certain quantum numbers. This spectral integral is then evaluated by assuming it is dominated by one (or two) of the lowest resonances, and using the experimentally measured resonance parameters [16]. There are many subtleties involved, which cannot be discussed here [16].

Another method for determining the absolute normalization of the quark masses, is to assume that the strange quark mass is equal to the SU(3) mass splitting in the baryon multiplets [14,16]. There is an uncertainty in this method since in the baryon octet one can use either the Σ -N or the Λ -N mass difference, which differ by about 75 MeV, to estimate the strange quark mass. But more importantly, there is no way to relate this normalization to any more fundamental definition of quark masses.

One can extend the chiral perturbation expansion Eq. (8) to second order in the quark masses M to get a more accurate determination of the quark mass ratios. There is a subtlety that arises at second order [17], because

$$M\left(M^{\dagger}M\right)^{-1}\det M^{\dagger} \tag{10}$$

transforms in the same way under $G\chi$ as M. One can make the replacement $M\to M(\lambda)=M+\lambda M\left(M^\dagger M\right)^{-1}\det M^\dagger$ in all formulæ,

$$M(\lambda) = \operatorname{diag}(m_u(\lambda), m_d(\lambda), m_s(\lambda))$$

$$= \operatorname{diag}(m_u + \lambda m_d m_s, m_d + \lambda m_u m_s, m_s + \lambda m_u m_d)$$
, (11)

so it is not possible to determine λ by fitting to data. One can only determine the ratios $m_i(\lambda)/m_j(\lambda)$ using second-order chiral perturbation theory, not the desired ratios $m_i/m_j = m_i(\lambda = 0)/m_j(\lambda = 0)$.

Dimensional analysis can be used to estimate [18] that second-order corrections in chiral perturbation theory due to the

Quark Particle Listings

Quarks

strange quark mass are of order $\lambda m_s \sim 0.25$. The ambiguity due to the redefinition Eq. (11) (which corresponds to a second-order correction) can produce a sizeable uncertainty in the ratio m_u/m_d . The lowest-order value $m_u/m_d = 0.56$ gets corrections of order $\lambda m_s(m_d/m_u - m_u/m_d) \sim 30\%$, whereas m_s/m_d gets a smaller correction of order $\lambda m_s(m_u/m_d - m_u m_d/m_s^2) \sim 15\%$. A more quantitative discussion of second-order effects can be found in Refs. 17,19,20. Since the second-order terms have a single parameter ambiguity, the value of m_u/m_d is related to the value of m_s/m_d .

The ratio m_u/m_d is of great interest since there is no strong CP problem if $m_u=0$. To determine m_u/m_d requires fixing λ in the mass redefinition Eq. (11). There has been considerable effort to determine the chiral Lagrangian parameters accurately enough to determine m_u/m_d , for example from the analysis of the decays $\psi' \to \psi + \pi^0, \eta$, the decay $\eta \to 3\pi$, using sum rules, and from the heavy meson mass spectrum [16,21–24]. A recent paper giving a critique of these estimates is Ref. 25.

Eventually, lattice gauge theory methods will be accurate enough to be able to compute meson masses directly from the QCD Lagrangian Eq. (1), and thus determine the light quark masses. For a reliable determination of quark masses, these computations will have to be done with dynamical fermions, and with a small enough lattice spacing that one can accurately compute the relation between lattice and continuum Lagrangians.

The quark masses for light quarks discussed so far are often referred to as current quark masses. Nonrelativistic quark models use constituent quark masses, which are of order 350 MeV for the u and d quarks. Constituent quark masses model the effects of dynamical chiral symmetry breaking, and are not related to the quark mass parameters m_k of the QCD Lagrangian Eq. (1). Constituent masses are only defined in the context of a particular hadronic model.

E. Numerical values and caveats

The quark masses in the particle data listings have been obtained by using the wide variety of theoretical methods outlined above. Each method involves its own set of approximations and errors. In most cases, the errors are a best guess at the size of neglected higher-order corrections. The expansion parameter for the approximations is not much smaller than unity (for example it is $m_K^2/\Lambda_\chi^2 \approx 0.25$ for the chiral expansion), so an unexpectedly large coefficient in a neglected higher-order term could significantly alter the results. It is also important to note that the quark mass values can be significantly different in the different schemes. For example, assuming that the b-quark pole mass is 5.0 GeV, and $\overline{\alpha}_s(m_b) \approx 0.22$ gives the $\overline{\rm MS}$ b-quark mass $\overline{m}_b(\mu=m_b)=4.6$ GeV using the one-loop term in Eq. (4), and $\overline{m}_b(\mu = m_b) = 4.3$ GeV including the one-loop and two-loop terms. The heavy quark masses obtained using HQET, QCD sum rules, or lattice gauge theory are consistent with each other if they are all converted into the same scheme. When using the data listings, it is important to remember that

the numerical value for a quark mass is meaningless without specifying the particular scheme in which it was obtained. All non- $\overline{\rm MS}$ quark masses have been converted to $\overline{\rm MS}$ values in the data listings using one-loop formulæ, unless an explicit two-loop conversion is given by the authors in the original article.

LIGHT QUARKS (u, d, s)

OMITTED FROM SUMMARY TABLE

u-QUARK MASS

The u-, d-, and s-quark masses are estimates of so-called "current-quark masses," in a mass- independent subtraction scheme such as MS. The ratios $m_{\it U}/m_{\it d}$ and $m_{\it s}/m_{\it d}$ are extracted from pion and kaon masses using chiral symmetry. The estimates of $\it d$ and $\it u$ masses are not without controversy and remain under active investigation. Within the literature there are even suggestions that the u quark could be essentially massless. The s-quark mass is estimated from SU(3) splittings in hadron masses.

Starting with this edition of the Review, we have normalized the MS masses at a renormalization scale of $\mu=2$ GeV. Results quoted in the literature at $\mu = 1$ GeV have been rescaled by dividing by 1.35.

VALUE (MeV) 1.5 to 5 OUR EVALUATION • • • We do not use the following data for averages, fits, limits, etc. • • • 3.9 ± 1.1 1 JAMIN 95 THEO MS scheme ² NARISON 95C THEO MS scheme 3.0 ± 0.7 ³ CHOI 92B THEO ⁴ BARDUCCI 88 THEO 5 GASSER 82 THEO 3.8 ± 1.1

- $^{1}\,\mathrm{JAMIN}$ 95 uses QCD sum rules at next-to-leading order. We have rescaled $m_{y}(\mathrm{1\,GeV})$
- = 5.3 \pm 1.5 to μ = 2 GeV. 2 For NARISON 95c, we have rescaled m_y (1 GeV) = 4 \pm 1 to μ = 2 GeV. 3 CHOI 928 argues that m_y = 0 is okay based on instanton contributions to the chiral coefficients. Disagrees with DONOGHUE 92 and DONOGHUE 92B.
- 4 BARDUCCI 88 uses a calculation of the effective potential for $\bar{\psi}\psi$ in QCD, and estimates for $\Sigma(p^2)$. We have rescaled $m_{\nu}(1 \, \text{GeV}) = 5.8$ to $\mu = 2 \, \text{GeV}$.
- To extract the absolute values. We have rescaled $m_{u}(1 \text{ GeV}) = 5.0 \pm 1.5$ and uses QCD sum rules to extract the absolute values. We have rescaled $m_{u}(1 \text{ GeV}) = 5.1 \pm 1.5$ to $\mu = 2 \text{ GeV}$.

d-QUARK MASS

See the comment for the u quark above.

Starting with this edition of the Review, we have normalized the MS masses at a renormalization scale of $\mu=2$ GeV. Results quoted in the literature at $\mu=1$ GeV have been rescaled by dividing by 1.35.

c-QUARK MASS

The c-quark mass is estimated from charmonium and D masses. It corresponds to the "running" mass m_C ($\mu=m_C$) in the $\overline{\rm MS}$ scheme. We have converted masses in other schemes to the $\overline{\rm MS}$ scheme using one-loop QCD pertubation theory with $\alpha_s(\mu=m_c)=0.39$. The range 1.0–1.6 GeV for the $\overline{\text{MS}}$ mass corresponds to 1.2–1.9 GeV for the pole mass (see the "Note on Quark Masses").

b-QUARK MASS

The b-quark mass is estimated from bottomonium and B masses. It corresponds to the "running" mass $m_{B}~(\mu=m_{B})$ in the $\overline{\rm MS}$ scheme. We have converted masses in other schemes to the $\overline{\rm MS}$ scheme using one-loop QCD pertubation theory with $\alpha_S(\mu=m_b)=0.22$. The range 4.1–4.5 GeV for the $\overline{\rm MS}$ mass corresponds to 4.5–4.9 GeV for the pole mass (see the "Note on Quark Masses").

¹ ABREU 981 determines the $\overline{\rm MS}$ mass $m_b=2.67\pm0.25\pm0.34\pm0.27$ GeV at $\mu={\rm M}_Z$ from three jet heavy quark production at LEP. ABREU 981 have rescaled the result to $\mu=m_b$ using α_s =0.118 \pm 0.003.

 2 GIMENEZ 97 uses lattice computations of the B-meson propagator and the B-meson binding energy \overline{A} in the HQET. Their systematic (second) error for the $\overline{\rm MS}$ mass is an estimate of the effects of higher-order corrections in the matching of the HQET operators

 3 JAMIN 97 apply the QCD moment method to the au system. They also find a pole mass

of 4.60 \pm 0.02. ⁴ RODRIGO 97 determines the $\overline{\rm M5}$ mass $m_b \approx 2.85 \pm 0.22 \pm 0.20 \pm 0.36$ GeV at $\mu=M_Z$ from three jet heavy quark production at LEP. We have rescaled the result.

5 NARISON 958 uses finite energy sum rules to two-loop accuracy to determine a b-quark pole mass of 4.61 ± 0.05 GeV.

 6 VOLOSHIN 95 result was converted from a pole mass of 4827 \pm 7 MeV using the oneloop formula. Pole mass was extracted using moments of the total cross section for → bhadrons

 7 DAVIES 94 uses lattice computation of au spectroscopy. They also quote a value of 5.0 ± 0.2 GeV for the *b*-quark pole mass. The numerical computation includes quark vacuum polarization (unquenched); they find that the masses are independent of n_f to within their errors. Their error for the pole mass is larger than the error for the $\overline{\rm MS}$ mass, because both are computed from the bare lattice quark mass, and the conversion for the pole mass is less accurate.

B LIGETI 94 computes lower bound of 4.66 GeV on pole mass using HQET, and experimental data on inclusive B and D decays.

9LUKE 94 computes lower bound of 4.60 GeV on pole mass using HQET, and experimental data on inclusive B and D decays.

 10 NARISON 94 uses spectral sum rules to two loops, and $J/\psi(15)$ and ${\cal T}$ systems.

 11 TITARD 94 uses one-loop computation of the quark potential with nonperturbative gluon condensate effects to fit $J/\psi(1S)$ and Υ states.

 $^{12}\,\text{DOMINGUEZ}$ 92 determines pole mass to be 4.72 \pm 0.05 using next-to-leading order in 1/m in moment sum rule.

13 NARISON 89 determines the Georgi-Politzer mass at $p^2 = -m^2$ to be 4.23 \pm 0.05 GeV using QCD sum rules.

¹⁴ REINDERS 88 determines the Georgi-Politzer mass at $p^2 = -m^2$ to be 4.17 \pm 0.02 using moments of $\overline{b}\gamma^{\mu}b$. This technique leads to a value for the mass of the B meson of 5.25 ± 0.15 GeV.

 15 NARISON 87 determines the pole mass to be 4.70 \pm 0.14 using QCD sum rules, with $\Lambda(\overline{MS}) = 180 \pm 80 \text{ MeV}.$

 16 GASSER 82 uses SVZ sum rules. The renormalization point is $\mu=$ quark mass.

mb - mc MASS DIFFERENCE

The mass difference m_b-m_c in the HQET scheme is 3.4 \pm 0.2 GeV (see the "Note on Quark Masses").

THE TOP QUARK

Revised April 1998 by M. Mangano (CERN) and T. Trippe (LBNL).

A. Introduction: The top quark is the Q = 2/3, $T_3 = +1/2$ member of the weak-isospin doublet containing the bottom quark (see our review on the "Standard Model of Electroweak Interactions" for more information). This note collects a summary of its currently measured properties, in addition to a discussion of the experimental and theoretical issues involved in the determination of its parameters (mass, production cross section, decay branching ratios, etc.) and some comments on of the prospects for future improvements.

B. Top quark production at the Tevatron: At the Tevatron energy, 1.8 TeV, top quarks are dominantly produced in pairs from pure QCD processes: $q\bar{q} \rightarrow t\bar{t}$ and $gg \rightarrow t\bar{t}$. The production cross section through these channels is expected to be approximately 5 pb at $m_t = 175 \text{ GeV/c}^2$, with a dominant 90% contribution from the $q\overline{q}$ annihilation process. Smaller contributions come from the single-top production mechanisms, namely $q\overline{q}' \to W^* \to t\overline{b}$ and $qg \to q't\overline{b}$, this last mediated by a t-channel virtual-W exchange. The combined rate from these processes is approximately 2.5 pb at $m_t = 175 \text{ GeV}$ (see Ref. 1 and references therein). The actual contribution of these channels to the detected final states is further reduced relative to the dominant pair-production mechanisms, due to the lower experimental acceptances.

With a mass above the Wb threshold, the top quark decay width is dominated by the two-body decay $t \to Wb$. Neglecting terms of order m_b^2/m_t^2 and of order $(\alpha_s/\pi)m_W^2/m_t^2$, this is predicted in the Standard Model to be [2]:

$$\Gamma_{t} = \frac{G_{F}m_{t}^{3}}{8\pi\sqrt{2}} \left(1 - \frac{M_{W}^{2}}{m_{t}^{2}}\right)^{2} \left(1 + 2\frac{M_{W}^{2}}{m_{t}^{2}}\right) \left[1 - \frac{2\alpha_{s}}{3\pi} \left(\frac{2\pi^{2}}{3} - \frac{5}{2}\right)\right]. \tag{1}$$

Quark Particle Listings

t

The use of G_F in this equation accounts for the largest part of the one-loop electroweak radiative corrections, providing an expression accurate to better than 2%. The width values increase with mass, going for example from 1.02 GeV at $m_t = 160$ GeV to 1.56 GeV at $m_t = 180$ GeV (we used $\alpha_S(\rm M_Z) = 0.118$). With such a correspondingly short lifetime, the top quark is expected to decay before top-flavored hadrons or $t\bar{t}$ -quarkonium bound states can form.

In top decay, the Ws and Wd final states are expected to be suppressed relative to Wb by the square of the CKM matrix elements V_{ts} and V_{td} , whose values can be estimated under the assumption of unitarity of the three-generation CKM matrix to be less than 0.042 and 0.013, respectively (see our review "The Cabibbo-Kobayashi-Maskawa Mixing Matrix" in the current edition for more information).

Typical final states for the leading pair-production process therefore belong to three classes:

- A. $t\overline{t} \to W b W \overline{b} \to q \overline{q}' b q'' \overline{q}''' \overline{b}$,
- B. $t\overline{t} \to W b W \overline{b} \to q \overline{q}' b \ell \overline{\nu}_{\ell} \overline{b} + \overline{\ell} \nu_{\ell} b q \overline{q}' \overline{b}$,
- C. $t\overline{t} \to W b W \overline{b} \to \overline{\ell} \nu_{\ell} b \ell' \overline{\nu}_{\ell'} \overline{b}$,

where A, B, and C are referred to as the all-jets, lepton + jets, and dilepton channels, respectively.

The final state quarks emit radiation and evolve into jets of hadrons. The precise number of jets reconstructed by the detectors varies event by event, as it depends on the decay kinematics, as well as on the precise definition of jet used in the analysis. The neutrinos are reconstructed via the large imbalance in detected transverse momentum of the event (missing E_T).

The observation of $t\bar{t}$ pairs has been reported in all of the above decay modes. As discussed in detail below, the top quark production and decay properties extracted from the three different decay channels above are all consistent with each other, within the present experimental sensitivity. In particular, the $t \to Wb$ decay mode has been confirmed by the reconstruction of the $W \to jj$ invariant mass in the $\ell \bar{\nu}_\ell b \bar{b} jj$ final state [3].

The extraction of the top-quark properties from the Tevatron data requires a good understanding of the production and decay mechanisms of the top itself, as well as of the large background processes. The theoretical estimates of the physics backgrounds have large uncertainties, since only leading order QCD calculations are available for most of the relevant processes (W+3 and 4 jets, or WW+2 jets). While this limitation is known to affect the estimates of the overall production rates, it is believed that the LO determination of the event kinematics and of the fraction of W plus multi-jet events containing b quarks is rather accurate. In particular, one expects the E_T spectrum of these jets to fall rather steeply, the jet direction to point preferentially at small angles from the beams, and the fraction of events with b quarks to be of the order of few percent. In the case of the top signal, vice versa, the b fraction is $\sim 100\%$ and the jets are rather energetic, since they come from the decay of a massive object. It is therefore possible to improve the S/B ratio by either requiring the presence of a b quark, or by selecting very energetic and central kinematical configurations.

A detailed study of control samples with features similar to those of the relevant backgrounds, but free from possible top contamination is required to provide a reliable check on the background estimates.

C. Measured top properties: All direct measurements of top quark production and decay have been made by the CDF and DØ experiments at the Fermilab Tevatron collider in $p\overline{p}$ collisions at $\sqrt{s}=1.8$ TeV. Since the first direct experimental evidence for the top quark in 1994 [4] by CDF (a 2.8 σ effect. See this review in our 1996 edition [5] for more details) and the conclusive observation by both CDF and DØ in 1995 [6,7], the integrated luminosity has increased to 109 pb⁻¹ for CDF and 125 pb⁻¹ for DØ, allowing significant improvements in the measurement of the top production cross section, mass, and decay properties.

DØ and CDF determine the $t\bar{t}$ cross section $\sigma_{t\bar{t}}$ from their numbers of top candidates, their estimated background, their $t\bar{t}$ acceptance, and their integrated luminosity, assuming Standard Model decays $t\to Wb$ with unity branching ratio. Table 1 shows the measured cross sections from DØ and CDF along with the range of theoretical expectations, evaluated at the m_t values used by the experiments in calculating their acceptances. There is fairly good agreement between the experiments and the theoretical expectations, although the CDF values are somewhat higher than the theory values. This agreement supports the hypothesis that the excess of events over background in all of these channels is due to $t\bar{t}$ production. A joint CDF/DØ working group is expected to produce a combined cross section for the two experiments in the near future.

Future precise determinations of the top production cross section will test the current theoretical understanding of the production mechanisms [8–11]. A precise understanding of top production at the Tevatron is important for the extrapolation to the higher energies of future colliders, like the LHC, where the expected large cross section will enable more extensive studies. Discrepancies in rate between theory and data, on the other hand, would be more exciting and might indicate the presence of exotic production channels, as predicted in some models. In this case, one should also expect a modification of kinematical distributions such as the invariant mass of the top pair or the top quark transverse momentum.

The top mass has been measured in the lepton + jets and dilepton channels by both DØ and CDF, and in the all-jets channel by CDF. At present, the most precise measurements come from the lepton + jets channel with four or more jets and large missing E_T . In this channel, each event is subjected to a two-constraint kinematic fit to the hypothesis $t\bar{t} \to W^+ b W^- \bar{b} \to \ell \nu_\ell q \bar{q}' b \bar{b}$, assuming that the four highest E_T jets are the $t\bar{t}$ daughters. The shape of the distribution of fitted top masses from these events is compared to templates

Table 1: Cross section for $t\bar{t}$ production in $p\bar{p}$ collisions at $\sqrt{s} = 1.8$ TeV from DØ $(m_t = 173.3 \text{ GeV/c}^2)$, CDF $(m_t = 175 \text{ GeV/c}^2)$, and theory.

4.75 - 5.5 pb	Theory	[8-11]	at $m_t = 175 \text{ GeV/c}^2$

expected from a mixture of background and signal distributions for a series of assumed top masses. This comparison yields values of the likelihood as a function of top mass, from which a best value of the top mass and its error are obtained. The results are shown in Table 2. The systematic error, the second error shown, is comparable to the statistical error and is primarily due to uncertainties in the jet energy scale and the Monte Carlo modeling.

Less precise determinations of the top mass come from the dilepton channel with two or more jets and large missing E_T , and from the all-jets channel. In the dilepton channel a kinematically constrained fit is not possible because there are two missing neutrinos, so experiments must use other mass estimators than the reconstructed top mass. Any quantity which is correlated with top mass can be used as a mass estimator. DØ uses the fact that if m_t is assumed, the $t\bar{t}$ system can be reconstructed (up to a four-fold ambiguity). They compare the resulting kinematic configurations to expectations from $t\bar{t}$ production and obtain a weight vs m_t curve for each event, which they coarsely histogram to obtain four shapesensitive quantities as their multidimensional mass estimator. Their method yields a significant increase in precision over onedimensional estimators. CDF does two analyses, one using the b quark jet energy and the other using the ℓ b-jet invariant mass. Both DØ and CDF obtain the top mass and error from these mass estimators using the same template likelihood method as for the lepton + jets channel. CDF also measures the mass in the all-jets channel using events with six or more jets, at least one of which is tagged as a b jet by the presence of a secondary vertex.

As seen in Table 2, all top mass results are in good agreement, giving further support to the hypothesis that these events are due to $t\bar{t}$ production. A joint CDF/DØ working group is expected to produce a combined CDF/DØ average top mass in the near future, taking into account correlations

Table 2: Top mass measurements from $D\emptyset$ and CDF.

^{*} Average does not include CDF all jets. See text.

between the systematic errors in the different measurements. In the meantime, the PDG obtains an average top mass as follows. Using DØ's approach to combining their own results [16], we assume a 100% correlation between the DØ lepton + jets and dilepton systematic errors for jet energy scale, signal model, and multiple interactions, and 0% correlation between their other systematic errors. CDF have not published their combined results, but we can include CDF results for lepton + jets [18] and dileptons [14] by assuming 100% correlation between the signal model errors in all four results and 100% correlation between the jet energy scale errors of the two CDF results. In addition, in a given channel, lepton + jets or dileptons, we assume a 100% correlation between systematic errors in the CDF and DØ background shapes. All other correlations are assumed to be zero. We do not include the CDF all jets channel because we do not know what correlation to assume for its signal model error. These assumptions yield a PDG average top mass of $m_t = 173.8 \pm 3.5 \pm 3.9 \text{ GeV}/c^2 = 173.8 \pm 5.2 \text{ GeV}/c^2$.

Given the experimental technique used to extract the top mass, the top mass values should be taken as representing the top *pole mass* (see our review "Note on Quark Masses" in the current edition).

The extraction of the value of the top mass from the analyses described requires, in addition to an understanding of the absolute energy calibration and resolution of the detectors, also an a priori knowledge of the structure of the final state. Given the hardness of a $t\bar{t}$ production process, jets can in fact arise not only from the top decays, but also from the initial state gluon radiation. Furthermore, quarks from the top decays can radiate additional jets. The presence of these additional jets will affect the shape of the mass spectrum, depending on the details of how the samples used for the mass determination were defined. QCD calculations used to model top production and decay are expected to be rather reliable, but residual uncertainties remain and are accounted for in the overall systematic error on the top mass. The larger samples that will become available in the future will allow more strict selection criteria, leading to purer samples of top quarks. For example, requesting the presence of four and only four jets in the event, two of which are b tagged jets and the other two of which are central jets of high- E_T , should largely reduce the possibility of erroneously including jets not coming from the top decays into the mass reconstruction. This will significantly improve the mass resolution and will make it less sensitive to the theoretical uncertainties. With a smaller error on the top mass, and with yet improved measurements of the electroweak parameters, it will be possible to get important constraints on the value of the Higgs mass. Current global fits performed within the Standard Model and its minimal supersymmetric extension provide indications for a relatively light Higgs (see the " H^0 Indirect Mass Limits from Electroweak Analysis" in the Particle Listings of the current edition), possibly within the range of the upcoming LEP2 experiments.

Measurements of other properties of top decays are underway. CDF reports a direct measurement of the $t \to Wb$ branching ratio [19]. Their preliminary result, obtained by comparing the number of events with 0, 1 and 2 tagged b jets and using the known tagging efficiency, is: $R = B(t \rightarrow Wb) / \sum_{q=d,s,b} B(t \rightarrow Wb) / \sum_{q=d$ $Wq) = 0.99 \pm 0.29$ where the error includes statistical and systematic uncertainties, or as a lower limit, R > 0.58 at 95% CL. Assuming that non-W decays of top can be neglected, that only three generations exist, and assuming the unitarity of the CKM matrix, they extract a CKM matrix-element $|V_{th}| = 0.99 \pm 0.15$ or $|V_{tb}| > 0.76$ at 95% CL. A more direct measurement of the Wtb coupling constant will be possible when enough data have been accumulated to detect the less frequent single-top production processes, such as $q\tilde{q}' \to W^* \to t\tilde{b}$ and $qb \to q't$ via W exchange. The cross-sections for these processes are proportional to $|V_{tb}|^2$, and no assumption on the number of families or the unitarity of the CKM matrix needs to be made to extract

Both CDF and DØ are searching for non-Standard Model top decays, particularly those expected in supersymmetric models. CDF [20] has published a direct search for top decay to a charged Higgs and a b quark followed by $H^+ \to \tau \nu_{\tau}$ with τ decaying to hadrons. This search focuses on large $\tan \beta$, the ratio of the vacuum expectation values for the two Higgs doublets. As $\tan \beta$ increases, the $t \to H^+ b$ and $H^+ \to \tau \nu_{\tau}$ branching fractions are both expected to approach one, maximizing sensitivity to this mode. CDF sees no excess of events over the expected background, giving an exclusion region in the $m_{H^+} vs \tan \beta$ plane (see their Fig. 3) which extends to m_{H^+} values higher than existing LEP limits for $\tan \beta$ above 100, assuming $m_t = 175 \text{ GeV}/c^2$ and $\sigma_{t\bar{t}} = 5.0 \text{ pb}$.

DØ and CDF are looking for top disappearance via $t \to H^+b$, $H^+ \to \tau \nu$ or $c\bar{s}$. These charged Higgs decays would not be detected in the lepton + jets or dilepton cross section analyses as efficiently as $t \to W^\pm b$, primarily because of the absence of energetic isolated leptons in the Higgs decays. This would give rise to measured cross sections lower than the Standard Model prediction, assuming that non-Standard Model $t\bar{t}$ production is negligible. The H^+ is expected to decay to $\tau \nu$ at high $\tan \beta$ and to $c\bar{s}$ or $Wb\bar{b}$ at low $\tan \beta$. The $\tau \nu$ and

 $c\overline{s}$ modes lead to disagreement with the observed cross section and thus to exclusion regions at both low and high $\tan \beta$. At high $\tan \beta$ these experiments can potentially probe m_{H^+} up to the top decay kinematic limit, while at low $\tan \beta$ the m_{H^+} reach is expected to be weakened to perhaps 140 GeV. This is because at higher m_{H^+} and low $\tan \beta$ the $H^+ \to W b \bar{b}$ decay mode dominates [21] and cannot easily be distinguished from Standard Model top decay.

Searches for other possible new particles such as a supersymmetric scalar top quark (\tilde{t}) via $t \to \tilde{t} \tilde{\chi}^0$, are under way both at CDF and DØ.

CDF reports a search for flavor changing neutral current (FCNC) decays of the top quark $t \to q\gamma$ and $t \to qZ$ [22], for which the Standard Model predicts such small rates that their observation here would indicate new physics. They assume that one top decays via FCNC while the other decays via Wb. For the $t \to q\gamma$ search, they search for two signatures, depending on whether the W decays leptonically or hadronically. For leptonic W decay, the signature is $\gamma \ell$ plus missing E_T and two or more jets, while for hadronic W decay, it is γ plus four or more jets, one with a secondary vertex b tag. They observe one event $(\mu\gamma)$ with an expected background of less than half an event, giving an upper limit on the top branching ratio of $B(t \to q\gamma) < 3.2\%$ at 95% CL.

For the $t\to qZ$ FCNC search, they look for $Z\to \mu\mu$ or ee and $W\to$ hadrons, giving a Z plus four jet signature. They observe one $\mu\mu$ event with an expected background of 1.2 events, giving an upper limit on the top branching ratio of $B(t\to qZ)<33\%$ at 95% CL. Both the γ and Z limits are non-background subtracted (i.e. conservative) estimates.

Studies of the decay angular distributions are also in progress using the current data sets. They will allow a first direct analysis of the V-A nature of the Wtb coupling, as well as providing direct information on the relative coupling of longitudinal and transverse W bosons to the top. In the Standard Model, the fraction of decays to transversely polarized W bosons is expected to be $1/(1+m_t^2/2M_W^2)$ (30% for $m_t=175~{\rm GeV}$. Deviations from this value would challenge the Higgs mechanism of spontaneous symmetry breaking.

t-Quark Mass in pp Collisions

The t quark has now been observed, Its mass is sufficiently high that decay is expected to occur before hadronization. OUR EVALUATION is an AVERAGE which incorporates correlations as described in the note "The Top Quark" above.

For earlier search limits see the Review of Particle Physics, Phys. Rev. D54.1 (1996).

⁴ ABE 97v searched for $t\bar{t} \to (\ell\nu_\ell) (\tau\nu_\tau) b\bar{b}$ events in 109 pb⁻¹ of $p\bar{p}$ collisions at $\sqrt{s}=1.8$ TeV. They observed 4 candidate events where one expects ~ 1 signal and ~ 2 background events. Three of the four observed events have jets identified as b candidates.

Indirect t-Quark Mass from Standard Model Electroweak Fit

VALUE (GeV)

"OUR EVALUATION" below is from the fit to electroweak data described in the "Electroweak Model and Constraints on New Physics" section of this Review. This fit result does not include direct measurements of m_t . The central value and first uncertainty are for $M_H=M_Z$. The second uncertainty is the shift from changing M_H to 300 GeV.

The RVUE values are based on the data described in the footnotes. RVUE's published before 1994 and superseded analyses are now omitted. For more complete listings of earlier results, see the 1994 edition (Physical Review **D50** 1173 (1994)).

160 +50 -60	18 ALITTI	92B UA2	m _W , m _Z					

⁵ DEBOER 97B result is from the five-parameter fit which varies m_Z , m_t , m_H , α_S , and $\alpha(m_Z)$ under the contraints: m_t =175 ± 6 GeV, $1/\alpha(m_Z)$ =128.896 ± 0.09. They found m_H =141 $^{+140}_{-77}$ GeV and $\alpha_S(m_Z)$ =0.1197 ± 0.0031.

⁶ ELLIS 96C result is a the two-parameter fit with free m_t and m_{H^+} yielding also m_H =65 $^+_-$ 17 GeV.

⁷ ERLER 95 result is from fit with free m_t and $\alpha_s(m_Z)$, yielding $\alpha_s(m_Z) = 0.127(5)(2)$.

⁸ MATSUMOTO 95 result is from fit with free m_t to Z parameters, M_W , and low-energy neutral-current data. The second error is for $m_H = 300 {+ 700 \atop 240}$ GeV, the third error is for $\alpha_s(m_Z) = 0.116 \pm 0.005$, the fourth error is for $\delta \alpha_{\rm had} = 0.0283 \pm 0.0007$.

⁹ ABREU 94 value is for $\alpha_s(m_Z)$ constrained to 0.123 \pm 0.005. The second error corresponds to $m_H = 300^{+700}_{-240}$ GeV.

 10 ACCIARRI 94 value is for $\alpha_s(m_Z)$ constrained to 0.124 \pm 0.006. The second error corresponds to $m_H=300^{+700}_{-240}$ GeV.

 11 AKERS 94 result is from fit with free α_5 . The second error corresponds to $m_H{=}300 {\,}^{+}700$ GeV. The 95%CL limit is m_t <210 GeV.

12 ARROYO 94 measures the ratio of the neutral-current and charged-current deep inelastic scattering of ν_{μ} on an iron target. By assuming the SM electroweak correction, they obtain $1-m_W^2/m_Z^2=0.2218\pm0.0059$, yielding the quoted $m_{\hat{t}}$ value. The second error corresponds to $m_H=300^{+700}_{-240}$ GeV.

 13 BUSKULIC 94 result is from fit with free $\alpha_{\rm S}.$ The second error is from $m_{H}{=}300^{+700}_{-240}$ GeV.

14 ELLIS 94B result is fit to electroweak data available in spring 1994, including the 1994 A_{LR} data from SLD. m_t and m_H are two free parameters of the fit for $\alpha_s(m_Z) = 0.118 \pm 0.007$ yielding m_t above, and $m_H = 35 {+}^{+}70_{-}$ GeV. ELLIS 94B also give results for fits including constraints from CDF's direct measurement of m_t and CDF's and DØ 's production cross-section measurements. Fits excluding the A_{LR} data from SLD are also given.

BYPCH.

15 GURTU 94 result is from fit with free m_t and $\alpha_s(m_Z)$, yielding m_t above and $\alpha_s(m_Z)$ $= 0.125 \pm 0.005 ^{+0.003}_{-0.001}$. The second errors correspond to $m_H = 300 ^{+700}_{-240}$ GeV. Uses LEP, M_W , νN , and SLD electroweak data available in spring 1994.

16 MONTAGNA 94 result is from fit with free m_t and $\alpha_s(m_Z)$, yielding m_t above and $\alpha_s(m_Z)=0.124$. The second errors correspond to $m_H=300^{+700}_{-240}$ GeV. Errors in $\alpha(m_Z)$ and m_D are taken into account in the fit. Uses LEP, SLC, and M_W/M_Z data available in spring 1994.

¹⁷ NOVIKOV 94B result is from fit with free m_t and $\alpha_s(m_Z)$, yielding m_t above and $\alpha_s(m_Z) = 0.125 \pm 0.005 \pm 0.002$. The second errors correspond to $m_H = 300^{+700}_{-240}$ GeV. Uses LEP and CDF electroweak data available in spring 1994.

 18 ALITTI 92B assume $m_H=$ 100 GeV. The 95%CL limit is $m_{\mbox{\it t}}<$ 250 GeV for $m_H<$ 1 TeV.

² Result is based on 109 \pm 7 pb⁻¹ of data at \sqrt{s} = 1.8 TeV.

 $^{^3}$ ABE 97R result is based on the first observation of all hadronic decays of $t\bar{t}$ pairs. Single b-quark tagging with jet-shape variable constraints was used to select signal enriched multi-jet events. Not used in OUR EVALUATION because of unknown correlations in the systematic errors. A joint CDF-DØ working group is considering how to include these results.

b' (4th Generation) Quark, Searches for

MASS LIMITS for b' (4th Generation) Quark or Hadron in $p\bar{p}$ Collisions

These experiments (except for MUKHOPADHYAYA 93 and ABACHI 97D) assume that no two-body modes such as $b' \rightarrow b\gamma$, $b' \rightarrow bg$, or $b' \rightarrow cH^+$ are available.

VALUE (GeV)	CL%	DOCUMENTID		IECN	COMMENT	
>128	95	¹ ABACHI	95F	D0	$\ell\ell$ + jets, ℓ + jets	
• • We do not use the	following	data for averages	, fits	, limits,	etc. • • •	
> 96	95	² ABACHI	97D	D0	FCNC $(b' \rightarrow b\gamma)$

> 85			92	CDF	$\ell\ell$	
> 72			90B	CDF	$e + \mu$	
> 54			90	UA2	$e + jets + missing E_T$	
> 43			90B	UA1	μ + jets	
> 34	95	⁸ ALBAJAR	88	UA1	e or μ + jets	

- ¹ ABACHI 95F bound on the top-quark also applies to b' and t' quarks that decay predominantly into W. See FROGGATT 97.
- ² ABACHI 97D searched for b' that decays mainly via FCNC. They obtained 95%CL upper bounds on B($b'\overline{b}' \rightarrow \gamma + 3$ jets) and B($b'\overline{b}' \rightarrow 2\gamma + 2$ jets), which can be interpreted as the lower mass bound $m_{b'} > m_Z + m_b$.
- 3 MUKHOPADHYAYA 93 analyze CDF dilepton data of ABE 92G in terms of a new quark decaying via flavor-changing neutral current. The above limit assumes $\mathsf{B}(b' \to$ $b\ell^+\ell^-$)=1%. For an exotic quark decaying only via virtual Z [B($b\ell^+\ell^-$) = 3%], the limit is 85 GeV.
- ⁴ ABE 92 dilepton analysis limit of >85 GeV at CL≈95% also applies to b' quarks, as discussed in ABE 908.

 ABE 908 exclude the region 28-72 GeV.
- 6 AKESSON 90 searched for events having an electron with $p_T > 12$ GeV, missing momentum > 15 GeV, and a jet with $E_{T}>$ 10 GeV, $|\eta|$ < 2.2, and excluded $m_{b'}$ between 30 and 69 GeV.
- 7 For the reduction of the limit due to non-charged-current decay modes, see Fig. 19 of
- ALBAJAR 908.

 8 ALBAJAR 88 study events at $E_{\rm cm}$ = 546 and 630 GeV with a muon or isolated electron, accompanied by one or more jets and find agreement with Monte Carlo predictions for the production of charm and bottom, without the need for a new quark. The lower mass limit is obtained by using a conservative estimate for the $b'\overline{b}'$ production cross section and by assuming that it cannot be produced in W decays. The value quoted here is revised using the full $O(\alpha_s^3)$ cross section of ALTARELLI 88.

MASS LIMITS for b^\prime (4th Generation) Quark or Hadron in e^+e^- Collisions

Search for hadrons containing a fourth-generation -1/3 quark denoted b'.

The last column specifies the assumption for the decay mode (CC denotes the conventional charged-current decay) and the event signature which is looked for.

- ⁹ DECAMP 90F looked for isolated charged particles, for isolated photons, and for four-jet final states. The modes $b'\to bg$ for B($b'\to bg$) > 65% $b'\to b\gamma$ for B($b'\to b\gamma$) > 5% are excluded. Charged Higgs decay were not discussed. ¹⁰ ADRIANI 93G search for vector quarkonium states near Z and give limit on quarkonium.
- Z mixing parameter $\delta m^2 < (10-30) \text{ GeV}^2$ (95%CL) for the mass 88-94.5 GeV. Using Richardson potential, a 1S $(b'\bar{b}')$ state is excluded for the mass range 87.7-94.7 GeV. This range depends on the potential choice.
- $^{11} \, \mathrm{ABREU}$ 90D assumed $m_{\ensuremath{H^-}} \, < m_{\ensuremath{b^+}} 3$ GeV.
- $^{12}\,\mathrm{Superseded}$ by ABREU 91F.
- 13 AKRAWY 90B search was restricted to data near the Z peak at $E_{
 m cm}=$ 91.26 GeV at LEP. The excluded region is between 23.6 and 41.4 GeV if no H^{+} decays exist. For charged Higgs decays the excluded regions are between ($m_{H^+}\,+1.5$ GeV) and 45.5
- GeV.

 14 AKRAWY 90J search for isolated photons in hadronic Z decay and derive $B(Z \to b' \bar{b}') \cdot B(b' \to \gamma X)/B(Z \to hadrons) < 2.2 \times 10^{-3}$. Mass limit assumes $B(b' \rightarrow \gamma X) > 10\%$.
- $^{15}\,\mathrm{ABE}$ 89E search at $E_{cm}=$ 56-57 GeV at TRISTAN for multihadron events with a spherical shape (using thrust and acoplanarity) or containing isolated leptons.
- 16 ABE 89G search was at $E_{cm} =$ 55–60.8 GeV at TRISTAN.
- 17 if the photonic decay mode is large (B($b'\to b\gamma$) > 25%), the ABRAMS 89c limit is 45.4 GeV. The limit for for Higgs decay ($b'\to cH^-,H^-\to \bar cs$) is 45.2 GeV.
- 18 ADACHI 89c search was at $E_{\it cm}=56.5$ –60.8 GeV at TRISTAN using multi-hadron events accompanying muons.
- ¹⁹ ADACHI 89C also gives limits for any mixture of C C and bg decays.
- 20 ENO 89 search at $E_{cm} = 50-60.8$ at TRISTAN.
- ²¹ ENO 89 considers arbitrary mixture of the charged current, bg, and $b\gamma$ decays.
- 22 IGARASHI 88 searches for leptons in low-thrust events and gives $\Delta R(b')<0.26$ (95% CL) assuming charged current decay, which translates to $m_{b'}>24.4$ GeV.
- ²³ SAGAWA 88 set limit $\sigma(top) < 6.1$ pb at CL=95% for top-flavored hadron production from event shape analyses at $E_{CM} = 52$ GeV. By using the quark parton model cross-section formula near threshold, the above limit leads to lower mass bounds of 23.8 GeV for charge -1/3 quarks.
- 24 ADEVA 86 give 95%CL upper bound on an excess of the normalized cross section, $\Delta R_{\rm i}$ as a function of the minimum c.m. energy (see their figure 3). Production of a pair of 1/3 charge quarks is excluded up to $E_{\rm cm}=45.4$ GeV.
- ²⁵ ALTHOFF 84C narrow state search sets limit $\Gamma(e^+e^-)$ B(hadrons) <2.4 keV CL = 95% and heavy charge 1/3 quark pair production m>21 GeV, CL = 95%.
- 26 ALTHOFF 84: exclude heavy quark pair production for 7 < m < 19 GeV (1/3 charge) using aplanarity distributions (CL = 95%).

Free Quark Searches

FREE QUARK SEARCHES

The basis for much of the theory of particle scattering and hadron spectroscopy is the construction of the hadrons from a set of fractionally charged constituents (quarks). A central but unproven hypothesis of this theory, Quantum Chromodynamics, is that quarks cannot be observed as free particles but are confined to mesons and baryons.

Experiments show that it is at best difficult to "unglue" quarks. Accelerator searches at increasing energies have produced no evidence for free quarks, while only a few cosmic-ray and matter searches have produced uncorroborated events.

This compilation is only a guide to the literature, since the quoted experimental limits are often only indicative. Reviews can be found in Refs. 1-3.

Quark Flux — Accelerator Searches

The definition of FLUX depends on the experiment

- (a) is the ratio of measured free quarks to predicted free quarks if there is no "con-
- (b) is the probability of fractional charge on nuclear fragments. Energy is in GeV/nucleon
- (c) is the 90%CL upper limit on fractionally-charged particles produced per interac-
- (d) is quarks per collision.
- (e) is inclusive quark-production cross-section ratio to $\sigma(e^+e^- \to \mu^+\mu^-)$.
- (f) is quark flux per charged particle.
- (g) is the flux per ν -event.
- (h) is quark yield per π^- yield.
- (i) is 2-body exclusive quark-production cross-section ratio to $\sigma(e^+e^-
 ightarrow$

	$\mu \cdot \mu$),

³¹ Also set limits for $Q = \pm e/6$.

nadronic fragmentation function is assumed. 12 CECCHINI 93 limit at 90%CL for $23/3 \le Z \le 40/3$, for 16A GeV O, 14.5A SI, and 200A S incident on Cu target. Other limits are 2.3×10^{-4} for $17/3 \le Z \le 20/3$ and $1.2 \times 10^{-4} \le Z \le 23/3$.

¹³ GHOSH 92 reports measurement of spallation fragment charge based on ionization in emulsion. Out of 650 measured tracks, 2 were consistent with charge 5e/3, and 4 with 7e/3.

¹⁴ Hadronic quark.

¹⁶ HE 91 limits are for charges of the form $N\pm1/3$ from 23/3 to 38/3, and correspond to

¹⁷ The limits apply to projectile fragment charges of 17, 19, 20, 22, 23 in units of e/3.

¹⁸ The limits apply to projectile fragment charges of 16, 17, 19, 20, 22, 23 in units of e/3.

¹⁹ Flux limits and mass range depend on charge.

²⁰ Bound to nuclei. 21 Quark lifetimes > 1 × 10⁻⁸ s. ²² One candidate m < 0.17 GeV.

²⁴ With telescope axis at zenith angle 40° to the south.

²⁵ Leptonic quarks. 25 Leptonic quarks. 26 Lifetime $> 10^{-8}$ s; charge ± 0.70 , 0.68, 0.42; and mass > 4.4, 4.8, and 20 GeV, respectively. tively.

27 Time delayed air shower search.

²⁸ Prompt air shower search.

²⁹ Also e/4 and e/6 charges.

³⁰ No events in subsequent experiments.

³² Note that in PHILLIPS 88 these authors report a subtle magnetic effect which could account for the apparent fractional charges.

³³ Limit inferred by JONES 77B.

LIGHT UNFLAVORED MESONS (S = C = B = 0)

For I=1 (π, b, ρ, a) : $u\overline{d}$, $(u\overline{u}-d\overline{d})/\sqrt{2}$, $d\overline{u}$; for I=0 $(\eta, \eta', h, h', \omega, \phi, f, f')$: $c_1(u\overline{u}+d\overline{d})+c_2(s\overline{s})$

PSEUDOSCALAR-MESON DECAY CONSTANTS Revised March 1998 by M. Suzuki (LBNL).

Charged mesons

The decay constant f_P for a charged pseudoscalar meson P is defined by

$$\langle 0|A_{\mu}(0)|P(\mathbf{q})\rangle = if_P q_{\mu} , \qquad (1)$$

where A_{μ} is the axial-vector part of the charged weak current after a Cabibbo-Kobayashi-Maskawa mixing-matrix element $V_{qq'}$ has been removed. The state vector is normalized by $\langle P(\mathbf{q})|P(\mathbf{q'})\rangle=(2\pi)^3$ $2E_q$ $\delta(\mathbf{q}-\mathbf{q'})$, and its phase is chosen to make f_P real and positive. Note, however, that in many theoretical papers our $f_P/\sqrt{2}$ is denoted by f_P .

In determining f_P experimentally, radiative corrections must be taken into account. Since the photon-loop correction introduces an infrared divergence that is canceled by soft-photon emission, we can determine f_P only from the combined rate for $P^\pm \to \ell^\pm \nu_\ell$ and $P^\pm \to \ell^\pm \nu_\ell \gamma$. This rate is given by

$$\Gamma(P \to \ell \nu_{\ell} + \ell \nu_{\ell} \gamma) =$$

$$\frac{G_F^2 |V_{qq'}|^2}{8\pi} f_P^2 m_\ell^2 m_P \left(1 - \frac{m_\ell^2}{m_P^2}\right)^2 [1 + \mathscr{O}(\alpha)] . \tag{2}$$

Here m_{ℓ} and m_P are the masses of the lepton and meson. Radiative corrections include inner bremsstrahlung, which is independent of the structure of the meson [1-3], and also a structure-dependent term [4,5]. After radiative corrections are made, there are ambiguities in extracting f_P from experimental measurements. In fact, the definition of f_P is no longer unique.

It is desirable to define f_P such that it depends only on the properties of the pseudoscalar meson, not on the final decay products. The short-distance corrections to the fundamental electroweak constants like $G_F|V_{qq'}|$ should be separated out. Following Marciano and Sirlin [6], we define f_P with the following form for the $\mathcal{O}(\alpha)$ corrections:

$$1 + \mathcal{O}(\alpha) = \left[1 + \frac{2\alpha}{\pi} \ln\left(\frac{m_Z}{m_\rho}\right)\right] \left[1 + \frac{\alpha}{\pi} F(x)\right]$$

$$\times \left\{1 - \frac{\alpha}{\pi} \left[\frac{3}{2} \ln\left(\frac{m_\rho}{m_P}\right) + C_1 + C_2 \frac{m_\ell^2}{m_\rho^2} \ln\left(\frac{m_\rho^2}{m_\ell^2}\right) + C_3 \frac{m_\ell^2}{m_\rho^2} + \dots\right]\right\},$$
(3)

where m_{ρ} and m_{Z} are the masses of the ρ meson and Z boson. Here

$$\begin{split} F(x) &= 3 \ln x + \frac{13 - 19x^2}{8(1 - x^2)} - \frac{8 - 5x^2}{2(1 - x^2)^2} \, x^2 \ln x \\ &- 2 \Big(\frac{1 + x^2}{1 - x^2} \ln x + 1 \Big) \ln(1 - x^2) + 2 \Big(\frac{1 + x^2}{1 - x^2} \Big) L(1 - x^2) \ , \end{split}$$

with

$$x \equiv m_{\ell}/m_P$$
, $L(z) \equiv \int_0^z \frac{\ln(1-t)}{t} dt$. (4)

The first bracket in the expression for $1 + \mathcal{O}(\alpha)$ is the short-distance electroweak correction. A quarter of $(2\alpha/\pi) \ln(m_Z/m_\rho)$ is subject to the QCD correction $(1-\alpha_s/\pi)$, which leads to a reduction of the total short-distance correction of 0.00033 from the electroweak contribution alone [6]. The second bracket together with the term $-(3\alpha/2\pi) \ln(m_\rho/m_P)$ in the third bracket corresponds to the radiative corrections to the point-like pion decay $(\Lambda_{\text{cutoff}} \approx m_\rho)$ [2]. The rest of the corrections in the third bracket are expanded in powers of m_ℓ/m_ρ . The expansion coefficients C_1 , C_2 , and C_3 depend on the hadronic structure of the pseudoscalar meson and in most cases cannot be computed accurately. In particular, C_1 absorbs the uncertainty in the matching energy scale between short- and long-distance strong interactions and thus is the main source of uncertainty in determining f_{π^+} accurately.

With the experimental value for the decay $\pi^+ \to \mu^+ \nu_\mu + \mu^+ \nu_\mu \gamma$, one obtains

$$f_{\pi^{+}} = 130.7 \pm 0.1 \pm 0.36 \text{ MeV}$$
 (5)

where the first error comes from the experimental uncertainty on $|V_{ud}|$ and the second comes from the uncertainty on C_1 (= 0 ± 0.24) [6]. Similarly, one obtains from the decay $K^+ \rightarrow \mu^+\nu_\mu + \mu^+\nu_\mu\gamma$ the decay constant

$$f_{K^+} = 159.8 \pm 1.4 \pm 0.44 \text{ MeV}$$
, (6)

where the first error is due to the uncertainty on $|V_{us}|$.

For the heavy pseudoscalar mesons, uncertainties in the experimental values for the decay rates are much larger than the radiative corrections. For the D^+ , only an upper bound can be obtained from the published data:

$$f_{D^+} < 310 \text{ MeV (CL} = 90\%)$$
 (7)

For the D_s^+ , the decay constant has been extracted from both the $D_s^+ \to \mu^+\nu_\mu$ and the $D_s^+ \to \tau^+\nu_\tau$ branching fractions. Two values have been reported since the last edition [7,8]:

$$\begin{split} f_{D_s^+} &= 194 \pm 35 \pm 20 \pm 14 \text{ MeV from } D_s^+ \to \mu^+ \nu_\mu \ , \\ f_{D_s^+} &= 309 \pm 58 \pm 33 \pm 38 \text{ MeV from } D_s^+ \to \tau^+ \nu_\tau \ . \end{split}$$
 There are now altogether five reported values for $f_{D_s^+}$ spread over a wide range,

$$f_{D^{+}} = 194 \text{ MeV} \sim 430 \text{ MeV}$$
 (8)

with large uncertainties attached. We must wait for better data before giving a meaningful value for $f_{D_s^+}$. (See the measurements of the $D_s^+ \to \ell^+ \nu_\ell$ modes in the Particle Listings for the numbers quoted by individual experiments.)

There have been many attempts to extract f_P from spectroscopy and nonleptonic decays using theoretical models. Since it is difficult to estimate uncertainties for them, we have listed here only values of decay constants that are obtained directly from the observation of $P^\pm \to \ell^\pm \nu_\ell$.

Meson Particle Listings

 π^{\pm}

Light neutral mesons

The decay constants for the light neutral pseudoscalar mesons π^0 , η , and η' are defined by

$$\langle 0|A_{\mu}(0)|P^{0}(\mathbf{q})\rangle = i(f_{P}/\sqrt{2})q_{\mu} ,$$
 (9)

where A_{μ} is a neutral axial-vector current of octet or singlet. However f_p for the neutral mesons cannot be extracted directly from the data.

In the limit of $m_P \to 0$, the Adler-Bell-Jackiw anomaly determines f_P through the matrix element of the two-photon decay $P^0 \to \gamma \gamma$ [9,10]. The extrapolation to the mass shell is needed to extract the physical value of f_P . In the case of f_{π^0} , the extrapolation is small and the experimental uncertainty in the π^0 lifetime dominates in the uncertainty of f_{π^0} :

$$f_{\pi^0} = 130 \pm 5 \text{ MeV} ,$$
 (10)

which is consistent with isospin symmetry.

For the η and η' , the extrapolation to the mass shell is larger and therefore the dominance of the anomaly on the mass shell is questionable, particularly for the η' ; and η - η' mixing adds to the uncertainty. If the corrections are computed for the octet with the chiral Lagrangian [11], one obtains $f_8 \approx 1.3 f_\pi$ for the decay constant of the I=0 octet state. For the singlet state, if the $\eta \to \gamma \gamma$ and $\eta' \to \gamma \gamma$ decay rates are fitted with the same form as the anomaly indicates, $f_1 \approx f_\pi$ would give a viable fit for $f_8 \approx 1.3 f_\pi$ and the η - η' mixing angle of $\theta_P \approx -20^\circ$. However, because of the arbitrariness even in defining the decay constants, we do not quote numbers for f_η or $f_{\eta'}$ here.

π[±] MASS

The most accurate charged pion mass measurements are based upon x-ray wavelength measurements for transitions in π^- -mesonic atoms. The observed line is the blend of three components, corresponding to different K-shell occupancies. JECKELMANN 94 revisits the occupancy question, with the conclusion that two sets of occupancy ratios, resulting in two different pion masses (Solutions A and B), are equally probable. We choose the higher Solution B since only this solution is consistent with a positive mass-squared for the muon neutrino, given the precise muon momentum measurements now available (DAUM 91, ASSAMAGAN 94, and ASSAMAGAN 96) for the decay of pions at rest. Earlier mass determinations with pi-mesonic atoms may have used incorrect K-shell screening corrections.

Measurements with an error of > 0.005 MeV have been omitted from this Listing.

- 1 JECKELMANN 94 Solution B (dominant 2-electron K-shell occupancy), chosen for consistency with positive $m_{\nu_-}^2$.
- ²ASSAMAGAN 96 measures the μ^+ momentum p_μ in $\pi^+ \to \mu^+ \nu_\mu$ decay at rest to be 29.79200 \pm 0.00011 MeV/c. Combined with the μ^+ mass and the assumption m_{ν_μ} = 0, this gives the π^+ mass above: if $m_{\nu_\mu} > 0$, m_{π^+} given above is a lower limit. Combined instead with m_μ and (assuming *CPT*) the π^- mass of JECKELMANN 94, p_μ gives an upper limit on m_{ν_μ} (see the ν_μ).
- ³ JECKELMANN 94 Solution A (small 2-electron K-shell occupancy) in combination with either the DAUM 91 or ASSAMAGAN 94 pion decay muon momentum measurement yields a significantly negative $m_{\nu_{\mu}}^2$. It is accordingly not used in our fits.
- ⁴ The DAUM 91 value includes the ABELA 84 result. The value is based on a measurement of the μ^+ momentum for π^+ decay at rest, $p_\mu=29.79179\pm0.00053$ MeV, uses $m_\mu=105.658389\pm0.000034$ MeV, and assumes that $m_{\nu_\mu}=0$. The last assumption means
- that in fact the value is a lower limit. ⁵ JECKELMANN 868 gives $m_\pi/m_e=273.12677(71)$. We use $m_e=0.51099906(15)$ MeV from COHEN 87. The authors note that two solutions for the probability distribution of K-shell occupancy fit equally well, and use other data to choose the lower of the two possible π^\pm masses.
- 6 These values are scaled with a new wavelength-energy conversion factor V\ = 1.23984244(37) \times 10^{-6} eV m from COHEN 87. The LU 80 screening correction relies upon a theoretical calculation of inner-shell refilling rates.
- 7 This MARUSHENKO 76 value used at the authors' request to use the accepted set of calibration γ energies. Error increased from 0.0017 MeV to include QED calculation error of 0.0017 MeV (12 ppm).

π^+ — POLARIZATION OF EMITTED μ^+

 $\pi^+ \rightarrow \mu^+ \nu$ Tests the Lorentz structure of leptonic charged weak interactions. DOCUMENT ID TECN CHG COMMENT VALUE CL% • • • We do not use the following data for averages, fits, limits, etc. • • • <(-0.9959) 90 ²⁰ FETSCHER 84 RVUE + 21 ABELA -0.99 ± 0.16 $^{20}\,\mbox{FETSCHER}$ 84 uses only the measurement of CARR 83. 21 Sign of measurement reversed in ABELA 83 to compare with μ^+ measurements. $\pi^{\pm} \to \ell^{\pm} \nu \gamma$ AND $K^{\pm} \to \ell^{\pm} \nu \gamma$ FORM FACTORS

Written by H.S. Pruys (Zürich University).

In the radiative decays $\pi^{\pm} \to \ell^{\pm} \nu \gamma$ and $K^{\pm} \to \ell^{\pm} \nu \gamma$, where ℓ is an e or a μ and γ is a real or virtual photon $(e^+e^-$ pair), both the vector and the axial-vector weak hadronic currents contribute to the decay amplitude. Each current gives a structure-dependent term (SD_V and SD_A) from virtual hadronic states, and the axial-vector current also gives a contribution from inner bremsstrahlung (IB) from the lepton and meson. The IB amplitudes are determined by the meson decay constants f_{π} and f_K [1]. The SD_V and SD_A amplitudes are parameterized in terms of the vector form factor F_V and the axial-vector form factors F_A and R [1-4]:

$$M(\mathrm{SD}_V) = rac{-eG_F V_{qq'}}{\sqrt{2} \ m_P} \epsilon^\mu \ \ell^
u \ F_V \ \epsilon_{\mu
u\sigma au} \ k^\sigma \ q^ au \ ,$$

$$M({\rm SD}_A) = \frac{-ie\,G_F V_{qq'}}{\sqrt{2}\,\,m_P}\,\epsilon^\mu\,\ell^\nu\,\big\{F_A\,[(s\,-\,t)g_{\mu\nu}\,-\,q_\mu\,k_\nu]\,+\,R\,t\,g_{\mu\nu}\big\}\ .$$

Here $V_{qq'}$ is the Cabibbo-Kobayashi-Maskawa mixing-matrix element; ϵ^{μ} is the polarization vector of the photon (or the effective vertex, $\epsilon^{\mu} = (e/t)\overline{u}(p_{-})\gamma^{\mu}v(p_{+})$, of the $e^{+}e^{-}$ pair); $\ell^{\nu} = \overline{u}(p_{\nu})\gamma^{\nu}(1-\gamma_5)v(p_{\ell})$ is the lepton-neutrino current; q and k are the meson and photon four-momenta, with $s = q \cdot k$ and $t = k^2 (= (p_+ + p_-)^2)$; and P stands for π or K. In the analysis of data, the s and t dependence of the form factors is neglected, which is a good approximation for pions [2] but not for kaons [4]. The pion vector form factor F_V^{π} is related via CVC to the π^0 lifetime, $|F_V^{\pi}| = (1/\alpha)\sqrt{2\Gamma_{\pi^0}/\pi m_{\pi^0}}$ [1]. PCAC relates R to the electromagnetic radius of the meson [2,4], $R^P = \frac{1}{3} m_P f_P \langle r_P^2 \rangle$. The calculation of the other form factors, F_A^{π} , F_V^K , and F_A^K , is model dependent [1,4].

When the photon is real, the partial decay rate can be given analytically [1,5]:

$$\frac{d^2\Gamma_{P\to\ell\nu\gamma}}{dxdy} = \frac{d^2\left(\Gamma_{\rm IB} + \Gamma_{\rm SD} + \Gamma_{\rm INT}\right)}{dxdy} \; , \label{eq:continuous}$$

where Γ_{IB} , Γ_{SD} , and Γ_{INT} are the contributions from inner bremsstrahlung, structure-dependent radiation, and their interference, and the Γ_{SD} term is given by

$$\frac{d^2\Gamma_{\rm SD}}{dxdy} = \frac{\alpha}{8\pi} \Gamma_{P \to \ell\nu} \frac{1}{r(1-r)^2} \left(\frac{m_P}{f_P}\right)^2 \times \left[(F_V + F_A)^2 \, \text{SD}^+ + (F_V - F_A)^2 \, \text{SD}^- \right] .$$

Here

$$SD^+ = (x + y - 1 - r)[(x + y - 1)(1 - x) - r]$$
,

$$SD^- = (1 - y + r)[(1 - x)(1 - y) + r]$$
,

where $x = 2E_{\gamma}/m_P$, $y = 2E_{\ell}/m_P$, and $r = (m_{\ell}/m_P)^2$.

In $\pi^{\pm} \to e^{\pm}\nu\gamma$ and $K^{\pm} \to e^{\pm}\nu\gamma$ decays, the interference terms are small, and thus only the absolute values $|F_A + F_V|$ and $|F_A - F_V|$ can be obtained. In $K^{\pm} \to \mu^{\pm} \nu \gamma$ decay, the interference term is important, and thus the signs of F_V and F_A can be obtained. In $\pi^{\pm} \to \mu^{\pm} \nu \gamma$ decay, bremsstrahlung completely dominates. In $\pi^{\pm} \to e^{\pm} \nu e^{+} e^{-}$ and $K^{\pm} \to \ell^{\pm} \nu e^{+} e^{-}$ decays, all three form factors, F_V , F_A , and R, can be determined.

We give the π^{\pm} form factors F_V , F_A , and R in the Listings below. In the K^{\pm} Listings, we give the sum $F_A + F_V$ and difference $F_A - F_V$.

The electroweak decays of the pseudoscalar mesons are investigated to learn something about the unknown hadronic structure of these mesons, assuming a standard V-A structure of the weak leptonic current. The experiments are quite difficult, and it is not meaningful to analyse the results using parameters for both the hadronic structure (decay constants, form factors) and the leptonic weak current (e.g., to add pseudoscalar or tensor couplings to the V-A coupling). Deviations from the V-A interactions are much better studied in purely leptonic systems such as muon decay.

CONSTRAINED FIT INFORMATION

An overall fit to 2 branching ratios uses 4 measurements and one constraint to determine 3 parameters. The overall fit has a χ^2 = 1.9 for 2 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ Γ_i/Γ_{total} . The fit constrains the x_i whose labels appear in this array to sum to one.

 7 This limit applies to all possible u
u' states as well as to other massless, weakly interacting

states. 8 LAM 91 considers the production of right-handed neutrinos produced from the cosmic thermal background at the temperature of about the pion mass through the reaction $\gamma\gamma \to \pi^0 \to \nu\bar{\nu}$. 9 NATALE 91 considers the excess energy-loss rate from SN 1987A if the process $\gamma\gamma \to 0$

 $\pi^0 \to \nu \overline{\nu}$ occurs, permitted if the neutrinos have a right-handed component. As pointed out in LAM 91 (and confirmed by Natale), there is a factor 4 error in the NATALE 91 published result (0.8×10^{-7}) .

π^0 ELECTROMAGNETIC FORM FACTOR

The amplitude for the process $\pi^0 \rightarrow e^+ e^- \gamma$ contains a form factor F(x) at the $\pi^0\gamma\gamma$ vertex, where $x=[m_{e^+e^-}/m_{\pi^0}]^2$. The parameter s in the linear expansion F(x)=1+sx is listed below.

All the measurements except that of BEHREND 91 are in the time-like region of momentum transfer.

14 BEHREND 91 estimates that their systematic error is of the same order of magnitude as their statistical error, and so we have included a systematic error of this magnitude. The value of a is obtained by extrapolation from the region of large space-like momentum transfer assuming vector dominance.

15 TUPPER 83 is a theoretical analysis of FISCHER 78 including 2-photon exchange in the

corrections.

16 The FISCHER 78 error is statistical only. The result without radiation corrections is $+0.05 \pm 0.03$

[b] C parity forbids this to occur as a single-photon process.

 $\Gamma_{20} = \pi^0 \mu^+ \mu^-$

 Γ_{21} $\mu^{+}e^{-} + \mu^{-}e^{+}$

CONSTRAINED FIT INFORMATION

An overall fit to a decay rate and 15 branching ratios uses 40 measurements and one constraint to determine 9 parameters. The overall fit has a $\chi^2 = 31.0$ for 32 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ $\Gamma_i/\Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to

	Mode	Rate (keV)	Scale factor
Γ ₂	2γ	[a] 0.46 ±0.04	1.8

0.56 ±0.16	56	WEINSTEIN	83 CBAL	$e^+e^- \rightarrow e^+e^-\eta$

 $^{1}\,\text{BEMPORAD}$ 67 gives $\Gamma(2\gamma)\,=\,1.21\,\pm\,0.26$ keV assuming $\Gamma(2\gamma)/\Gamma(\text{total})\,=\,0.314.$ Bemporad private communication gives $\Gamma(2\gamma)^2/\Gamma(\text{total}) = 0.318$. Bemporad private communication gives $\Gamma(2\gamma)^2/\Gamma(\text{total}) = 0.380 \pm 0.01$. Not included in average because the uncertainty resulting from the separation of the coulomb and nuclear amplitudes has apparently been underestimated.

$\pi^+\pi^-\gamma$ LEFT-RIGHT ASYMMETRY PARAMETER

Measurements with an error $> 2.0 \times 10^{-2}$ have been omitted.

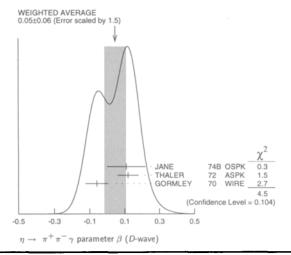

VALUE (units 10-2)	EVTS	DOCUMENT ID	TECN
0.9 ±0.4 OUR AV	ERAGE	-	
1.2 ± 0.6	35k	JANE	74B OSPK
0.5 ± 0.6	36k	THALER	72 ASPK
1.22 ± 1.56	7257	GORMLEY	70 ASPK

$\pi^+\pi^-\gamma$ PARAMETER β (*D*-wave)

Sensitive to a *D*-wave contribution: $dN/d\cos\theta = \sin^2\theta \ (1 + \beta \cos^2\theta)$ ALUE <u>EVTS</u> <u>DOCUMENT ID TECN</u>

0.05 ±0.06 OUR AVERAGE Error includes scale factor of 1.5. See the Ideogram 0.11 ±0.11 JANE 74B OSPK 7 THALER 0.12 ±0.06 72 ASPK -0.060 ± 0.065 7250 GORMLEY 70 WIRE

 $^7{\rm The}$ authors don't believe this indicates ${\it D}{\rm -wave}$ because the dependence of β on the γ energy is inconsistent with theoretical prediction. A $\cos^2\theta$ dependence may also come from P- and F-wave interference.

ENERGY DEPENDENCE OF $\eta \to 3\pi$ DALITZ PLOTS

PARAMETERS FOR $\eta \to \pi^+\pi^-\pi^0$

See the "Note on η Decay Parameters" in our 1994 edition, Phys. Rev. **D50**, 1 August 1994, Part I, p. 1454. The following experiments fit to one or more of the coefficients a, b, c, d, or e for $|\text{matrix element}|^2 = 1 + ay + by^2 + cx + dx^2 + exy$. DOCUMENT ID TECN COMMENT VALUE

19 AUGUSTIN

89 DM2 ¹⁸ Reanalysis of data from HYAMS 73, GRAYER 74, SRINIVASAN 75, and ROSSELET 77 using the interfering amplitude method.

19 Breit-Wigner fit to S-wave intensity measured in $\pi N \to \pi^- \pi^+ N$ on polarized targets. The fit does not include $f_0(980)$.
20 Uses data from ASTON 88, OCHS 73, HYAMS 73, ARMSTRONG 918, GRAYER 74, CASON 83, ROSSELET 77, and BEIER 72B. Coupled channel analysis with flavor symmetry and all light two-pseudoscalars systems.
21 Uses $\pi^0 \pi^0$ data from ANISOVICH 94, AMSLER 94D, and ALDE 95B, $\pi^+ \pi^-$ data from OCHS 73, GRAYER 74 and ROSSELET 77, and $\eta \eta$ data fromANISOVICH 94.
22 The pole is on Sheet III. Demonstrates explicitly that $f_0(400-1200)$ and $f_0(1370)$ are two different poles.

23 Analysis of data from OCHS 73, ESTABROOKS 75, ROSSELET 77, and MUKHIN 80.

THE $\rho(770)$

Written February 1998 by S. Eidelman (Novosibirsk).

Determination of the parameters of the $\rho(770)$ is beset with many difficulties because of its large width. In physical region fits, the line shape does not correspond to a relativistic Breit-Wigner function with a P-wave width, but requires some additional shape parameter. This dependence on parametrization was demonstrated long ago by PISUT 68. Bose-Einstein correlations are another source of shifts in the $\rho(770)$ line shape, particularly in the multiparticle final state systems (LAFFERTY 93).

The same model dependence afflicts any other source of the resonance parameters, such as the energy dependence of the phase shift δ_1^1 or the pole position. It is therefore not surprising that a study of $\rho(770)$ dominance in the decays of the η and η' reveals the need for specific dynamical effects in addition to the $\rho(770)$ pole (BENAYOUN 93, ABELE 97B). Recently BENAYOUN 98 compared the predictions of different Vector Meson Dominance (VMD) based models with the data on the $e^+e^- \to \pi^+\pi^-$ cross section below 1 GeV as well as with the phase and near-threshold behaviour of the timelike pion form factor. They showed that only the model based on a hidden local symmetry (HLS) is able to account consistently for all lowenergy information, if one also requires a point-like coupling $\gamma \pi^+ \pi^-$ which is excluded by common VMD but predicted by HLS.

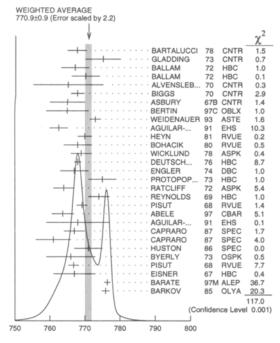

The cleanest determination of the $\rho(770)$ mass and width comes from the e^+e^- annihilation and τ -lepton decays. BARA-TE 97M showed that the charged $\rho(770)$ parameters measured from τ -lepton decays are consistent with those of the neutral one determined from e^+e^- data of BARKOV 85.

[a] The $e^+\,e^-$ branching fraction is from $e^+\,e^- \to \pi^+\pi^-$ experiments only. The $\omega \rho$ interference is then due to $\omega \rho$ mixing only, and is expected to be small. If $e\mu$ universality holds, $\Gamma(\rho^0 \to \mu^+ \mu^-) = \Gamma(\rho^0 \to e^+ e^-)$ \times 0.99785.

CONSTRAINED FIT INFORMATION

An overall fit to the total width and a partial width uses 10 measurements and one constraint to determine 3 parameters. The overall fit has a $\chi^2 = 10.7$ for 8 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left<\delta p_i \delta p_j \right>/(\delta p_i \cdot \delta p_j)$, in percent, from the fit to parameters p_i , including the branching fractions, $x_i \equiv \Gamma_i/\Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to one.

 $^{^1}$ Qbserved by threshold-crossing technique. Mass resolution = 4.8 MeV FWHM. 2 From best-resolution sample of COYNE 71. 3 From $\omega\text{-}\rho$ interference in the $\pi^+\pi^-$ mass spectrum assuming ω width 12.6 MeV.

⁵Observed by threshold-crossing technique. Mass resolution = 4.8 MeV FWHM.

DOCUMENT ID TECN COMMENT

 $(\Gamma_2+\Gamma_4)/(\Gamma_1+\Gamma_3)$

CONSTRAINED FIT INFORMATION

An overall fit to 6 branching ratios uses 20 measurements and one constraint to determine 4 parameters. The overall fit has a $\chi^2=10.3$ for 17 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to one.

CONSTRAINED FIT INFORMATION

An overall fit to the total width, a partial width, 2 combinations of partial widths obtained from integrated cross section, and 16 branching ratios uses 46 measurements and one constraint to determine $\bar{7}$ parameters. The overall fit has a $\chi^2=34.4$ for 40 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left<\delta p_i \delta p_j\right>/(\delta p_i \cdot \delta p_j)$, in percent, from the fit to parameters p_i , including the branching fractions, $x_i \equiv \Gamma_i/\Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to one.

Erom	Invariant	marc	fit
Frioin	invariant	111455	m.

²On sheet II in a 2 pole solution. The other pole is found on sheet III at (963-29i) MeV. ³ Reanalysis of data from HYAMS 73, GRAYER 74, SRINIVASAN 75, and ROSSELET 77 using the Interfering amplitude method.

⁴ At high |t|.

⁵ At low |t|.

⁶ On sheet II in a 4-pole solution, the other poles are found on sheet III at (953–55/) MeV and on sheet IV at (938-35/) MeV.

7 Combined fit of ALDE 958, ANISOVICH 94, AMSLER 94D. 8 On sheet II in a 2 pole solution. The other pole is found on sheet III at (996 – 103/) MeV. ⁹ On sheet II in a 2 pole solution. The other pole is found on sheet III at (797–1851) MeV and can be interpreted as a shadow pole.

10 On sheet II in a 2 pole solution. The other pole is found on sheet III at (978–28/) MeV.

11 From coupled channel analysis.

12 Coupled channel analysis with finite width corrections.

13 Included In AGUILAR-BENITEZ 78 fit.

ჩ₀(980) WIDTH

Width determination very model dependent. Peak width in $\pi\pi$ is about 50 MeV, but decay width can be much larger.

 $14\,{\rm From}$ invariant mass fit. $15\,{\rm On}$ sheet II in a 2 pole solution. The other pole is found on sheet III at (963-29I) MeV. 16 Reanalysis of data from HYAMS 73, GRAYER 74, SRINIVASAN 75, and ROSSELET 77 using the interfering amplitude method. $^{17}{\rm At~high~}|t|.$

 18 At low |t|.

19 On sheet II in a 4-pole solution, the other poles are found on sheet III at (953–55/) MeV and on sheet IV at (938–35/) MeV.

20 Combined fit of ALDE 95B, ANISOVICH 94, 21 On sheet II in a 2 pole solution. The other pole is found on sheet III at (996–103/) MeV. 22 On sheet II in a 2 pole solution. The other pole is found on sheet III at (797–185/) MeV and can be interpreted as a shadow pole.

23 On sheet II in a 2 pole solution. The other pole is found on sheet III at (978–28/) MeV.

²⁴ From coupled channel analysis.

²⁵ Coupled channel analysis with finite width corrections.

26 From coupled channel fit to the HYAMS 73 and PROTOPOPESCU 73 data. With a simultaneous fit to the $\pi\pi$ phase-shifts, inelasticity and to the $K^0_SK^0_S$ invariant mass.

27 Included in AGUILAR-BENITEZ 78 fit.

CONSTRAINED FIT INFORMATION

An overall fit to 9 branching ratios uses 29 measurements and one constraint to determine 4 parameters. The overall fit has a χ^2 = 26.9 for 26 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ Γ_i/Γ_{total} . The fit constrains the x_i whose labels appear in this array to sum to

 $a_1(1260)$

$$I^G(J^{PC}) = 1^-(1^{++})$$

THE $a_1(1260)$

Written March 1998 by S. Eidelman (Novosibirsk).

The main experimental data on the $a_1(1260)$ may be grouped into two classes:

(1) Hadronic Production. This comprises diffractive production with incident π^- (DAUM 80, 81B) and chargeexchange production with low-energy π^- (DANKOWYCH 81, ANDO 92). The 1980's experiments explain the I^GLJ^P = 1+S0+ data using a phenomenological amplitude consisting of a rescattered Deck amplitude plus a direct resonance-production term. They agree on an $a_1(1260)$ mass of about 1270 MeV and a width of 300-380 MeV. ANDO 92 finds rather lower values for the mass (1121 MeV) and width (239 MeV) in a partial-wave analysis based on the isobar model of the $\pi^+\pi^-\pi^0$ system. However, in this analysis, only Breit-Wigner terms were considered.

(2) \(\tau \) decay. Five experiments reported good data on $\tau \rightarrow a_1(1260)\nu_{\tau} \rightarrow \rho\pi\nu_{\tau}$ (RUCKSTUHL 86, SCHMIDKE 86, ALBRECHT 86B, BAND 87, and ACKERSTAFF 97R). They are somewhat inconsistent concerning the $a_1(1260)$ mass, which can, however, be attributed to model-dependent systematic uncertainties (BOWLER 86, ALBRECHT 93C, ACKERSTAFF 97R). They all find a width greater than 400 MeV.

The discrepancies between the hadronic- and τ -decay results have stimulated several reanalyses. BASDEVANT 77, 78 used the early diffractive dissociation and τ decay data and showed that they could be well reproduced with an a_1 resonance mass of 1180 ± 50 MeV and width of 400 ± 50 MeV. Later, BOWLER 86, TORNQVIST 87, ISGUR 89, and IVANOV 91 have studied the process $\tau \to 3\pi\nu_{\tau}$. Despite quite different approaches, they all found a good overall description of the τ -decay data with an $a_1(1260)$ mass near 1230 MeV, consistent with the hadronic data. However, their widths remain significantly larger (400-600 MeV) than those extracted from diffractive-hadronic data. This is also the case with the later OPAL experiment (ACKERSTAFF 97R). In the high statistics analysis of ACKERSTAFF 97R the models of ISGUR 89 and KUHN 90 are used to fit distributions of the 3π invariant mass as well as the 2π invariant mass projections of the Dalitz plot and neither model is found to provide a completely satisfactory description of the data. Another recent high statistics analysis of ABREU 98G obtains good description of the $\tau \to 3\pi$ data using the model of FEINDT 90 which includes the a'_1 meson, a radial excitation of the $a_1(1260)$ meson, with a mass of 1700 MeV and a width of 300 MeV.

BOWLER 88 showed that good fits to both the hadronic and the τ -decay data could be obtained with a width of about 400 MeV. However, applying the same type of analysis to the ANDO 92 data, the low mass and narrow width they obtained with the Breit-Wigner PWA do not change appreciably.

CONDO 93 found no evidence for charge-exchange photoproduction of the $a_1(1260)$ (but found a clear signal of $a_2(1320)$ photoproduction). They show that it is consistent with either an extremely large $a_1(1260)$ hadronic width or with a small radiative width to $\pi\gamma$, which could be accommodated if the a_1 mass is somewhat below 1260 MeV.

CONSTRAINED FIT INFORMATION

An overall fit to the total width, 4 partial widths, a combination of partial widths obtained from integrated cross sections, and 6 branching ratios uses 39 measurements and one constraint to determine 8 parameters. The overall fit has a $\chi^2 = 70.7$ for 32 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta p_i \delta p_j \rangle / (\delta p_i \cdot \delta p_j)$, in percent, from the fit to parameters p_i , including the branching fractions, $x_i \equiv \Gamma_i/\Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to one.

 $\Gamma(\gamma\gamma)$ Γ_{γ} The value of this width depends on the theoretical model used. Unitarised models with scalars give values clustering around \simeq 2.6; without an S-wave contribution, values are systematically higher (typically around 3). Since it is used to average results obtained with variety of models, we prefer to quote our own estimate.

CONSTRAINED FIT INFORMATION

An overall fit to 7 branching ratios uses 14 measurements and one constraint to determine 5 parameters. The overall fit has a χ^2 = 23.7 for 10 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ Γ_i/Γ_{total} . The fit constrains the x_i whose labels appear in this array to sum to

$f_1(1285) \Gamma(I)\Gamma(\gamma\gamma)/\Gamma(total)$

$\Gamma(\eta\pi\pi)\times\Gamma(\gamma\gamma)/\Gamma$	total			Γ ₆ Γ	$\Gamma_{14}/\Gamma = (\Gamma_7 + \Gamma_8)\Gamma_{14}/\Gamma$

CONSTRAINED FIT INFORMATION

< 8

< 2.3

% $\times 10^{-7}$ CL=90%

CL=90%

An overall fit to 5 branching ratios uses 18 measurements and one constraint to determine 4 parameters. The overall fit has a χ^2 = 9.3 for 15 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to one.

NOTE ON SCALAR MESONS

Written March 1998 by S. Spanier (Zürich) and N. Törnqvist (Helsinki).

In contrast to the vector and tensor mesons the identification of the scalar mesons is a long standing puzzle. The problem originates from their large decay widths causing a strong overlap of individual resonances within the same partial wave, and at the same time several decay channels open up within a short mass interval. In addition the $K\overline{K}$ and $\eta\eta$ thresholds produce sharp cusps in the energy dependence of the resonant amplitude. Furthermore, one expects non- $q\overline{q}$ scalar objects like glueballs and multiquark states in the mass range below 1800 MeV. In

spite of these problems the understanding of the scalars has improved considerably during the last few years, because we now have high statistics measurements of different production modes from: $p\bar{p}$ annihilation at rest, πN -scattering on polarized/unpolarized targets, central production, $J/\psi(1S)$ decays, D-meson decays, $\gamma\gamma$ -formation. Furthermore, we have had a strong development of better theoretical models for the reaction amplitudes, which are based on common fundamental principles. These allow direct comparison and interpretation of many different experimental results. Two-body unitarity, analyticity, Lorentz invariance, chiral- and flavor-symmetry constraints have been implemented into the transition amplitudes using different general methods (K-matrix formalism, N/D-method, Dalitz-Tuan ansatz, unitarized quark models with coupled channels, etc.). In general, mass and width parameters of a resonance are found from the position of the nearest pole in the T-matrix (or equivalently the S-matrix) at an unphysical sheet of the complex energy plane: $(E-i\frac{\Gamma}{2})$. It is important to realize, that only in the case of well separated resonances, far away from the opening of decay channels, does a naive Breit-Wigner parametrization (or K-matrix pole parametrization) agree approximately with the T-matrix pole position in the amplitude. Breit-Wigner parameters are sensitive to background, nearby thresholds etc., while T-matrix poles depend only on the limitations of the theoretical model.

In this note we discuss all light scalars organized in the listings under the entries (I=1/2) $K_0^{\star}(1430)$, (I=1) $a_0(980)$, $a_0(1450)$, and (I=0) σ or $f_0(400-1200)$, $f_0(980)$, $f_0(1370)$, and $f_0(1500)$. The list is minimal and does not necessarily exhaust the list of actual resonances.

The I=1/2 states

The $K_0^\star(1430)$ (ASTON 88) is the least controversial of the light scalar mesons. The phase shift rises smoothly from threshold, passes 90° at 1350 MeV, and then continues to rise to about 170° at 1600 MeV at the first important inelastic threshold $K\eta'(958)$. Thus it behaves like a single broad, nearly elastic resonance. ABELE 98 finds for the T-matrix pole parameters, $m\approx 1430$ MeV and $\Gamma\approx 290$ MeV, while the K-matrix pole of the same data is at about 1340 MeV using $K\overline{K}\pi$ in $p\overline{p}$ annihilation at rest. This agrees with the LASS (ASTON 88) determination. The scattering length near threshold is $a=2.56\pm0.20~({\rm GeV/c})^{-1}$ (ABELE 98).

The I=1 states

Two states are established, the well-known $a_0(980)$, and the $a_0(1450)$ found by Crystal Barrel (AMSLER 94D). Independently of any model about the nature of the $a_0(980)$ the $K\overline{K}$ component in the wave function of the state must be large: the $a_0(980)$ lies very close to the opening of the $K\overline{K}$ channel to which it couples strongly. This gives an important cusplike behaviour in the resonant amplitude. Hence, its mass and width parameters are strongly distorted. To reveal its true coupling constants a coupled channel model with energy-dependent

widths and mass shift contributions must be applied. A naive Breit-Wigner form is certainly inadequate.

The relative coupling $K\overline{K}/\pi\eta$ in previous editions was determined only indirectly from $f_1(1285)$ (CORDEN 78, DEFOIX 72) or $\eta(1410)$ decays (BAI 90C, BOLTON 92B, AMSLER 95F) or from the line shape observed in the $\pi\eta$ decay mode (FLATTE 76, AMSLER 94D, BUGG 94, JANSSEN 95). From analysis of $\pi\pi\eta$ and $K\overline{K}\pi$ final states of $\overline{p}p$ annihilation at rest a relative production ratio $B(\overline{p}p\to\pi a_0;a_0\to K\overline{K})/B(\overline{p}p\to\pi a_0;a_0\to\pi\eta)=0.23\pm0.05$ is obtained by ABELE 98. Tuning of the couplings in a coupled channel formula to reproduce the production ratio for the integrated mass distributions gives a relative branching ratio $\Gamma(K\overline{K})/\Gamma(\pi\eta)=1.03\pm0.14$. Analysis of $p\overline{p}$ annihilation data also found that the width determined from the T-matrix pole is 92 ± 8 MeV, while the observed width of the peak in the $\pi\eta$ mass spectrum is about 45 MeV.

In our table the mass position comes out very consistently near 980 MeV in all measurements, but the width takes values between 50 and 300 MeV, because of the differences in the models used in the analyses. Using the relative production ratio and the observed 2-photon generation of $a_0(980)$ one can calculate the 2-photon width of $a_0(980)$ to be $\Gamma_{\gamma\gamma}=(0.30\pm0.10)$ keV, which is similar to that of $f_0(980)$.

The $a_0(1450)$ is seen by the Crystal Barrel experiment in its $\pi\eta$, $K\overline{K}$, and $\pi\eta'(958)$ decay modes. The relative couplings to the different final states are found to be close to SU(3)-flavor predictions for an ordinary $q\overline{q}$ meson.

The I=0 states

The I=0 $J^{PC}=0^{++}$ sector is the most complex one both experimentally and theoretically. The data have been obtained from $\pi\pi$, $K\overline{K}$, $\eta\eta$, 4π , and $\eta\eta'(958)$ systems produced in S-waves by nonstrange initial states. From the high statistics data sets collected from $\overline{p}p$ annihilation at rest into $\pi^0 f_0$'s, where the f_0 decay into the above mentioned channels, one concludes that at least four poles are needed in the mass range from $\pi\pi$ threshold to about 1600 MeV. The claimed isoscalar resonances are found under the separate entries σ or $f_0(400-1200)$, $f_0(980)$, $f_0(1370)$, and $f_0(1500)$.

Below 1100 MeV the important data come from $\pi\pi$ and $K\overline{K}$ final states. Information on the $\pi\pi$ S-wave phase shift $\delta_J^I = \delta_0^0$ was extracted already 20 years ago from πN scattering with unpolarized (GRAYER 74) and polarized target (BECKER 79) and near threshold from K_{e4} -decay (ROSSELET 77). The $\pi\pi$ S-wave inelasticity is not accurately known, and the reported $\pi\pi \to K\overline{K}$ cross sections (WETZEL 76, POLYCHRONAKOS 79, COHEN 80, ETKIN 82B) may have large uncertainties. Recently, the πN data (GRAYER 74, BECKER 79) have been reevaluated in a combined partial-wave analysis (KAMINSKI 97). Out of four, two relevant solutions are found with the S-wave phase-shift rising slower than the P-wave $[\rho(770)]$, which is used as reference. One of these corresponds to the well known "down" solution of (GRAYER 74), the other "up"

solution shows a decrease of the modulus in the mass interval 800-980 MeV. Both solutions exhibit at 1 GeV a sudden drop in the modulus and in the inelasticity parameter η_0^0 , which is due to the appearance of $f_0(980)$ very close to the opening of the $K\overline{K}$ -threshold. The phase shift δ_0^0 rises smoothly up to this point where it jumps by 120° (in the "up") or 140° (in the "down"-solution) to reach 230°, from which point both continue to rise slowly.

SVEC 97 using data on πN (polarized) producing the $\pi\pi$ system from 600 to 900 MeV suggests that there exists a narrow state at 750 MeV with a small width of 100 to 200 MeV. Such a solution is also found by (KAMINSKI 97) using the CERN-Munich(-Cracow) data considering both π -and $a_1(1260)$ -exchange in the reaction amplitudes. However, they show that unitarity is violated for this solution; therefore a narrow light f_0 state below 900 MeV seems to be excluded. Also, the $2\pi^0$ invariant mass spectra of $p\bar{p}$ annihilation at rest (AMSLER 95B, ABELE 96) and central collision (ALDE 97) do not show a narrow resonance below 900 MeV, and these data are consistently described with the standard "down" solution (GRAYER 74, KAMINSKI 97), which allows for the existence of the broad ($\Gamma \approx 500$ MeV) σ listed under $f_0(400-1200)$.

For low-energy $\pi\pi$ scattering the predicted Weinberg scattering length for the isoscalar S-wave a_0^0 is 0.16, chiral perturbation theory including one-loop corrections increases this value to $a_0^0\approx 0.20$ while the slope parameter is $b_0^0\approx 0.18$ (GASSER 83, RIGGENBACH 91). With two-loop corrections one still gets a little larger value $a_0^0=0.217$ (BIJNENS 96), but electromagnetic corrections reduce this value to 0.208 (MALT-MAN 97). Experimentally the region near the $\pi\pi$ threshold is difficult to investigate. Current values of these quantities are $a_0^0=0.26\pm 0.05$ and $b_0^0=0.25\pm 0.03$ (NAGELS 79).

An experimentally very well studied meson resonance is the $f_0(1500)$ seen by the Crystal Barrel experiment in five decay modes: $\pi\pi$, $K\overline{K}$, $\eta\eta$, $\eta\eta'(958)$, and 4π (AMSLER 95D, ABELE 96, ABELE 98). Due to its interference with the $f_0(1370)$ the peak attributed to $f_0(1500)$ can appear shifted in mass to 1590 MeV, where it was observed by the GAMS collaboration (BINON 83) in the $\eta\eta$ mass spectrum. They applied a sum of Breit-Wigner functions for the dynamics in the resonant amplitude. In central production (ANTINORI 95) a peak at 1450 MeV having a width of 60 MeV can be interpreted as the coherent sum of $f_0(1370)$ and $f_0(1500)$. The $\overline{p}p$ and $\overline{n}p/\overline{p}n$ reactions show a single enhancement at 1400 MeV in the invariant 4π mass (GASPERO 93, ADAMO 93, AMSLER 94, ABELE 96). In the $5\pi^0$ channel (ABELE 96) this structure was resolved into $f_0(1500)$ and $f_0(1370)$, found at a somewhat lower mass around 1300 MeV. An additional scalar in mass above 1700 MeV had to be introduced in the re-analysis of the reaction $J/\psi(1S) \rightarrow \gamma 4\pi$ (BUGG 95). According to these investigations the $f_0(1500)$ decay proceeds dominantly via $\sigma\sigma \to 4\pi$ where σ denotes the $\pi\pi$ S-wave below $K\overline{K}$ threshold. The $K\overline{K}$ decay of $f_0(1500)$ is suppressed (ABELE 98).

 $f_0(1370)$

The determination of the $\pi\pi$ coupling of $f_0(1370)$ is inhibited by the strong overlap with the broad background from the $f_0(400-1200)$. Since it does not show up prominently in the 2π spectra its mass and width are difficult to fix. A resonance band in the $\pi^0\eta\eta$ final state of $p\bar{p}$ annihilation at rest (AM-SLER 95D) is attributed to it. Data on $\pi\pi \to K\overline{K}$ show an enhancement at around 1300 MeV in the scalar partial wave (WETZEL 76, COHEN 80, POLYCHRONAKOS 79, COSTA 80, LONGACRE 86). According to the phase shift the resonance is found around 1400 MeV (COHEN 80), while a recent re-analysis (BUGG 96) claims a trend to lower mass. Further information about the $K\overline{K}$ decay of the scalars are most welcome, in particular those which clearly distinguish between the I = 0 and the I = 1 system.

In the analysis of (ANISOVICH 97, 97C) using data of πN and $\bar{p}p$ annihilation reactions a fifth pole at 1530 MeV about 1 GeV off the physical region is added.

Interpretation

Almost every model on the scalar states agrees that the $K_0^*(1430)$ is the 1 3P_0 quark model $s\overline{u}$ or $s\overline{d}$ state, but the other scalars remain controversial.

The $f_0(980)$ and $a_0(980)$ are often interpreted as being multiquark states (JAFFE 77) or $K\overline{K}$ bound states (WEINSTEIN 90). This picture is supported by their 2-photon widths which are smaller than expected for $q\bar{q}$ mesons, if one neglects the $K\bar{K}$ component. Using a simple quark model one is led to put the $f_0(1370)$, $a_0(1450)$, and $K_0^*(1430)$ into the same SU(3) flavor nonet being the $(u\overline{u} + d\overline{d})$, $u\overline{d}$ and the $u\overline{s}$ state, respectively. In this picture the $s\overline{s}$ state is missing experimentally. Compared with these states the $f_0(1500)$ is too narrow to be the isoscalar partner, and too light to be the first radial excitation. A non- $q\bar{q}$ (gluonium) interpretation seems likely (CLOSE 97B). See our Note on Non- $q\bar{q}$ states. As to the light $f_0(400-1200)$ structure it is far from the physical region and its interpretation in terms of a $q\bar{q}$ state or cross channel effect remains open. Such a state is often referred to as the σ or $f_0(500)$ meson.

More detailed models exist, which include more theoretical input at least phenomenologically. One such unitarized quark model with coupled channels can understand 6 of the light scalars as different unitarized manifestations of bare quarks model ${}^{3}P_{0}$ $q\overline{q}$ states (TORNQVIST 82, 95, 96). The σ , f_{0} (980), $f_0(1370)$, $a_0(980)$, $a_0(1450)$, and $K_0^{\star}(1430)$ are described as unitarized remnants of strongly shifted and mixed $q\bar{q}$ 1 $^{3}P_{0}$ states using 6 parameters. Here the σ is the $(u\overline{u} + d\overline{d})$ state and at the same time also the chiral partner of the π . The $f_0(980)$ and $f_0(1370)$ as well as $a_0(980)$ and $a_0(1450)$ are two manifestations of the same $q\bar{q}$ state. The interpretation of $f_0(1500)$ in this scheme is an open question; it can be a glueball or a deuteron-like $\rho\rho + \omega\omega$ bound state. For other models and more details discussing the light scalar resonances see also (AU 87, MORGAN 93, ZOU 94B, JANSSEN 95, CLOSE 92, ANISOVICH 97, 97B, 97C, 97D, BEVEREN 86, KAMINSKI 94, 97B, OLLER 97, ISHIDA 96).

THE $\eta(1440)$, $f_1(1420)$, AND $f_1(1510)$

Written March 1998 by M. Aguilar-Benitez (CIEMAT, Madrid) and C. Amsler (Zürich).

The first observation of $\eta(1440)$ was made in $p\overline{p}$ annihilation at rest into $\eta(1440)\pi^+\pi^-$, $\eta(1440) \to K\overline{K}\pi$ (BAIL-LON 67). This state was reported to decay through $a_0(980)\pi$ and $K^*(892)\overline{K}$ with roughly equal contributions. The $\eta(1440)$ has also been observed in radiative $J/\psi(1S)$ decay to $K\overline{K}\pi$ (SCHARRE 80, EDWARDS 82E, AUGUSTIN 90).

The $f_i(1420)$, decaying to $K^*\overline{K}$ was reported in π^-p reactions at 4 GeV/c (DIONISI 80). However, later analyses found that the 1400-1500 MeV region is far more complex. In π^-p experiments (CHUNG 85, REEVES 86, BIRMAN 88) reported 0^{-+} with a dominant $a_0(980)\pi$ contribution to $K\overline{K}\pi$. The π^-p data of RATH 89 at 21 GeV/c suggest the presence of two pseudoscalars decaying to $K\overline{K}\pi$, one around 1410 MeV decaying through $a_0(980)\pi$ and the other around 1470 MeV, decaying to $K^*\overline{K}$. A reanalysis of the MARK III data in radiative $J/\psi(1S)$ decay to $K\overline{K}\pi$ (BAI 90C) also claims the existence of two pseudoscalars in the 1400-1500 MeV range, the lower mass state decaying through $a_0(980)\pi$ and the higher mass state decaying via $K^*\overline{K}$. In addition, $f_1(1420)$ is observed to decay into $K^*\overline{K}$.

In $\pi^- p \to \eta \pi \pi n$ charge-exchange reactions at 8-9 GeV/c the $\eta\pi\pi$ mass spectrum is dominated by $\eta(1440)$ and $\eta(1295)$ (ANDO 86, FUKUI 91C) and at 100 GeV ALDE 97B report $\eta(1295)$ and $\eta(1440)$ decaying to $\eta \pi^0 \pi^0$ with a weak $f_1(1285)$ and no evidence for $f_1(1420)$.

²Using data published by ANTONELLI 92.

⁴Using data published by ANTONELLI 92.

An experiment in $\overline{p}p$ annihilation at rest into $K\overline{K}3\pi$ (BERTIN 95) reports two pseudoscalars with decay properties similar to BAI 90C, although the lower state shows, apart from $a_0(980)\pi$, a large contribution from the direct decay $\eta(1440) \to K\overline{K}\pi$. We note that the data from AUGUSTIN 92 also suggest two states but their intermediate states, $a_0(980)\pi$ and $K^*\overline{K}$, are reversed relative to BAI 90C.

In $J/\psi(1S)$ radiative decay $\eta(1440)$ decays to $K\overline{K}\pi$ through $a_0(980)\pi$ and hence a signal is also expected in the $\eta\pi\pi$ mass spectrum. This has indeed been observed by MARK III in $\eta\pi^+\pi^-$ (BOLTON 92B) which report a mass of 1400 MeV, in line with the existence of a low mass pseudoscalar in the $\eta(1440)$ structure, decaying to $a_0(980)\pi$. This state is also observed in $\overline{p}p$ annihilation at rest into $\eta\pi^+\pi^-\pi^0\pi^0$ where it decays to $\eta\pi\pi$ (AMSLER 95F). The intermediate $a_0(980)\pi$ accounts for roughly half of the $\eta\pi\pi$ rate, in accord with MARK III (BOLTON 92B) and DM2 (AUGUSTIN 90). However, ALDE 97B reports only a very small contribution of $a_0(980)\pi$.

One of these two pseudoscalars could be the first radial excitation of the η' , with $\eta(1295)$ the first radial of the η . Ideal mixing suggested by the $\eta(1295)$ and $\pi(1300)$ mass degeneracy would then imply that the second isoscalar in the nonet is mainly $s\bar{s}$ and hence couples to $K^*\bar{K}$, in accord with observations for the upper $\eta(1440)$ state. This scheme then favors an exotic interpretation of the lower state, perhaps gluonium mixed with $q\bar{q}$ (CLOSE 97B) or a bound state of gluinos (FARRAR 96). The gluonium interpretation is, however, not favoured by lattice gauge theories, which predict the 0^{-+} state above 2 GeV (BALI 93).

Axial (1^{++}) mesons are not observed in $\overline{p}p$ annihilation at rest in liquid hydrogen which proceeds dominantly through S-wave annihilation. However, in gaseous hydrogen P-wave annihilation is enhanced and, indeed, BERTIN 97 report $f_1(1420)$ decaying to $K^*\overline{K}$ in gaseous hydrogen, while confirming their earlier evidence for two pseudoscalars (BERTIN 95).

In $\gamma\gamma$ fusion from e^+e^- annihilations, a signal around 1420 MeV is seen in single-tag events (GIDAL 87B, AIHARA 88B, BEHREND 89, HILL 89) where one of the two photons is off-shell. However, it is totally absent in the untagged events where both photons are real. This points to a spin 1 object which is not produced by two real (massless) photons (Yang-Landau theorem). The 2γ decays also implies C=+1. For the parity, AIHARA 88C and BEHREND 89 both find angular distributions with positive parity preferred, but negative parity cannot be excluded.

The $f_1(1420)$ is definitively observed in $K\overline{K}\pi$ in pp central production at 300 and 450 GeV, together with $f_1(1285)$. The latter decays via $a_0(980)\pi$ and the former only via $K^*\overline{K}$, while $\eta(1440)$ is absent (ARMSTRONG 89, BARBERIS 97C). The $K_SK_S\pi^0$ decay mode of $f_1(1420)$ establishes unambiguously that C=+1. On the other hand, there is no evidence for any state decaying to $\eta\pi\pi$ around 1400 MeV and hence the $\eta\pi\pi$ mode of $f_1(1420)$ is suppressed (ARMSTRONG 91B).

We now turn to the experimental evidence for $f_1(1510)$. Two states, $f_1(1420)$ and $f_1(1510)$, decaying to $K^*\overline{K}$, compete for the $s\overline{s}$ assignment in the 1^{++} nonet. The $f_1(1510)$ was seen in $K^-p \to \Lambda K\overline{K}\pi$ at 4 GeV/c (GAVILLET 82) and at 11 GeV/c (ASTON 88C). Evidence is also reported in π^-p at 8 GeV/c, based on the phase motion of the 1^{++} $K^*\overline{K}$ wave (BIRMAN 88).

The absence of $f_1(1420)$ in K^-p (ASTON 88C) argues against $f_1(1420)$ being the $s\bar{s}$ member of the 1⁺⁺ nonet. However, $f_1(1420)$ has been reported in K^-p but not in $\pi^- p$ (BITYUKOV 84) while two experiments do not observe $f_1(1510)$ in K^-p (BITYUKOV 84, KING 91). It is also not seen in radiative $J/\psi(1S)$ decay (BAI 90C, AUGUSTIN 92), central collisions (BARBERIS 97C), nor in $\gamma\gamma$ collisions (AI-HARA 88C), although and surprisingly for an ss state, a signal is reported in 4π decays (BAUER 93B). These facts led to the conclusion that $f_1(1510)$ is not well established and that its assignment as $s\bar{s}$ member of the 1⁺⁺ nonet is premature (CLOSE 97D). The Particle Data Group agrees and has removed this state from the Summary Table. Assigning instead $f_1(1420)$ to the 1⁺⁺ nonet one finds a nonet mixing angle of \sim 50° (CLOSE 97D). This is derived from the mass formula and from $f_1(1285)$ radiative decays to $\phi\gamma$ (BITYUKOV 88) and $\rho\gamma$ (AMELIN 95).

Arguments favoring $f_1(1420)$ being a hybrid $q\bar{q}g$ meson or a four-quark state are put forward by ISHIDA 89 and by CALDWELL 90, respectively, while LONGACRE 90 argues that this particle is a molecular state formed by the π orbiting in a P-wave around an S-wave $K\bar{K}$ state.

Summarizing, there is strong evidence for $f_1(1420)$, mostly produced in central collisions and decaying to $K^*\overline{K}$, and for $\eta(1440)$ mostly produced in radiative $J/\psi(1S)$ decay and $\overline{p}p$ annihilation at rest, decaying to $K^*\overline{K}$ and $a_0(980)\pi$. Confusion remains as to which states are observed in π^-p interactions. The $f_1(1510)$ is not well established. Furthermore, there are experimental indications for the presence of two pseudoscalars in the $\eta(1440)$ structure. Accordingly, the Particle Data Group has split the $K\overline{K}\pi$ entry for $\eta(1440)$ into $a_0(980)\pi$ and $K^*\overline{K}$.

CONSTRAINED FIT INFORMATION

An overall fit to the total width, 2 partial widths, a combination of partial widths obtained from integrated cross sections, and 3 branching ratios uses 14 measurements and one constraint to determine 5 parameters. The overall fit has a $\chi^2 = 11.4$ for 10

The following off-diagonal array elements are the correlation coefficients $\left<\delta p_i \delta p_j \right>/(\delta p_i \cdot \delta p_j)$, in percent, from the fit to parameters p_i , including the branching fractions, $x_i \equiv \Gamma_i/\Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this

CONSTRAINED FIT INFORMATION

An overall fit to 4 branching ratios uses 6 measurements and one constraint to determine 4 parameters. The overall fit has a $\chi^2 =$ 1.9 for 3 degrees of freedom.

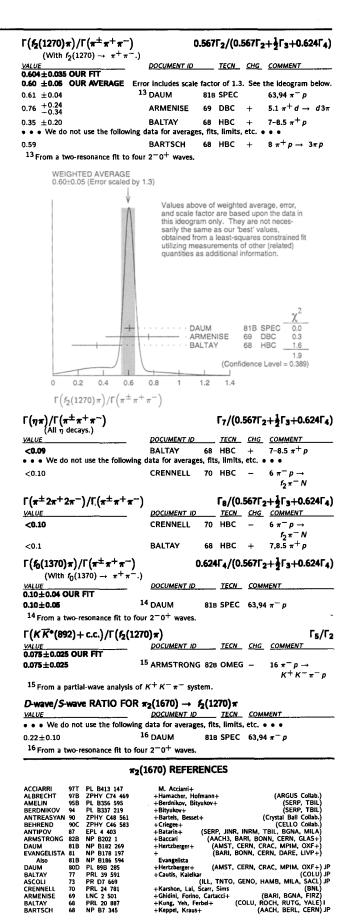

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ $\Gamma_i/\Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to

 $^{^{1}}$ Mass errors enlarged by us to $\Gamma/\sqrt{N};$ see the note with the $K^{*}(892)$ mass.

² Uses same data as HYAMS 75. ³ From a phase shift solution containing a $f_2'(1525)$ width two times larger than the $K\overline{K}$

result.

From phase-shift analysis. Error takes account of spread of different phase-shift solutions.

 $\rho_3(1690)$

¹⁵ Width errors enlarged by us to $4\Gamma/\sqrt{N}$; see the note with the $K^*(892)$ mass. 16 Uses same data as HYAMS 75 and BECKER 79. 17 From a phase shift solution containing a $I_2'(1525)$ width two times larger than the $K\overline{K}$

result.

18 From phase-shift analysis. Error takes account of spread of different phase-shift solutions.

CONSTRAINED FIT INFORMATION

An overall fit to 5 branching ratios uses 10 measurements and one constraint to determine 4 parameters. The overall fit has a $\chi^2=$ 14.7 for 7 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left\langle \delta x_i \delta x_j \right\rangle / (\delta x_i \cdot \delta x_j),$ in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\rm total}.$ The fit constrains the x_i whose labels appear in this array to sum to one.

 $\rho(1700)$

$$I^{G}(J^{PC}) = 1^{+}(1^{-})$$

THE $\rho(1450)$ AND THE $\rho(1700)$

Written March 1998 by S. Eidelman (Novosibirsk) and J. Hernandez (Valencia).

In our 1988 edition, we replaced the $\rho(1600)$ entry with two new ones, the $\rho(1450)$ and the $\rho(1700)$, because there was emerging evidence that the 1600-MeV region actually contains two ρ -like resonances. ERKAL 86 had pointed out this possibility with a theoretical analysis on the consistency of 2π and 4π electromagnetic form factors and the $\pi\pi$ scattering length. DONNACHIE 87, with a full analysis of data on the 2π and 4π final states in e^+e^- annihilation and photoproduction reactions, had also argued that in order to obtain a consistent picture two resonances were necessary. The existence of $\rho(1450)$ was supported by the analysis of $\eta\rho^0$ mass spectra obtained in photoproduction and e^+e^- annihilation (DONNACHIE 87B) as well as that of $e^+e^- \to \omega\pi$ (DONNACHIE 91).

The analysis of DONNACHIE 87 was further extended by CLEGG 88, 94 to include new data on 4π systems produced in e^+e^- annihilation and in τ decays (τ decays to 4π and e^+e^- annihilation to 4π can be related by the Conserved Vector Current assumption). These systems were successfully analyzed using interfering contributions from two ρ -like states, and from the tail of the $\rho(770)$ decaying into two-body states. While specific conclusions on $\rho(1450) \to 4\pi$ were obtained, little could be said about the $\rho(1700)$.

An analysis by CLEGG 90 of 6π mass spectra from e^+e^- annihilation and from diffractive photoproduction provides evidence for two ρ mesons at about 2.1 and 1.8 GeV that decay strongly into 6π states. While the former is a candidate for a new resonance ($\rho(2150)$), the latter could be a manifestation of the $\rho(1700)$ distorted by threshold effects.

Independent evidence for two 1⁻ states is provided by KILLIAN 80 in 4π electroproduction at $\langle Q^2 \rangle = 1$ (GeV/c)², and by FUKUI 88 in a high-statistics sample of the $\eta\pi\pi$ system in π^-p charge exchange.

This scenario with two overlapping resonances is supported by other data. BISELLO 89 measured the pion form factor in the interval 1.35–2.4 GeV and observed a deep minimum around 1.6 GeV. The best fit was obtained with the hypothesis of ρ -like resonances at 1420 and 1770 MeV with widths of about 250 MeV. ANTONELLI 88 found that the $e^+e^- \to \eta \pi^+ \pi^-$ cross section is better fitted with two fully interfering Breit-Wigners, with parameters in fair agreement with those of DONNACHIE 87 and BISELLO 89. These results can be considered as a confirmation of the $\rho(1450)$.

Decisive evidence for the $\pi\pi$ decay mode of both $\rho(1450)$ and $\rho(1700)$ came from recent results in $\overline{p}p$ annihilation at rest (ABELE 97). According to ABELE 98 these resonances also possess a $K\overline{K}$ decay mode. High statistics studies of the $\tau \to \pi\pi\nu_{\tau}$ decay also require the $\rho(1450)$ (BARATE 97M, URHEIM 97), but are not sensitive to the $\rho(1700)$ because it is too close to the τ mass.

The structure of these ρ states is not yet completely clear. BARNES 97 and CLOSE 97C claim that $\rho(1450)$ has a mass consistent with radial 2S, but its decays show characteristics of hybrids and suggest that this state may be a 2S-hybrid mixture.

We also list under the $\rho(1450)$ the $\phi\pi$ state with $J^{PC}=1^{--}$ or C(1480) observed by BITYUKOV 87. While ACHASOV 96B shows that it may be a threshold effect, CLEGG 88 and LANDSBERG 92 suggest two independent vector states with this decay mode. Note, however, that C(1480) in its $\phi\pi$ decay mode was not confirmed by e^+e^- (DOLINSKY 91, BISELLO 91C) and $\bar{p}p$ (ABELE 97H) experiments.

Several observations on the $\omega\pi$ system in the 1200-MeV region (FRENKIEL 72, COSME 76, BARBER 80C, ASTON 80C, ATKINSON 84C, BRAU 88, AMSLER 93B) may be interpreted in terms of either $J^P=1^ \rho(770)\to\omega\pi$ production (LAYSSAC 71) or $J^P=1^+$ $b_1(1235)$ production (BRAU 88, AMSLER 93B). We argue that no special entry for a $\rho(1250)$ is needed. The LASS amplitude analysis (ASTON 91B) showing evidence for $\rho(1270)$ is preliminary and needs confirmation. For completeness, the relevant observations are listed under the $\rho(1450)$.

 $f_J(1710)$

 $I^G(J^{PC}) = 0^+(\text{even}^{++})$

THE $f_J(1710)$

Written March 1998 by M. Doser (CERN).

The $f_J(1710)$ is seen in the radiative decay $J/\psi(1S) \rightarrow \gamma f_J(1710)$; therefore C=+1. It decays into 2η and $K_S^0 K_S^0$, which implies $I^G J^{PC}=0^+(\text{even})^{++}$. The spin of the $f_J(1710)$ is controversial. Combined amplitude analyses of the K^+K^- , K_SK_S and $\pi^+\pi^-$ systems produced in $J/\psi(1S)$ radiative decay (in recent and some earlier unpublished analyses by the Mark III Collaboration) find a large spin-0 component, as well as reproducing known parameters of the $f_2(1270)$ and $f_2'(1525)$. A recent reanalysis (BUGG 95) of the 4π channel from MARK III, allowing both $\rho\rho$ and two $\pi\pi$ S waves, finds two states, a 0^{++} at ~ 1750 MeV and a 2^{++} at ~ 1620 MeV. Earlier analyses of the $\rho\rho$ final state (BISELLO 89B, BALTRU-SAITIS 86B) found only pseudoscalar activity in the $f_J(1710)$

region, but considered only the process $J/\psi(1S) \to \gamma\rho\rho$. In contrast, a spin 2 was found for the $f_J(1710)$ in earlier analyses of the $\eta\eta$ (BLOOM 83) or K^+K^- (BALTRUSAITIS 87) systems based on less statistics. More recently, an analysis of the K^+K^- channel finds indications for a lower mass tensor as well as a higher mass scalar state (BAI 96C).

In pp central production at 300 GeV/c in both K^+K^- and $K_S^0K_S^0$, $f_J(1710)$ is definitely spin 2 (ARMSTRONG 89D). More recent analyses with greater statistics (E690 Collaboration, unpublished) are, however, not able to differentiate between spin 0 and 2. Generally, analyses preferring spin 2 concentrate on angular distributions in the $f_J(1710)$ region, and do not include possible interferences or distortion due to the nearby $f_Z'(1525)$.

The $f_J(1710)$ is also observed in $K\overline{K}$ (FALVARD 88) in $J/\psi(1S) \to \omega K\overline{K}$ and $J/\psi(1S) \to \phi K\overline{K}$, but with no spin-parity analysis. ARMSTRONG 93C also sees a broad peak at 1747 MeV in $p\overline{p}$ annihilation into $\eta\eta$, which may be the $f_J(1710)$. This resonance is not observed in the hypercharge-exchange reactions $K^-p \to K_S^0K_S^0\Lambda$ (ASTON 88D) and $K^-p \to K_S^0K_S^0\Lambda^*$ (BOLONKIN 86).

A partial-wave analysis of the $K_S^0K_S^0$ system in $\pi^-p \to K_S^0K_S^0n$ (BOLONKIN 88) finds a D_0 -wave behavior ($J^{PC}=2^{++}$) near 1700 MeV, but the width (~ 30 MeV) is much smaller than those observed in $J/\psi(1S)$ decays and in hadroproduction. The 0^{++} wave shows, however a broad enhancement around 1720 MeV.

 $f_J(2220)$

 $f_J(2220)$

$$I^{G}(J^{PC}) = 0^{+}(2^{++} \text{ or } 4^{++})$$

OMITTED FROM SUMMARY TABLE

THE $f_{J}(2220)$

Written March 1998 by M. Doser (CERN).

This state has been seen in $J/\psi(1S)$ radiative decay into $K\overline{K}$ (K^+K^- and $K_S^0K_S^0$ modes seen (BALTRUSAITIS 86D, BAI 96B)). An upper limit from DM2 for these modes (AUGUSTIN 88) is at the level at which observation is claimed. There are also indications for further decay modes ($\pi^+\pi^-$ and $\overline{p}p$) in the same production process (BAI 96B), although again at the level at which previous upper limits had been obtained (BALTRUSAITIS 86D); also seen in $\eta\eta$ (ALDE 86B), $K_S^0K_S^0$ (ASTON 88D) and in K^+K^- (ALDE 88F), albeit with very low statistics. Its J^{PC} is determined from the angular distributions of these observations.

It is not seen in Υ radiative decays (BARU 89), B inclusive decays (BEHRENDS 84), nor in $\gamma\gamma$ (GODANG 97). It is also not seen in formation in $\overline{p}p \to K^+K^-$ (BARDIN 87, SCULLI 87), in $\overline{p}p \to K_SK_S$ (BARNES 93, EVANGELISTA 97), nor in $\overline{p}p \to \pi^+\pi^-$ (HASAN 96). The upper limit in $\overline{p}p$ formation can be related to the claimed decay into $\overline{p}p$ to give a lower limit for the process $J/\psi(1S) \to \gamma f_J(2220)$ of $\sim 2.5 \times 10^{-3}$. Such a signal should be visible in the inclusive photon spectrum (BLOOM 82). The limit also leads to the conclusion that two-body final states constitute only a small fraction of all decay modes of the $f_J(2220)$. Observation of further decay modes would be very desirable.

X(1900-3600)

OMITTED FROM SUMMARY TABLE

THE X(1900-3600) REGION

This high-mass region is covered nearly continuously with evidence for peaks of various widths and decay modes. As no satisfactory grouping into particles is yet possible, we list together in order of increasing mass all the Y=0 bumps above 1900 MeV that are coupled neither to $\overline{N}N$ nor to e^+e^- .

X(1900-3600) MASSES AND WIDTHS

We do not use the following data for averages, fits, limits, etc.

THE CHARGED KAON MASS

Revised 1994 by T.G. Trippe, (LBNL).

The average of the six charged kaon mass measurements which we use in the Particle Listings is

$$m_{K^{\pm}} = 493.677 \pm 0.013 \text{ MeV (S} = 2.4),$$
 (1)

where the error has been increased by the scale factor S. The large scale factor indicates a serious disagreement between different input data. The average before scaling the error is

$$m_{K^{\pm}} = 493.677 \pm 0.005 \text{ MeV}$$
,
 $\chi^2 = 22.9 \text{ for 5 D.F., Prob.} = 0.04\%$, (2)

where the high χ^2 and correspondingly low χ^2 probability further quantify the disagreement.

The main disagreement is between the two most recent and precise results,

$$m_{K^{\pm}} = 493.696 \pm 0.007 \text{ MeV}$$
 DENISOV 91
 $m_{K^{\pm}} = 493.636 \pm 0.011 \text{ MeV}$ (S = 1.5) GALL 88
 Average = $493.679 \pm 0.006 \text{ MeV}$

$$\chi^2 = 21.2$$
 for 1 D.F., Prob. = 0.0004\%, (3)

both of which are measurements of x-ray energies from kaonic atoms. Comparing the average in Eq. (3) with the overall average in Eq. (2), it is clear that DENISOV 91 and GALL 88 dominate the overall average, and that their disagreement is responsible for most of the high χ^2 .

The GALL 88 measurement was made using four different kaonic atom transitions, K^- Pb (9 \to 8), K^- Pb (11 \to 10), K^- W (9 \to 8), and K^- W (11 \to 10). The m_{K^\pm} values they obtain from each of these transitions is shown in the Particle Listings and in Fig. 1Their K^- Pb (9 \to 8) m_{K^\pm} is below and somewhat inconsistent with their other three transitions. The average of their four measurements is

$$m_{K^{\pm}} = 493.636 \pm 0.007$$
 ,
$$\chi^2 = 7.0 \ \ {\rm for} \ \ 3 \ {\rm D.F., \ Prob.} \ \ = 7.2\% \ . \eqno(4)$$

This is a low but acceptable χ^2 probability so, to be conservative, GALL 88 scaled up the error on their average by S=1.5 to obtain their published error ± 0.011 shown in Eq. (3) above and used in the Particle Listings average.

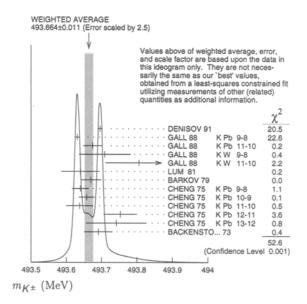

Figure 1: Ideogram of $m_{K^{\pm}}$ mass measurements. GALL 88 and CHENG 75 measurements are shown separately for each transition they measured.

The ideogram in Fig. 1 shows that the DENISOV 91 measurement and the GALL 88 K^- Pb (9 \rightarrow 8) measurement yield two well-separated peaks. One might suspect the GALL 88 K^- Pb (9 \rightarrow 8) measurement since it is responsible both for the internal inconsistency in the GALL 88 measurements and the disagreement with DENISOV 91.

To see if the disagreement could result from a systematic problem with the K^- Pb (9 \rightarrow 8) transition, we have separated the CHENG 75 data, which also used K^- Pb, into its separate transitions. Fig. 1shows that the CHENG 75 and GALL 88 K^- Pb (9 \rightarrow 8) values are consistent, suggesting the possibility of a common effect such as contaminant nuclear γ rays near the K^- Pb (9 \rightarrow 8) transition energy, although the CHENG 75 errors are too large to make a strong conclusion. The average of all 13 measurements has a χ^2 of 52.6 as shown in Fig. 1and the first line of Table 1, yielding an unacceptable χ^2 probability of 0.00005%. The second line of Table 1 excludes both the GALL 88 and CHENG 75 measurements of the K^- Pb (9 \rightarrow 8) transition and yields a χ^2 probability of 43%. The third [fourth] line of Table 1 excludes only the GALL 88 K^- Pb (9 \rightarrow 8) [DENISOV 91] measurement and yields a χ^2 probability of 20% [8.6%]. Table 1 shows that removing both measurements of the K^- Pb (9 \rightarrow 8) transition produces the most consistent set of data, but that excluding only the GALL 88 K^- Pb (9 \rightarrow 8) transition or DENISOV 91 also produces acceptable probabilities.

Yu.M. Ivanov, representing DENISOV 91, has estimated corrections needed for the older experiments because of improved 192 Ir and 198 Au calibration γ -ray energies. He estimates

Table 1: $m_{K^{\pm}}$ averages for some combinations of Fig. 1data.

$m_{K^{\pm}} \text{ (MeV)}$	χ^2	D.F.	Prob. (%	6)	Measurements used
493.664 ± 0.004	52.6	12	0.00005	all	13 measurements
493.690 ± 0.006	10.1	10	43	no	$K^- \text{Pb}(9 \rightarrow 8)$
493.687 ± 0.006	14.6	11	20	no	GALL 88 K^- Pb(9 \rightarrow 8)
493.642 ± 0.006	17.8	11	8.6	no	DENISOV 91

that CHENG 75 and BACKENSTOSS 73 m_{K^\pm} values could be raised by about 15 keV and 22 keV, respectively. With these estimated corrections, Table 1 becomes Table 2. The last line of Table 2 shows that if such corrections are assumed, then GALL 88 K^- Pb (9 \to 8) is inconsistent with the rest of the data even when DENISOV 91 is excluded. Yu.M. Ivanov warns that these are rough estimates. Accordingly, we do not use Table 2 to reject the GALL 88 K^- Pb (9 \to 8) transition, but we note that a future reanalysis of the CHENG 75 data could be useful because it might provide supporting evidence for such a rejection.

Table 2: $m_{K^{\pm}}$ averages for some combinations of Fig. 1data after raising CHENG 75 and BACKENSTOSS 73 values by 0.015 and 0.022 MeV respectively.

$m_{K^{\pm}}$ (MeV)	χ^2	D.F.	Prob. (%	ور و	Measurements used
$\overline{493.666 \pm 0.004}$	53.9	12	0.00003	all	13 measurements
493.693 ± 0.006	9.0	10	53	no	$K^- \text{Pb}(9 \rightarrow 8)$
493.690 ± 0.006	11.5	11	40	no	GALL 88 K^- Pb(9 \rightarrow 8)
493.645 ± 0.006	23.0	11	1.8	no	DENISOV 91

The GALL 88 measurement uses a Ge semiconductor spectrometer which has a resolution of about 1 keV, so they run the risk of some contaminant nuclear γ rays. Studies of γ rays following stopped π^- and Σ^- absorption in nucleii (unpublished) do not show any evidence for contaminants according to GALL 88 spokesperson, B.L. Roberts. The DENISOV 91 measurement uses a crystal diffraction spectrometer with a resolution of 6.3 eV for radiation at 22.1 keV to measure the 4f-3d transition in $K^{--12}C$. The high resolution and the light nucleus reduce the probability for overlap by contaminant γ rays, compared with the measurement of GALL 88. The DENISOV 91 measurement is supported by their high-precision measurement of the 4d-2p transition energy in $\pi^{--12}C$, which is good agreement with the calculated energy.

While we suspect that the GALL 88 K^- Pb (9 \rightarrow 8) measurements could be the problem, we are unable to find clear grounds for rejecting it. Therefore, we retain their measurement in the average and accept the large scale factor until further information can be obtained from new measurements and/or from reanalysis of GALL 88 and CHENG 75 data.

We thank B.L. Roberts (Boston Univ.) and Yu.M. Ivanov (Petersburg Nuclear Physics Inst.) for their extensive help in understanding this problem.

RARE KAON DECAYS

Revised November 1997 by L. Littenberg (BNL) and G. Valencia (Iowa State University)

- A. Introduction: There are several useful reviews on rare kaon decays and related topics [1-10]. The current activity in rare kaon decays can be divided roughly into four categories:
- 1. Searches for explicit violations of the Standard Model
- 2. Measurements of Standard Model parameters
- 3. Searches for CP violation
- 4. Studies of strong interactions at low energy.

The paradigm of Category 1 is the lepton flavor violating decay $K_L \to \mu e$. Category 2 includes processes such as $K^+ \to \pi^+ \nu \overline{\nu}$, which is sensitive to $|V_{td}|$. Much of the interest in Category 3 is focussed on the decays $K_L \to \pi^0 \ell \overline{\ell}$, where $\ell \equiv e, \mu, \nu$. Category 4 includes reactions like $K^+ \to \pi^+ \ell^+ \ell^-$ which constitute a testing ground for the ideas of chiral perturbation theory. Other reactions of this type are $K_L \to \pi^0 \gamma \gamma$, which also scales a CP-conserving background to CP violation in $K_L \to \pi^0 \ell^+ \ell^-$ and $K_L \to \gamma \ell^+ \ell^-$, which could possibly shed light on long distance contributions to $K_L \to \mu^+ \mu^-$.

B. Explicit violations of the Standard Model: Most of the activity here is in searches for lepton flavor violation (LFV). This is motivated by the fact that many extensions of the minimal Standard Model violate lepton flavor and by the potential to access very high energy scales. For example, the tree-level exchange of a LFV vector boson of mass M_X that couples to lefthanded fermions with electroweak strength and without mixing angles yields $B(K_L \to \mu e) = 3.3 \times 10^{-11} (91 \text{ TeV}/M_X)^4$ [5]. This simple dimensional analysis may be used to read from Table 1 that the reaction $K_L \to \mu e$ is already probing scales of nearly 100 TeV. Table 1 summarizes the present experimental situation vis a vis LFV, along with the expected near-future progress. The decays $K_L \to \mu^{\pm} e^{\mp}$ and $K^+ \to \pi^+ e^{\mp} \mu^{\pm}$ (or $K_L \to \pi^0 e^{\mp} \mu^{\pm}$) provide complementary information on potential family number violating interactions since the former is sensitive to axial-vector (or pseudoscalar) couplings and the latter is sensitive to vector (or scalar) couplings.

Table 1: Searches for lepton flavor violation in K decay

Mode	90% CL upper limit	t Exp't	Yr./Ref	(Near-) . future aim
$\overline{K^+ \to \pi^+ e\mu}$	$2.1 \cdot 10^{-10}$	BNL-777	90/11	3 · 10 ⁻¹² (BNL-865)
$K_L\! o\!\mu e$	$3.3 \cdot 10^{-11}$	BNL-791	93/12	$3 \cdot 10^{-12}$ (BNL-871)
$K_L \rightarrow \pi^0 e \mu$	$3.2 \cdot 10^{-9}$	FNAL-799	94/13	$5 \cdot 10^{-11} \text{ (KTeV)}$

Another forbidden decay currently being pursued is $K^+ \to \pi^+ X^0$, where X^0 is a very light, noninteracting particle (e.g. hyperphoton, axion, familon, etc.). Recently the upper limit on this process has been improved to 3×10^{-10} [15]. Data already collected by BNL-787 are expected to yield a further factor in sensitivity to this process.

C. Measurements of Standard Model parameters: Until recently, searches for $K^+ \to \pi^+ \nu \overline{\nu}$ have been motivated by the possibility of observing non-SM physics because the sensitivity attained was far short of the SM prediction for this decay [16] and long-distance contributions were known to be negligible [2]. However, BNL-787 has attained the sensitivity at which the observation of an event can no longer be unambiguously attributed to non-SM physics. The previous 90% CL upper limit [14] is 2.4×10^{-9} , but running with an upgraded beam and detector BNL-787 recently observed one candidate event, corresponding to a branching ratio of $(4.2^{+9.7}_{-3.5}) \times 10^{-10}$ [15]. Further data already collected are expected to increase the sensitivity by more than a factor 2, and there are plans to collect data representing a further large increase in sensitivity. This reaction is now interesting from the point of view of constraining SM parameters. The branching ratio can be written in terms of the very well-measured rate of K_{e3} as [2]:

$$B(K^{+} \to \pi^{+} \nu \overline{\nu}) = \frac{\alpha^{2} B(K^{+} \to \pi^{o} e^{+} \nu)}{V_{us}^{2} 2\pi^{2} \sin^{4} \theta_{W}} \times \sum_{l=e,\mu,\tau} |V_{cs}^{*} V_{cd} X_{NL}^{\ell} + V_{ts}^{*} V_{td} X(m_{t})|^{2}$$
(1)

to eliminate the *a priori* unknown hadronic matrix element. Isospin breaking corrections to the ratio of matrix elements reduce this rate by 10% [17]. In Eq. (1) the Inami-Lim function $X(m_t)$ is of order 1 [18], and X_{NL}^{ℓ} is several hundred times smaller. This form exhibits the strong dependence of this branching ratio on $|V_{td}|$. QCD corrections, which are contained in X_{NL}^{ℓ} , are relatively small and now known [10] to \leq 10%. Evaluating the constants in Eq. (1) with $m_t = 175$ GeV, one can cast this result in terms of the CKM parameters A, ρ and η (see our Section on "The Cabibbo-Kobayashi-Maskawa mixing matrix") [10]

$$B(K^+ \to \pi^+ \nu \overline{\nu}) \approx 1.0 \times 10^{-10} A^4 [\eta^2 + (\rho_o - \rho)^2]$$
 (2)

where $ho_o \equiv 1 + (\frac{2}{3} X_{NL}^e + \frac{1}{3} X_{NL}^{\tau})/(A^2 V_{us}^4 X(m_t)) \approx 1.4$. Thus, $\mathrm{B}(K^+ \to \pi^+ \nu \overline{\nu})$ determines a circle in the ρ , η plane with center $(\rho_o,0)$ and radius $\approx \frac{1}{A^2} \sqrt{\frac{\mathrm{B}(K^+ \to \pi^+ \nu \overline{\nu})}{1.0 \times 10^{-10}}}$. The decay $K_L \to \mu^+ \mu^-$ also has a short distance contribu-

The decay $K_L \to \mu^+\mu^-$ also has a short distance contribution sensitive to the CKM parameter ρ . For $m_t = 175$ GeV it is given by [10]:

$$B_{SD}(K_L \to \mu^+ \mu^-) \approx 1.7 \times 10^{-9} A^4 (\rho_o' - \rho)^2$$
 (3)

where ρ'_{α} depends on the charm quark mass and is around 1.2. This decay, however, is dominated by a long-distance contribution from a two-photon intermediate state. The absorptive (imaginary) part of the long-distance component is calculated in terms of the measured rate for $K_L \to \gamma \gamma$ to be $B_{abs}(K_L \to \gamma \gamma)$ $\mu^+\mu^-$) = $(7.07 \pm 0.18) \times 10^{-9}$; and it almost completely saturates the observed rate B($K_L \rightarrow \mu^+\mu^-$) = $(7.2 \pm 0.5) \times 10^{-9}$ listed in the current edition. The difference between the observed rate and the absorptive component can be attributed to the (coherent) sum of the short-distance amplitude and the real part of the long-distance amplitude. In order to use this mode to constrain ρ it is, therefore, necessary to know the real part of the long-distance contribution. Unlike the absorptive part, the real part of the long-distance contribution cannot be derived from the measured rate for $K_L \to \gamma \gamma$. At present, it is not possible to compute this long-distance component reliably and, therefore, it is not possible to constrain ρ from this mode. It is expected that studies of the reactions $K_L \to \ell^+\ell^-\gamma$, and $K_L \to \ell^+ \ell^- \ell'^+ \ell'^-$ for $\ell, \ell' = e$ or μ will improve our understanding of the long distance effects in $K_L \to \mu^+\mu^-$ (the current data is parameterized in terms of α_K^* , discussed on page 24 of the K_L^0 Particle Properties Listing in our 1997 WWW update).

D. Searches for CP violation: The mode $K_L \to \pi^0 \nu \overline{\nu}$ is dominantly CP-violating and free of hadronic uncertainties [2,19]. The Standard Model predicts a branching ratio $\sim 10^{-11}-10^{-10}$; for $m_t=175$ GeV it is given approximately by [10]:

$$B(K_L \to \pi^0 \nu \overline{\nu}) \approx 4.1 \times 10^{-10} A^4 \eta^2$$
 (4)

The current published upper bound is $B(K_L \to \pi^0 \nu \overline{\nu}) \le 5.8 \times 10^{-5}$ [20] and KTeV (FNAL799II) is expected to place a

bound of order 10^{-8} [21]. The KTeV group has recently quoted a preliminary result of 1.8×10^{-6} [22]. If lepton flavor is conserved, the 90% CL bound on $K^+ \to \pi^+ \nu \bar{\nu}$ provides the model independent bound $B(K_L \to \pi^0 \nu \bar{\nu}) < 1.1 \times 10^{-8}$ [23]. A recent proposal, BNL-926 [24], aims to make a $\sim 15\%$ measurement of $B(K_L \to \pi^0 \nu \bar{\nu})$. There is also a Fermilab EOI [25] with comparable goals.

The decay $K_L \to \pi^0 e^+ e^-$ also has sensitivity to the product $A^4 \eta^2$. It has a direct CP-violating component that depends on the value of the top-quark mass, and that for $m_t = 175$ GeV is given by [10]:

$$B_{\rm dir}(K_L \to \pi^0 e^+ e^-) \approx 6.7 \times 10^{-11} A^4 \eta^2$$
 (5)

However, like $K_L \to \mu^+\mu^-$ this mode suffers from large theoretical uncertainties due to long distance strong interaction effects. It has an indirect CP-violating component given by:

$$B_{\rm ind}(K_L \to \pi^0 e^+ e^-) = |\epsilon|^2 \frac{\tau_{K_L}}{\tau_{K_S}} B(K_S \to \pi^0 e^+ e^-) ,$$
 (6)

that has been estimated to be less than 10^{-12} [26], but that will not be known precisely until a measurement of $K_S \to \pi^0 e^+ e^-$ is available [4,27]. There is also a CP-conserving component dominated by a two-photon intermediate state that cannot be computed reliably at present. This component has an absorptive part that can be, in principle, determined from a detailed analysis of $K_L \to \pi^0 \gamma \gamma$.

An analysis of $K_L \to \pi^0 \gamma \gamma$ within chiral perturbation theory has been carried out in terms of a parameter a_V [28] that determines both the rate and the shape of the distribution $d\Gamma/dm_{\gamma\gamma}$. A fit to the distribution has given $-0.32 < a_V < 0.19$ [29]; a value that suggests that the absorptive part of the CP-conserving contribution to $K_L \to \pi^0 e^+ e^-$ is significantly smaller than the direct CP-violating component [29]. However, there remains some uncertainty in the interpretation of $K_L \to \pi^0 \gamma \gamma$ in terms of a_V . Analyses that go beyond chiral perturbation theory have found larger values of a_V , helping with understanding the rate in that process [30]. This would indicate a sizeable CP-conserving component to $K_L \to \pi^0 e^+ e^-$. The real part of the CP-conserving contribution to $K_L \to \pi^0 e^+ e^-$ is also unknown. The related process, $K_L \to \pi^0 \gamma e^+ e^-$, is an additional background in some region of phase space [31].

Finally, BNL-845 observed a potential background to $K_L \to \pi^0 e^+ e^-$ from the decay $K_L \to \gamma \gamma e^+ e^-$ [32]. This was later confirmed with an order of magnitude larger sample by FNAL-799 [33], which measured additional kinematic quantities. It has been estimated that this background will enter at the level of 10^{-11} [34], comparable to the signal level. Because of this, the observation of $K_L \to \pi^0 e^+ e^-$ will depend on background subtraction with good statistics.

The current upper bound for the process $K_L \to \pi^0 e^+ e^-$ is 4.3×10^{-9} [35]. For the closely related muonic process, the upper bound is $B(K_L \to \pi^0 \mu^+ \mu^-) \le 5.1 \times 10^{-9}$ [36]. KTeV expects to reach a sensitivity of roughly 10^{-11} for both reactions [21].

E. Other long distance dominated modes: The decays $K^+ \to \pi^+ \ell^+ \ell^-$ ($\ell = e$ or μ) are described by chiral perturbation theory in terms of one parameter, ω^+ [37]. This parameter determines both the rate and distribution $d\Gamma/dm_{\ell\ell}$ for these processes. A careful study of these two reactions can provide a measurement of ω^+ and a test of the chiral perturbation theory description. A simultaneous fit to the rate and spectrum of $K^+ \to \pi^+ e^+ e^-$ gives: $\omega^+ = 0.89^{+0.24}_{-0.14}$; $B(K^+ \to \pi^+ e^+ e^-) = (2.99 \pm 0.22) \times 10^{-7}$ [38]. These two results satisfy the prediction of chiral perturbation theory within two standard deviations [4]. Improved statistics for this mode and a measurement of the mode $K^+ \to \pi^+ \mu^+ \mu^-$ are thus desired. BNL-787 has recently measured $B(K^+ \to \pi^+ \mu^+ \mu^-) = (5.0 \pm 1.0) \times 10^{-8}$ [39] which is at about the predicted level, but the result is not yet accurate enough to provide additional constraints.

CONSTRAINED FIT INFORMATION

An overall fit to the mean life, 2 decay rate, and 20 branching ratios uses 60 measurements and one constraint to determine 8 parameters. The overall fit has a $\chi^2=78.1$ for 53 degrees of

The following off-diagonal array elements are the correlation coefficients $\left<\delta
ho_i \delta
ho_j \right>/(\delta
ho_i \cdot \delta
ho_j)$, in percent, from the fit to parameters ho_i , including the branching fractions, $x_i \equiv \Gamma_i/\Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to one.

 67 AOKI 94 measures $\ell P_{\mu} = -0.9996 \pm 0.0030 \pm 0.0048$. The above limit is obtained by summing the statistical and systematic errors in quadrature, normalizing to the physically significant region $(|\xi P_{\mu}|<1)$ and assuming that $\xi{=}1$, its maximum value.

DALITZ PLOT PARAMETERS FOR $K \rightarrow 3\pi$ DECAYS

Revised 1994 by T.G. Trippe (LBNL).

The Dalitz plot distribution for $K^{\pm} \rightarrow \pi^{\pm}\pi^{\pm}\pi^{\mp}$, $K^{\pm} \rightarrow$ $\pi^0\pi^0\pi^{\pm}$, and $K_L^0\to\pi^+\pi^-\pi^0$ can be parameterized by a series expansion such as that introduced by Weinberg [1]. We use the form

$$\left| M \right|^2 \propto 1 + g \frac{(s_3 - s_0)}{a m_{\pi^+}^2} + h \left[\frac{s_3 - s_0}{m_{\pi^+}^2} \right]^2 + j \frac{(s_2 - s_1)}{m_{\pi^+}^2} + k \left[\frac{s_2 - s_1}{m_{\pi^+}^2} \right]^2 + \cdots , \tag{1}$$

where $m_{\pi^+}^2$ has been introduced to make the coefficients g, h, j, and k dimensionless, and

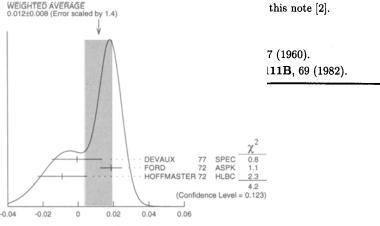

$$s_i = (P_K - P_i)^2 = (m_K - m_i)^2 - 2m_K T_i , i = 1, 2, 3,$$

$$s_0 = \frac{1}{3} \sum_i s_i = \frac{1}{3} (m_K^2 + m_1^2 + m_2^2 + m_3^2)$$

Here the P_i are four-vectors, m_i and T_i are the mass and kinetic energy of the i^{th} pion, and the index 3 is used for the odd pion.

The coefficient g is a measure of the slope in the variable s_3 (or T_3) of the Dalitz plot, while h and k measure the quadratic dependence on s_3 and $(s_2 - s_1)$, respectively. The coefficient jis related to the asymmetry of the plot and must be zero if CPinvariance holds. Note also that if CP is good, g, h, and k must be the same for $K^+ \to \pi^+ \pi^+ \pi^-$ as for $K^- \to \pi^- \pi^- \pi^+$.

Since different experiments use different forms for $|M|^2$, in order to compare the experiments we have converted to g, h, j, and k whatever coefficients have been measured. Where such conversions have been done, the measured coefficient a_y , a_t , a_u , or a_{ν} is given in the comment at the right. For definitions of these coefficients, details of this conversion, and discussion of

$K_{\ell 3}^{\pm}$ AND $K_{\ell 3}^{0}$ FORM FACTORS

Written by T.G. Trippe (LBNL).

Assuming that only the vector current contributes to $K \rightarrow$ $\pi \ell \nu$ decays, we write the matrix element as

$$M \propto f_{+}(t) \left[(P_K + P_{\pi})_{\mu} \bar{\ell} \gamma_{\mu} (1 + \gamma_5) \nu \right]$$

+ $f_{-}(t) \left[m_{\ell} \bar{\ell} (1 + \gamma_5) \nu \right] ,$ (1)

where P_K and P_{π} are the four-momenta of the K and π mesons, m_{ℓ} is the lepton mass, and f_{+} and f_{-} are dimensionless form factors which can depend only on $t = (P_K - P_\pi)^2$, the square of the four-momentum transfer to the leptons. If time-reversal invariance holds, f_+ and f_- are relatively real. $K_{\mu3}$ experiments measure f_+ and f_- , while K_{e3} experiments are sensitive only to f_+ because the small electron mass makes the f_- term

(a) $K_{\mu 3}$ experiments. Analyses of $K_{\mu 3}$ data frequently assume a linear dependence of f_+ and f_- on t, i.e.,

$$f_{\pm}(t) = f_{\pm}(0) \left[1 + \lambda_{\pm}(t/m_{\pi}^2) \right]$$
 (2)

Most $K_{\mu3}$ data are adequately described by Eq. (2) for f_+ and a constant f_{-} (i.e., $\lambda_{-}=0$). There are two equivalent parametrizations commonly used in these analyses:

(1) $\lambda_+, \xi(0)$ parametrization. Analyses of $K_{\mu 3}$ data often introduce the ratio of the two form factors

$$\xi(t) = f_{-}(t)/f_{+}(t)$$
.

⁷⁴ Experiments with large errors not included in average.

 ⁷⁵ Also includes DBC events.
 76 No radiative corrections included.

The $K_{\mu3}$ decay distribution is then described by the two parameters λ_+ and $\xi(0)$ (assuming time reversal invariance and $\lambda_-=0$). These parameters can be determined by three different methods:

Method A. By studying the Dalitz plot or the pion spectrum of $K_{\mu 3}$ decay. The Dalitz plot density is (see, e.g., Chounet et al. [1]):

$$\rho(E_{\pi}, E_{\mu}) \propto f_{+}^{2}(t) \left[A + B\xi(t) + C\xi(t)^{2} \right]$$

where

See key on page 213

$$egin{align} A &= m_K \left(2 E_\mu E_
u - m_K E_\pi'
ight) + m_\mu^2 \left(rac{1}{4} E_\pi' - E_
u
ight) \;, \ \ B &= m_\mu^2 \left(E_
u - rac{1}{2} E_\pi'
ight) \;, \ \ C &= rac{1}{4} m_\mu^2 E_\pi' \;, \ E_\pi' &= E_\pi^{
m max} - E_\pi = \left(m_K^2 + m_\pi^2 - m_
u^2
ight) / 2 m_K - E_\pi \;. \end{split}$$

Here E_{π} , E_{μ} , and E_{ν} are, respectively, the pion, muon, and neutrino energies in the kaon center of mass. The density ρ is fit to the data to determine the values of λ_{+} , $\xi(0)$, and their correlation.

Method B. By measuring the $K_{\mu3}/K_{e3}$ branching ratio and comparing it with the theoretical ratio (see, e.g., Fearing et al. [2]) as given in terms of λ_+ and $\xi(0)$, assuming μ -e universality:

$$\begin{split} \Gamma(K_{\mu 3}^{\pm})/\Gamma(K_{e 3}^{\pm}) &= 0.6457 + 1.4115\lambda_{+} + 0.1264\xi(0) \\ &+ 0.0192\xi(0)^{2} + 0.0080\lambda_{+}\xi(0) \; , \\ \Gamma(K_{\mu 3}^{0})/\Gamma(K_{e 3}^{0}) &= 0.6452 + 1.3162\lambda_{+} + 0.1264\xi(0) \\ &+ 0.0186\xi(0)^{2} + 0.0064\lambda_{+}\xi(0) \; . \end{split}$$

This cannot determine λ_+ and $\xi(0)$ simultaneously but simply fixes a relationship between them.

Method C. By measuring the muon polarization in $K_{\mu 3}$ decay. In the rest frame of the K, the μ is expected to be polarized in the direction ${\bf A}$ with ${\bf P}={\bf A}/\left|{\bf A}\right|$, where ${\bf A}$ is given (Cabibbo and Maksymowicz [3]) by

$$\begin{split} \mathbf{A} &= a_1(\xi) \mathbf{p}_{\mu} \\ &- a_2(\xi) \left[\frac{\mathbf{p}_{\mu}}{m_{\mu}} \left(m_K - E_{\pi} + \frac{\mathbf{p}_{\pi} \cdot \mathbf{p}_{\mu}}{\left| \mathbf{p}_{\mu} \right|^2} (E_{\mu} - m_{\mu}) \right) + \mathbf{p}_{\pi} \right] \\ &+ m_K \mathrm{Im} \xi(t) (\mathbf{p}_{\pi} \times \mathbf{p}_{\mu}) \ . \end{split}$$

If time-reversal invariance holds, ξ is real, and thus there is no polarization perpendicular to the K-decay plane. Polarization experiments measure the weighted average of $\xi(t)$ over the t range of the experiment, where the weighting accounts for the variation with t of the sensitivity to $\xi(t)$.

(2) λ_+, λ_0 parametrization. Most of the more recent $K_{\mu 3}$ analyses have parameterized in terms of the form factors f_+

and f_0 which are associated with vector and scalar exchange, respectively, to the lepton pair. f_0 is related to f_+ and f_- by

$$f_0(t) = f_+(t) + \left[t/(m_K^2 - m_\pi^2)\right] f_-(t)$$
.

Here $f_0(0)$ must equal $f_+(0)$ unless $f_-(t)$ diverges at t=0. The earlier assumption that f_+ is linear in t and f_- is constant leads to f_0 linear in t:

$$f_0(t) = f_0(0) \left[1 + \lambda_0(t/m_\pi^2) \right]$$
.

With the assumption that $f_0(0) = f_+(0)$, the two parametrizations, $(\lambda_+, \xi(0))$ and (λ_+, λ_0) are equivalent as long as correlation information is retained. (λ_+, λ_0) correlations tend to be less strong than $(\lambda_+, \xi(0))$ correlations.

The experimental results for $\xi(0)$ and its correlation with λ_+ are listed in the K^{\pm} and K_L^0 sections of the Particle Listings in section ξ_A , ξ_B , or ξ_C depending on whether method A, B, or C discussed above was used. The corresponding values of λ_+ are also listed.

Because recent experiments tend to use the (λ_+, λ_0) parametrization, we include a subsection for λ_0 results. Wherever possible we have converted $\xi(0)$ results into λ_0 results and vice versa.

See the 1982 version of this note [4] for additional discussion of the $K^0_{\mu3}$ parameters, correlations, and conversion between parametrizations, and also for a comparison of the experimental results.

(b) K_{e3} experiments. Analysis of K_{e3} data is simpler than that of $K_{\mu 3}$ because the second term of the matrix element assuming a pure vector current [Eq. (1) above] can be neglected. Here f_+ is usually assumed to be linear in t, and the linear coefficient λ_+ of Eq. (2) is determined.

If we remove the assumption of a pure vector current, then the matrix element for the decay, in addition to the terms in Eq. (2), would contain

$$+2m_K f_S \overline{\ell}(1+\gamma_5)\nu$$

$$+(2f_T/m_K)(P_K)_{\lambda}(P_{\pi})_{\mu} \overline{\ell} \sigma_{\lambda\mu}(1+\gamma_5)\nu ,$$

where f_S is the scalar form factor, and f_T is the tensor form factor. In the case of the K_{e3} decays where the f_- term can be neglected, experiments have yielded limits on $|f_S/f_+|$ and $|f_T/f_+|$.

K FORM FACTORS

in the form factor comments, the following symbols are used.

 f_{+} and f_{-} are form factors for the vector matrix element.

 f_{S} and f_{T} refer to the scalar and tensor term.

 $f_0 = f_+ + f_- t/(m_K^2 - m_\pi^2).$

 λ_+ , λ_- , and λ_0 are the linear expansion coefficients of f_+ , f_- , and f_0 .

 λ_+ refers to the $K_{\mu 3}^\pm$ value except in the K_{e3}^\pm sections.

 $d\xi(0)/d\lambda_{+}$ is the correlation between $\xi(0)$ and λ_{+} in $K_{\mu 3}^{\pm}$.

 $d\lambda_0/d\lambda_+$ is the correlation between λ_0 and λ_+ in $K_{\mu3}^{\pm}$.

t = momentum transfer to the π in units of m_{π}^2 .

DP = Dalitz plot analysis.

 $PI = \pi$ spectrum analysis.

 $MU = \mu$ spectrum analysis.

POL= μ polarization analysis.

BR = $K_{\mu 3}^{\pm}/K_{e3}^{\pm}$ branching ratio analysis.

E = positron or electron spectrum analysis.

RC = radiative corrections.

λ_{+} (LINEAR ENERGY DEPENDENCE OF f_{+} IN K_{e3}^{\pm} DECAY)

For radiative correction of K_{e3}^{\pm} Dalitz plot, see GINSBERG 67 and BECHERRAWY 70.

+1.8 ±0.6		76	BROWN	628	XEBC	+	DP+BR, $\lambda_{\perp}=0$

⁸⁴ ARNOLD 74 figure 4 was used to obtain ξ_A and $d\xi(0)/d\lambda_+$.

- ⁸⁸ CHIANG 72 figure 10 was used to obtain $d\xi(0)/d\lambda_+$. Fit had $\lambda_-=\lambda_+$ but would not change for $\lambda_{--} = 0$. L.Pondrom, (private communication 74).
- ⁸⁹ HAIDT 71 table 8 (Dalitz plot analysis) gives $d\xi(0)/d\lambda_+=(-1.1+0.5)/(0.050-0.029)=-29$, error raised from 0.50 to agree with $d\xi(0)=0.20$ for fixed λ_+ .
- 90 KIJEWSKI 69 figure 17 was used to obtain $d\xi(0)/d\lambda_+$ and errors.
- 91 CALLAHAN 66 table 1 (π analysis) gives $d\xi(0)/d\lambda_{+} = (0.72-0.05)/(0-0.04) = -17$, error raised from 0.80 to agree with $d\xi(0) = 0.37$ for fixed λ_{+} . t unknown.
- 92 JENSEN 64 gives $\lambda_+^\mu = \lambda_+^e = -0.020 \pm 0.027$. $d\xi(0)/d\lambda_+$ unknown. Includes SHAK-LEE 64 $\xi_B(K_{\mu 3}/K_{e3})$.

$\xi_B = f_-/f_+$ (determined from $K_{\mu 3}^{\pm}/K_{e 3}^{\pm}$)

The $K_{\mu3}^{\pm}/K_{e3}^{\pm}$ branching ratio fixes a relationship between $\xi(0)$ and λ_+ . We quote the author's $\xi(0)$ and associated λ_+ but do not average because the λ_+ values differ. The fit result and scale factor given below are not obtained from these ξ_B values. Instead they are obtained directly from the fitted $K_{\pm J}^{\pm}/K_{\pm 3}^{\pm}$ ratio $\Gamma(\pi^0\mu^+\nu_{\mu l})/\Gamma(\pi^0e^+\nu_e)$, with the exception of HEINTZE 77. The parameter ξ is redundant with λ_0 below and is not put into the Meson Summary Table.

 $^{^{93}}$ Calculated by us from λ_0 and λ_+ given below.

 $\xi_C = f_-/f_+$ (determined from μ polarization in $K_{\mu 3}^{\pm}$)

The μ polarization is a measure of $\xi(t)$. No assumptions on λ_{+-} necessary, t (weighted by sensitivity to $\xi(t)$) should be specified. In λ_+ , $\xi(0)$ parametrization this is $\xi(0)$ for $\lambda_{+}=0$. $d\xi/d\lambda=\xi t$. For radiative correction to muon polarization in K_{u3}^{\pm} , see GINSBERG 71. The parameter ξ is redundant with λ_0 below and is not put into the Meson Summary Table.

 $^{^{104}\,\}mathrm{HEINTZE}$ 77 uses $\lambda_+=0.029\pm0.003,~d\lambda_0/d\lambda_+$ estimated by us.

 $^{^{105}\}lambda_0$ value is for $\lambda_+=$ 0.03 calculated by us from $\xi(0)$ and $d\xi(0)/d\lambda_+$.

 $^{^{106}}$ MERLAN 74 λ_0 and $d\lambda_0/d\lambda_+$ were calculated by us from $\xi_A,\,\lambda_+^\mu,$ and $d\xi(0)/d\lambda_+.$ Their figure 6 gives $\lambda_0 = -0.025 \pm 0.012$ and no $d\lambda_0/d\lambda_+$.

 $^{^{107}}$ This value and error are taken from BRAUN 75 but correspond to the BRAUN 73c λ_{\perp}^{μ} result. $d\lambda_0/d\lambda_+$ is from BRAUN 73C $d\xi(0)/d\lambda_+$ in ξ_A above.

 $^{^{108}\}lambda_0$ calculated by us from $\xi(0)$, λ_+^μ , and $d\xi(0)/d\lambda_+$.

 $^{^{109}}$ BRAUN 74 is a combined $K_{\mu3}$ - K_{e3} result. It is not independent of BRAUN 73C ($K_{\mu3}$) and BRAUN 73B (K_{e3}) form factor results.

¹CARITHERS 75 value is for $m_{K_L^0} - m_{K_S^0} \Delta m = 0.5301 \pm 0.0013$. The Δm dependence

of the total decay rate (inverse mean life) is $\Gamma(K_0^0)=[(1.122\pm0.004)+0.16(\Delta m-0.5348)/\Delta m]10^{10}/s$, or, in terms of meanlife $\tau_s=0.8913\pm0.0032-0.238(\Delta m-0.5348)$ where Δm and τ_s are in units of $10^{10}\hbar s^{-1}$ and $10^{-10}s$ respectively.

² HILL 68 has been changed by the authors from the published value (0.865 \pm 0.009) because of a correction in the shift due to η_{+-} . SKJEGGESTAD 72 and HILL 68 give detailed discussions of systematics encountered in this type of experiment.

 3 ARONSON 82 find that K_S^0 mean life may depend on the kaon energy.

⁴ FACKLER 73 does not include systematic errors.

5 Pre-1971 experiments are excluded from the average because of disagreement with later more precise experiments.

⁶ HILL 68 has been changed by the authors from the published value (0.865 \pm 0.009) because of a correction in the shift due to η_{+-} . SKJEGGESTAD 72 and HILL 68 give detailed discussions of systematics encountered in this type of experiment.

- [b] Most of this radiative mode, the low-momentum γ part, is also included in the parent mode listed without γ 's.
- [c] Calculated from K_L^0 semileptonic rates and the K_S^0 lifetime assuming $\Delta S = \Delta O$.

CONSTRAINED FIT INFORMATION

An overall fit to 3 branching ratios uses 17 measurements and one constraint to determine 2 parameters. The overall fit has a $\chi^2=16.5$ for 16 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to

CP VIOLATION IN $K_S \rightarrow 3\pi$

Written 1996 by T. Nakada (Paul Scherrer Institute) and L. Wolfenstein (Carnegie-Mellon University).

The possible final states for the decay $K^0 \to \pi^+\pi^-\pi^0$ have isospin I = 0, 1, 2, and 3. The I = 0 and I = 2 states have CP = +1 and K_S can decay into them without violating CPsymmetry, but they are expected to be strongly suppressed by centrifugal barrier effects. The I=1 and I=3 states, which have no centrifugal barrier, have CP = -1 so that the K_S decay to these requires CP violation.

In order to see CP violation in $K_S \to \pi^+\pi^-\pi^0$, it is necessary to observe the interference between K_S and K_L decay, which determines the amplitude ratio

$$\eta_{+-0} = \frac{A(K_S \to \pi^+ \pi^- \pi^0)}{A(K_L \to \pi^+ \pi^- \pi^0)} \ .$$

If η_{+-0} is obtained from an integration over the whole Dalitz plot, there is no contribution from the I = 0 and I = 2 final states and a nonzero value of η_{+-0} is entirely due to CPviolation.

Only I = 1 and I = 3 states, which are CP = -1, are allowed for $K^0 \to \pi^0 \pi^0 \pi^0$ decays and the decay of K_S into $3\pi^0$ is an unambiguous sign of CP violation. Similarly to η_{+-0} , η_{000} is defined as

$$\eta_{000} = rac{A(K_S o \pi^0 \pi^0 \pi^0)}{A(K_L o \pi^0 \pi^0 \pi^0)} \; .$$

If one assumes that CPT invariance holds and that there are no transitions to I = 3 (or to nonsymmetric I = 1 states), it can be shown that

$$\eta_{+-0} = \eta_{000}$$

$$= \epsilon + i \frac{\operatorname{Im} a_1}{\operatorname{Re} a_1} \ .$$

With the Wu-Yang phase convention, a1 is the weak decay amplitude for K^0 into I=1 final states; ϵ is determined from CP violation in $K_L \to 2\pi$ decays. The real parts of η_{+-0} and η_{000} are equal to $\mathrm{Re}(\epsilon)$. Since currently-known upper limits on $|\eta_{+-0}|$ and $|\eta_{000}|$ are much larger than $|\epsilon|$, they can be interpreted as upper limits on $\text{Im}(\eta_{+-0})$ and $\text{Im}(\eta_{000})$ and so as limits on the CP-violating phase of the decay amplitude a_1 .

CP-VIOLATION PARAMETERS IN KO DECAY

 $\begin{array}{l} \text{Im}(\eta_{+-0})^2 = \Gamma(K_S^0 \to \pi^+\pi^-\pi^0, \textit{CP-violating}) \; / \; \Gamma(K_L^0 \to \pi^+\pi^-\pi^0) \\ \textit{CPT} \; \text{assumed valid} \; \text{(i.e.} \; \operatorname{Re}(\eta_{+-0}) \simeq \; 0). \end{array}$

1	^			

- 1 ADLER 95 uses \overline{K}_{e3}^0 and K_{e3}^0 strangeness tagging at production and decay.

 2 Fits Δm and ϕ_{+-} simultaneously. GIBBONS 93C systematic error is from B. Winstein via private communitication.

 3 These two experiments have a common systematic error due to the uncertainty in the momentum scale, as pointed out in WAHL 89.

 4 ADLER 96C is the result of a fit which includes nearly the same data as entered into the "OUR FIT" value above.

 5 GIBBONS 93 value assume $\phi_{+-} = \phi_{00} = \phi_{\text{SW}} = (43.7 \pm 0.2)^{\circ}$.

 6 ARONSON 82 find that Δm may depend on the kaon energy.

 7 ARONSON 70 and CARNEGIE 71 use K_{0}° mean life = $(0.862 \pm 0.006) \times 10^{-10}$ s. We have not attempted to adjust these values for the subsequent change in the K_{0}° mean have not attempted to adjust these values for the subsequent change in the K^0_S mean If e or in η_{+-} .

- [a] The value is for the sum of the charge states of particle/antiparticle states indicated.
- [b] See the Particle Listings below for the energy limits used in this measure-
- [c] Most of this radiative mode, the low-momentum γ part, is also included in the parent mode listed without γ 's.
- [d] Allowed by higher-order electroweak interactions.
- [e] Violates CP in leading order. Test of direct CP violation since the indirect CP-violating and CP-conserving contributions are expected to be suppressed.

CONSTRAINED FIT INFORMATION

An overall fit to the mean life, 4 decay rate, and 12 branching ratios uses 46 measurements and one constraint to determine 8 parameters. The overall fit has a $\chi^2=41.2$ for 39 degrees of

The following off-diagonal array elements are the correlation coefficients $\langle \delta p_i \delta p_j \rangle / (\delta p_i \cdot \delta p_j)$, in percent, from the fit to parameters p_i , including the branching fractions, $x_i \equiv \Gamma_i/\Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to one.

KY FORM FACTORS

For discussion, see note on form factors in the K^{\pm} section of the Particle Listings above.

In the form factor comments, the following symbols are used.

 f_{+} and f_{-} are form factors for the vector matrix element.

 f_S and f_T refer to the scalar and tensor term.

 $f_0 = f_+ + f_- t/(m_K^2 - m_\pi^2).$

 λ_+ , λ_- , and λ_0 are the linear expansion coefficients of f_+ , f_- , and f_0 .

 λ_+ refers to the $K^0_{\mu3}$ value except in the K^0_{e3} sections.

 $d\xi(0)/d\lambda_{+}$ is the correlation between $\xi(0)$ and λ_{+} in $K_{\mu3}^{0}$.

 $d\lambda_0/d\lambda_+$ is the correlation between λ_0 and λ_+ in $K^0_{~\mu3}.$

 $t = momentum transfer to the x in units of <math>m_x^2$.

DP = Dalitz plot analysis.

 $PI = \pi$ spectrum analysis.

 $MU = \mu$ spectrum analysis.

POL= μ polarization analysis.

BR = $K_{\mu 3}^0/K_{e3}^0$ branching ratio analysis.

E = positron or electron spectrum analysis.

RC = radiative corrections.

λ_{+} (LINEAR ENERGY DEPENDENCE OF f_{+} IN K_{43}^{0} DECAY)

For radiative correction of K_{e3}^0 DP, see GINSBERG 67 and BECHERRAWY 70.

⁷⁰ BIRULEV 81 error, $d\xi(0)/d\lambda_+$ calculated by us from λ_0 , λ_+ . $d\lambda_0/d\lambda_+=0$ used.

 $^{^{71}}$ HILL 79 and CHO 80 calculated by us from $\lambda_0,\,\lambda_+,$ and $d\lambda_0/d\lambda_+.$

⁷² BUCHANAN 75 is calculated by us from λ_0 , λ_+ and $d\lambda_0/d\lambda_+$ because their appendix A value -0.20 ± 22 assumes $\xi(t)$ constant, i.e. $\lambda_-=\lambda_+$.

 $^{^{73}}$ DONALDSON 748 gives $\xi=-0.11\pm0.02$ not including systematics. Above error and $d\xi(0)/d\lambda_+$ were calculated by us from λ_0 and λ_+ errors (which include systematics) and $d\lambda_0/d\lambda_+$.

 $^{^{74}}$ PEACH 73 gives $\xi(0)=-0.95\pm0.45$ for $\lambda_{+}=\lambda_{-}=0.025$. The above value is for $\lambda_{-} \approx 0$. K.Peach, private communication (1974).

$\xi_b = f_-/f_+$ (determined from $K_{\mu3}^0/K_{e3}^0$)

The K_{u3}^0/K_{e3}^0 branching ratio fixes a relationship between $\xi(0)$ and λ_+ . We quote the author's $\xi(0)$ and associated λ_+ but do not average because the λ_+ values differ. The fit result and scale factor given below are not obtained from these ξ_b values. Instead they are obtained directly from the authors $\kappa^0_{\mu 3}/\kappa^0_{e 3}$ branching ratio via the fitted $K_{\mu3}^0/K_{e3}^0$ ratio $(\Gamma(\pi^\pm\mu^\mp\nu)/\Gamma(\pi^\pm e^\mp\nu_e))$. The parameter ξ is redundant with λ_0 below and is not put into the Meson Summary Table.

VALUE EVTS

−0.11±0.09 OUR EVALUATION

Error includes scale factor of 2.3. Correlation is $d\xi(0)/d\lambda_+$ =−14. From a fit discussed in note on K₂₃ form factors in 1982 edition, PL **111B** (April 1982).

• • • We do not use the following data for averages, fits, limits, etc. • • •

0.5 ± 0.4	6700		73	HBC	BR, $\lambda_{+}=0.019\pm0.013$

⁷⁹ EVANS 73 replaces EVANS 69.

$\xi_c = f_-/f_+$ (determined from μ polarization in $K_{\mu 3}^0$)

The μ polarization is a measure of $\xi(t)$. No assumptions on λ_+ necessary, t (weighted by sensitivity to $\xi(t)$) should be specified. In λ_+ , $\xi(0)$ parametrization this is $\xi(0)$ for $\lambda_{+}=0$. $d\xi/d\lambda=\xi t$. For radiative correction to μ polarization in $K_{\mu,3}^{0}$, see GINSBERG 73. The parameter ξ is redundant with λ_0 below and is not put into the

FITS FOR K_L^0 CP-VIOLATION PARAMETERS

Revised April 1998 by T.G. Trippe (LBNL).

In recent years, K_L^0 CP-violation experiments have improved our knowledge of CP-violation parameters and their consistency with the expectations of CPT invariance and unitarity. For definitions of K_L^0 CP-violation parameters and a brief discussion of the theory, see the article "CP Violation" by L. Wolfenstein in Section 12 of this Review.

This note describes our two fits for the CP-violation parameters in $K_L^0 \to \pi^+\pi^-$ and $\pi^0\pi^0$ decay, one for the phases ϕ_{+-} and ϕ_{00} , and another for the amplitudes $|\eta_{+-}|$ and $|\eta_{00}|$.

Fit to ϕ_{+-} , ϕ_{00} , $\Delta\phi$, Δm , and au_s data: We perform a joint fit to the data on ϕ_{+-} , ϕ_{00} , the phase difference $\Delta \phi = \phi_{00} - \phi_{+-}$, the $K_L^0 - K_S^0$ mass difference Δm , and the K_S^0 mean life τ_S , including the effects of correlations. Measurements of ϕ_{+-} and ϕ_{00} are highly correlated with Δm and τ_s . Some measurements of τ_s are correlated with Δm . The correlations are given in the footnotes of the ϕ_{+-} and ϕ_{00} sections of the K_L^0 Particle Listings and the τ_s section of the K_s^0 Particle listings. In editions of the Review prior to 1996, we adjusted the experimental values of ϕ_{+-} and ϕ_{00} to account for correlations with Δm and τ_s but did not include the effects of these correlations when evaluating Δm and τ_s . When a joint fit including these correlations is done, the ϕ_{+-} measurements have a strong influence on the fitted value of Δm . This is because the CERN NA31 vacuum regeneration experiments (CAROSI 90 [1] and GEWENIGER 74B [2]), the Fermilab E773/E731 regenerator experiments (SCHWIN-GENHEUER 95 [3] and GIBBONS 93 [4]), and the CPLEAR $K^0 - \overline{K}^0$ asymmetry experiment (ADLER 95B [5]) have very different dependences of ϕ_{+-} on Δm , as can be seen from their diagonal bands in Fig. 1. The region where the ϕ_{+-} bands from these experiments cross gives a powerful measurement of Δm which decreases the fitted Δm relative to our pre-1996 average Δm and earlier measurements such as CULLEN 70 [6], GEWENIGER 74C [7], and GJESDAL 74 [8]. This decrease brings the Δm -dependent ϕ_{+-} measurements into good agreement with each other and with ϕ (superweak), where

$$\phi(\text{superweak}) = \tan^{-1}\left(\frac{2\Delta m}{\Delta \Gamma}\right) = \tan^{-1}\left(\frac{2\Delta m \tau_S \tau_L}{\hbar(\tau_L - \tau_S)}\right)$$
. (1)

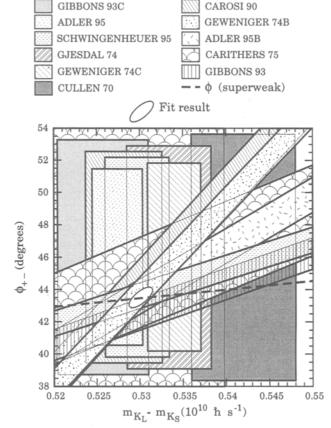

Figure 1: ϕ_{+-} vs Δm . Δm measurements appear as vertical bands spanning $\Delta m \pm 1\sigma$, some of which are cut near the top to aid the eye. The ϕ_{+-} measurements appear as diagonal bands spanning $\phi_{+-} \pm \sigma_{\phi}$. The dashed line shows ϕ (superweak). The ellipse shows the 1σ contour of the fit result. See Table 1 for data references.

The (ϕ_{+-},τ_s) correlations influence the τ_s fit result in a similar manner, as can be seen in Fig. 2. The influence of the ϕ_{+-} experiments is not as great on τ_s as it is on Δm because the indirect measurements of τ_s derived from the diagonal crossing bands in Fig. 2 are not as precise as the direct measurements of τ_s from E773 (SCHWINGENHEUER 95 [3]), E731 (GIBBONS 93 [4]), and NA31 (BERTANZA 97 [9]).

In Fig. 1 [Fig. 2] the slope of the diagonal ϕ_{+-} bands shows the Δm [τ_s] dependence; the unseen τ_s [Δm] dependent term is evaluated using the fitted τ_s [Δm]. The vertical half-width σ_{ϕ} of each band is the ϕ_{+-} error for fixed Δm [τ_s] and includes the systematic error due to the error in the fitted τ_s [Δm].

Table 2 gives the resulting fit values for the parameters and Table 3 gives the correlation matrix. The resulting ϕ_{+-} is in good agreement with $\phi(\text{superweak}) = 43.50 \pm 0.08^{\circ}$ obtained from Eq. (1) using Δm and τ_s from Table 2.

The χ^2 is 15.4 for 18 degrees of freedom, indicating good agreement of the input data. Nevertheless, there has been criticism that Fermilab E773 (SCHWINGENHEUER 95 [3]) and E731 (GIBBONS 93 [4]) measure $\phi_{+-} - \phi_f$ and calculate

Table 1: References and location of input data for Fig. 1 and Fig. 2. Unless otherwise indicated by a footnote, a check (\checkmark) indicates that the data can be found in the ϕ_{+-} or Δm sections of the K_L Particle Listings, or the τ_S section of the K_S Particle Listings, according to the column headers

^{*} from $\phi_{00}(\Delta m, \tau_s)$ in ϕ_{00} Particle Listings.

the regeneration phase ϕ_f from the power law momentum dependence of the regeneration amplitude using analyticity and dispersion relations. In the E731 result, a systematic error of ± 0.5 degrees for departures from a pure power-law is included. For the E773 result, they modeled a variety of effects that do distort the amplitude from a pure power law and ascribed a $\pm 0.35^{\circ}$ systematic error from uncertainties in these effects. Even so, the E731 result remains valid within its quoted errors. KLEINKNECHT 94 [16] and KLEINKNECHT 95 [17] argue that these systematic errors should be around 3°, primarily because of the absence of data on the momentum dependence of the regeneration amplitude above 160 GeV/c. BRIERE 95 [18] and BRIERE 95C [19] reply that the current understanding of regeneration is sufficient to allow a precise and reliable correction for the region above 160 GeV/c. The question is one of judgement about the reliability of the assumptions used. In the absence of any contradictory evidence, we choose to accept the judgement of the E731/E773 experimenters in setting their systematic errors.

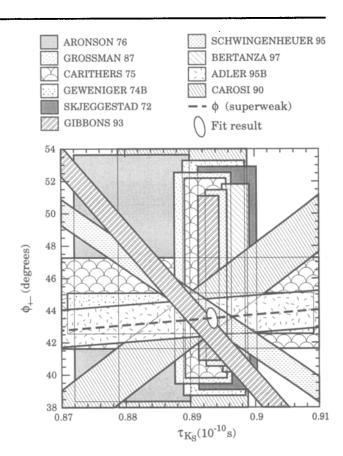

Figure 2: ϕ_{+-} vs τ_s . τ_s measurements appear as vertical bands spanning $\tau_s \pm 1\sigma$, some of which are cut near the top to aid the eye. The ϕ_{+-} measurements appear as diagonal bands spanning $\phi_{+-}\pm\sigma_{\phi}$. The dashed line shows $\phi(\text{superweak})$. The ellipse shows the fit result's 1σ contour. See Table 1 for data references.

Table 2: Results of the fit for ϕ_{+-} , ϕ_{00} , $\phi_{00} - \phi_{+-}$, Δm , and τ_s . The fit has $\chi^2 = 15.4$ for 18 degrees of freedom (22 measurements -5 parameters +1 constraint).

Quantity	Fit Result				
φ+-	$43.5\pm0.6^{\circ}$				
Δm	$(0.5301 \pm 0.0014) \times 10^{10} h \text{ s}^{-1}$				
$ au_{_{S}}$	$(0.8934 \pm 0.0008) \times 10^{-10}$ s				
ϕ_{00}	$43.4 \pm 1.0^{\circ}$				
$\Delta\phi$	$-0.1\pm0.8^{\circ}$				

A similar analysis has been done by the CPLEAR Collaboration [20]. The small differences between their results and ours are due primarily to different treatments of τ_s . Their fit constrains τ_s to the PDG 1994 value, while our fit includes the more recent SCHWINGENHEUER 95 [3] and BERTANZA 97 [9] τ_s measurements.

[†] from $\phi_{+-}(\Delta m)$ in ϕ_{+-} Particle Listings.

[‡] from $\tau_s(\Delta m)$ in τ_s Particle Listings.

Table 3: Correlation matrix for the fitted parameters.

	ϕ_{+-}	Δm	$ au_{\scriptscriptstyle S}$	ϕ_{00}	$\Delta\phi$
$\overline{\phi_{+-}}$	1.00	0.72	-0.35	0.60	-0.02

Fit for ϵ'/ϵ , $|\eta_{+-}|$, $|\eta_{00}|$, and $\mathrm{B}(K_L \to \pi\pi)$

We list measurements of $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$ and ϵ'/ϵ . Independent information on $|\eta_{+-}|$ and $|\eta_{00}|$ can be obtained from measurements of the K_L^0 and K_S^0 lifetimes $(\tau_L, \, \tau_S)$ and branching ratios (B) to $\pi\pi$, using the relations

$$|\eta_{+-}| = \left[\frac{B(K_L^0 \to \pi^+ \pi^-)}{\tau_L} \frac{\tau_S}{B(K_S^0 \to \pi^+ \pi^-)} \right]^{1/2} ,$$
 (2a)

$$|\eta_{00}| = \left[\frac{\mathrm{B}(K_L^0 \to \pi^0 \pi^0)}{\tau_L} \frac{\tau_S}{\mathrm{B}(K_S^0 \to \pi^0 \pi^0)} \right]^{1/2} .$$
 (2b)

For historical reasons the branching ratio fits and the CPviolation fits are done separately, but we want to include the influence of $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$, and ϵ'/ϵ measurements on ${\rm B}(K_L^0 \to \pi^+\pi^-)$ and ${\rm B}(K_L^0 \to \pi^0\pi^0)$ and vice versa. We approximate a global fit to all of these measurements by first performing two independent fits: 1) BRFIT, a fit to the K_L^0 branching ratios, rates, and mean life, and 2) ETAFIT, a fit to the $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{+-}/\eta_{00}|$, and ϵ'/ϵ measurements. The results from fit 1, along with the K_S^0 values from this edition are used to compute values of $|\eta_{+-}|$ and $|\eta_{00}|$ which are included as measurements in the $|\eta_{00}|$ and $|\eta_{+-}|$ sections with a document ID of BRFIT 98. Thus the fit values of $|\eta_{+-}|$ and $|\eta_{00}|$ given in this edition include both the direct measurements and the results from the branching ratio fit.

The process is reversed in order to include the direct $|\eta|$ measurements in the branching ratio fit. The results from fit 2 above (before including BRFIT 98 values) are used along with the K_L^0 and K_S^0 mean lives and the $K_S^0 \to \pi\pi$ branching fractions to compute the K_L^0 branching ratios $\Gamma(K_L^0 \to \pi^+\pi^-)/\Gamma(\text{total}) \text{ and } \Gamma(K_L^0 \to \pi^0\pi^0)/\Gamma(K_L^0 \to \pi^+\pi^-).$ These branching ratio values are included as measurements in the branching ratio section with a document ID of ETAFIT 98. Thus the K_L^0 branching ratio fit values in this edition include the results of direct measurements of $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$, and ϵ'/ϵ . A more detailed discussion of these fits is given in the 1990 edition of this Review [21].

- PARAMETERS FOR $K_L^0 \rightarrow 2\pi$ DECAY

$$\eta_{+-} = A(K_L^0 \to \pi^+\pi^-) / A(K_5^0 \to \pi^+\pi^-)
\eta_{00} = A(K_L^0 \to \pi^0\pi^0) / A(K_5^0 \to \pi^0\pi^0)$$

The fitted values of $|\eta_{+-}|$ and $|\eta_{00}|$ given below are the results of a fit to $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$, and $\mathrm{Re}(\epsilon'/\epsilon)$. Independent information on $|\eta_{+-}|$ and $|\eta_{00}|$ can be obtained from the fitted values of the \mathcal{K}_L^0 ightarrow $\pi\pi$ and $K^0_S \to \pi\pi$ branching ratios and the K^0_L and K^0_S lifetimes. This information is included as data in the $|\eta_{+-}|$ and $|\eta_{00}|$ sections with a Document ID "BRFIT." See the note "Fits for K_L^0 CP-Violation Parameters" above for details.

 109 These values are derived from $|\eta_{00}/\eta_{+-}|$ measurements. They enter the average in this section but enter the fit via the $|\eta_{00}/\eta_{+-}|$ section only.

 $^{110}\,\mathrm{This}$ is the combined results from BARR 93D and BURKHARDT 88, taking into account their common systematic uncertainty.

¹¹¹ These values are derived from $|\eta_{00}/\eta_{+-}|$ measurements.

ı

 ϕ_{+--} , PHASE of η_{+--} The dependence of the phase on Δm and τ_S is given for each experiment in the Comments below, where Δm is the K_L^0 - K_S^0 mass difference in units $10^{10}~h {
m s}^{-1}$ and $\tau_{\rm S}$ is the $K_{\rm S}$ mean life in units $10^{-10}\,{\rm s.}$ For the "used" data, we have evaluated these mass dependences using our 1996 values, $\Delta m=0.5304\pm0.0014$, $\tau_{\rm S}=0.8927\pm0.0009$ to obtain the values quoted below. We also give the regeneration phase ϕ_f in the

OUR FIT is described in the note on "Fits for K_L^0 CP-Violation Parameters" in the €0 Darticle Listings

¹¹³SCHWINGENHEUER 95 reports $\phi_{+-} = 43.53 \pm 0.76 + 173 [\Delta m - 0.5282] - 275 [au_{s} - 0.5282]$

 114 These experiments measure ϕ_{+-} - ϕ_f and calculate the regeneration phase from the power law momentum dependence of the regeneration amplitude using analyticity and dispersion relations. SCHWINGENHEUER 95 [GIBBONS 93] Includes a systematic error of 0.35° [0.5°] for uncertainties in their modeling of the regeneration amplitude. See the discussion of these systematic errors, including criticism that they could be underestimated, in the note on "C violation in K_I^0 decay."

115 GIBBONS 93 measures $\phi_+ - \phi_f$ and calculates the regeneration phase ϕ_f from the power law momentum dependence of the regeneration amplitude using analyticity. An error of 0.6° is included for possible uncertainties in the regeneration phase. They find $\phi_{+-}=42.21\pm0.9+189~[\Delta m-0.5257]-460~[\tau_5-0.8922]^\circ$, as given in SCHWINGEN-HEUER 95, footnote 8. GIBBONS 93 reports ϕ_{+-} (42.2 \pm 1.4)°

116 CAROSI 90 $\phi_{+-} \approx$ 46.9 \pm 1.4 \pm 0.7 +579 [Δm \sim 0.5351] +303 [τ_{s} - 0.8922] $^{\circ}$.

117 CARITHERS 75 $\phi_{+-} = (45.5 \pm 2.8) + 224 [\Delta m - 0.5348]^{\circ}$. $\phi_{f} = -40.9 \pm 2.6^{\circ}$.

¹¹⁸GEWENIGER 748 $\phi_{+-} = (49.4 \pm 1.0) + 565 [\Delta m - 0.540]^{\circ}$.

¹¹⁹ ADLER 96c fit gives $(43.82 \pm 0.41)^{\circ} + 339(\Delta m - 0.5307)^{\circ} - 252(\tau_5 - 0.8922)^{\circ}$.

120 ADLER 96C is the result of a fit which includes nearly the same data as entered into the "OUR FIT" value above.

121 ADLER 92B quote separately two systematic errors: ±0.4 from their experiment and ± 1.0 degrees due to the uncertainty in the value of Δm .

122 KARLSSON 90 systematic error does not include regeneration phase uncertainty.

123 ARONSON 82 find that ϕ_{+-} may depend on the kaon energy.

¹²⁴CARNEGIE 72 ϕ_{+-} is insensitive to Δm . $\phi_f = -56.2 \pm 5.2^{\circ}$.

¹²⁵BALATS 71 $\phi_{+-} = (39.0 \pm 12.0) + 198[\Delta m - 0.544]^{\circ}$. $\phi_{f} = -43.0 \pm 4.0^{\circ}$.

¹²⁶ JENSEN 70 $\phi_{+-} = (42.4 \pm 4.0) + 576 [\Delta m - 0.538]^{\circ}$.

```
^{127} BENNETT 69 uses measurement of (\phi_{+-})–(\phi_f) of ALFF-STEINBERGER 66B. BEN-
   NETT 69 \phi_{+-} = (34.9 \pm 10.0) + 69 [\Delta m - 0.545]^{\circ}. \phi_f = -49.9 \pm 5.4^{\circ}.
```

¹²⁸BOHM 69B $\phi_{+-} = (41.0 \pm 12.0) + 479(\Delta m - 0.526)^{\circ}$.

130 BENNETT 69 is a re-evaluation of BENNETT 68B. 131 Old experiments with large errors not included in average.

ϕ_{00} , PHASE OF η_{00}

See comment in ϕ_{+-} header above for treatment of Δm and τ_{S} dependence.
