CONSTRAINED FIT INFORMATION

An overall fit to 9 branching ratios uses 17 measurements and one constraint to determine 8 parameters. The overall fit has a $\chi^2=8.9$ for 10 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to one

This combination of a partial width with the partial width into e^+e^- and with the total width is obtained from the integrated cross section into channel, in the e^+e^- annihilation. We list only data that have not been used to determine the partial width $\Gamma(1)$ or the branching ratio $\Gamma(1)/\text{total}$.

bb MESONS

WIDTH DETERMINATIONS OF THE Υ STATES

As is the case for the $J/\psi(1S)$ and $\psi(2S)$, the full widths of the $b\bar{b}$ states $\Upsilon(1S)$, $\Upsilon(2S)$, and $\Upsilon(3S)$ are not directly measurable, since they are much narrower than the energy resolution of the e^+e^- storage rings where these states are produced. The common indirect method to determine Γ starts from

$$\Gamma = \Gamma_{\ell\ell}/B_{\ell\ell} \,\,, \tag{1}$$

where $\Gamma_{\ell\ell}$ is one leptonic partial width and $B_{\ell\ell}$ is the corresponding branching fraction ($\ell=e, \mu, \text{ or } \tau$). One then assumes e- μ - τ universality and uses

$$\Gamma_{\ell\ell} = \Gamma_{ee}$$

$$B_{\ell\ell}$$
 = average of B_{ee} , $B_{\mu\mu}$, and $B_{\tau\tau}$. (2)

The electronic partial width Γ_{ee} is also not directly measurable at e^+e^- storage rings, only in the combination $\Gamma_{ee}\Gamma_{\rm had}/\Gamma$, where $\Gamma_{\rm had}$ is the hadronic partial width and

$$\Gamma_{\text{had}} + 3\Gamma_{ee} = \Gamma . \tag{3}$$

This combination is obtained experimentally from the energyintegrated hadronic cross section

$$\int \sigma(e^+e^- \to \Upsilon \to \text{hadrons})dE$$

resonance

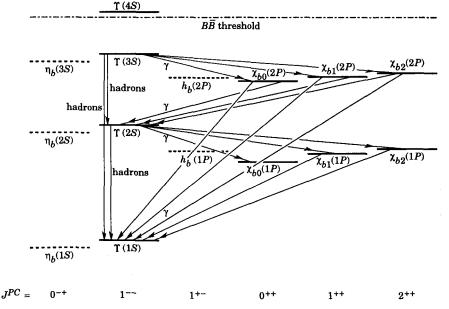

$$=\frac{6\pi^2}{M^2}\frac{\Gamma_{ee}\Gamma_{had}}{\Gamma}C_r = \frac{6\pi^2}{M^2}\frac{\Gamma_{ee}^{(0)}\Gamma_{had}}{\Gamma}C_r^{(0)}, \qquad (4)$$

where M is the Υ mass, and C_r and $C_r^{(0)}$ are radiative correction factors. C_r is used for obtaining Γ_{ee} as defined in Eq. (1), and contains corrections from all orders of QED for describing $(b\bar{b}) \to e^+e^-$. The lowest order QED value $\Gamma_{ee}^{(0)}$, relevant for comparison with potential-model calculations, is defined by the lowest order QED graph (Born term) alone, and is about 7% lower than Γ_{ee} .

THE BOTTOMONIUM SYSTEM

Υ (11020)

T (10860)

The level scheme of the $b\bar{b}$ states showing experimentally established states with solid lines. Singlet states are called η_b and h_b , triplet states Υ and χ_{bJ} . In parentheses it is sufficient to give the radial quantum number and the orbital angular momentum to specify the states with all their quantum numbers. E.g., $h_b(2P)$ means 2^1P_1 with n=2, L=1, S=0, J=1, PC=+-. If found, D-wave states would be called $\eta_b(nD)$ and $\Upsilon_J(nD)$, with J=1,2,3 and $n=1,2,3,4,\cdots$. For the χ_b states, the spins of only the $\chi_{b2}(1P)$ and $\chi_{b1}(1P)$ have been experimentally established. The spins of the other χ_b are given as the preferred values, based on the quarkonium models. The figure also shows the observed hadronic and radiative transitions.

Bottomonium, $\Upsilon(1S)$

The Listings give experimental results on B_{ee} , $B_{\mu\mu}$, $B_{\tau\tau}$, and $\Gamma_{ee}\Gamma_{had}/\Gamma$. The entries of the last quantity have been re-evaluated consistently using the correction procedure of KURAEV 85. The partial width Γ_{ee} is obtained from the average values for $\Gamma_{ee}\Gamma_{had}/\Gamma$ and $B_{\ell\ell}$ using

$$\Gamma_{ee} = \frac{\Gamma_{ee}\Gamma_{had}}{\Gamma(1 - 3B_{\ell\ell})} \ . \tag{5}$$

The total width Γ is then obtained from Eq. (1). We do not list Γ_{ee} and Γ values of individual experiments. The Γ_{ee} values in the Meson Summary Table are also those defined in Eq. (1).

 $\overline{\Upsilon(1S)}$

$$I^{G}(J^{PC}) = 0^{-}(1^{-})$$

NON-qq CANDIDATES

We include here mini-reviews and reference lists on gluonium and other non- $q\overline{q}$ candidates. See also $N\overline{N}(1100\text{--}3600)$ for possible bound states.

$NON-q\overline{q}$ MESONS

Written March 1998 by R. Landua (CERN).

The constituent quark model describes the observed meson spectrum as bound $q\overline{q}$ states grouped into SU(3) flavour nonets. The existence of gluon self-coupling in QCD suggests that additional bound states of gluons (glueballs gg,ggg) or hybrids $(q\overline{q}g)$ might exist. Another possible kind of non- $q\overline{q}$ mesons is multiquark states $(qq\overline{q}q, \text{ or } q\overline{q}-q\overline{q})$.

A glueball has no place in a $q\bar{q}$ nonet, it is a flavour-singlet, produced mainly in gluon-rich channels (radiative $J/\psi(1S)$ decays, antiproton-proton annihilation), and has a small gammagamma coupling. However, mixing with $q\bar{q}$ mesons of the same quantum numbers will modify the expected glueball signatures, such as flavour-blind decay modes. If the mixing is large, only the finding of more states than predicted by the quark model remains a clear signal for a non- $q\bar{q}$ state. Theoretical calculations based on lattice gauge theory and QCD sum rules agree that the lightest glueball should be a scalar resonance ($J^{PC}=0^{++}$) with a mass of 1600 \pm 150 MeV (BALI 93, SEXTON 95), followed by a tensor (2^{++}) and a pseudoscalar (0^{-+}) glueball in the 2000–2500 MeV mass region (SZCZEPANIAK 96).

Hybrid mesons are $q\overline{q}$ states combined with a gluonic excitation, allowing exotic (non- $q\overline{q}$) quantum numbers such as $J^{PC}=1^{-+}$). Hybrids span flavour nonets. In flux tube models, they are predicted to have characteristic decay modes into a pair of $S^-(l=0)$ and $P^-(l=1)$ wave mesons (ISGUR 85, CLOSE 95). The lightest hybrid nonets are expected in the 1500-2000 MeV mass range in the flux tube model and the ground state around 2000 MeV in lattice gauge theories (LACOCK 97). Charm hybrids $(c\overline{c}g)$ are expected in the 4000-4400 MeV mass range and are attractive experimentally since they may appear as supernumerary states in the predictable charmonium spectrum.

Multiquark states might exist as a colour-singlet configuration of four or more quarks. A four-quark state can be either baglike $(qq\overline{qq})$ or like a meson-meson bound state $(q\overline{q}-q\overline{q})$. Several well-established non- $q\overline{q}$ candidates have masses close to meson-meson thresholds. Examples include the $f_0(980)$ (close to the $K\overline{K}$ threshold), the $f_1(1420)$ $(K\overline{K}^*)$, the $f_2(1565)$ and $f_0(1500)(\omega\omega$ and $\rho\rho$), the $f_J(1710)$ $(K^*\overline{K}^*)$, and the $\psi(4040)$ $(D^*\overline{D}^*)$.

The following discussion is restricted to well-established resonances which are difficult to interpret as conventional $q\overline{q}$ states. We do not see it as our task to discuss theoretical interpretations of the candidates, but merely to summarize the observations of possible relevance. See also the corresponding Note in the 1996 issue of *Review of Particle Physics*.

Resonances with exotic quantum numbers

The first direct evidence for a non- $q\overline{q}$ state is the exotic $J^{PC}=1^{-+}$ isovector resonance $\hat{\rho}(1405)$. It has been clearly observed in $\overline{p}d$ annihilation at rest (ABELE 98B), corroborating earlier evidence from πp scattering experiments (ALDE 88B, THOMPSON 97). The $\hat{\rho}(1405)$ is observed as a resonant $(\eta\pi^-)$ P-wave with a width of 200–300 MeV. There is weaker evidence for a $J^{PC}=1^{-+}$ state around 1900 MeV (LEE 94).

The mass of the $\hat{\rho}(1405)$ is lower than expected by the flux tube model and lattice gauge theories for a hybrid meson, and its decay into two S-wave mesons does not correspond to the expected hybrid decay pattern. A 1⁻⁺ hybrid around 1400 MeV is, however, predicted by the bag model (BARNES 83). Whatever the correct interpretation will be (hybrid or four-quark state), it is expected to be part of a multiplet in the same mass region, and its identification will be an important goal for future experiments.

A resonance-like structure has been observed in $\gamma\gamma$ collisions near the $\rho\rho$ threshold, decaying into $\rho^0\rho^0$ and $\rho^+\rho^-$, and with a dominating 2^{++} partial wave. The small relative branching ratio $\rho^+\rho^-/\rho^0\rho^0$ (1:4) (ALBRECHT 91F) requires both I=0 and I=2 for the $\rho\rho$ system, which might be due to the presence of a $qq\overline{qq}$ resonance with I=2 (ACHASOV 90).

Scalar glueball

Four isoscalar resonances with $J^{PC}=0^{++}$ are considered as well-established: the σ or $f_0(400-1200)$, a very broad structure with a width of 600–1000 MeV, the $f_0(980)$, the $f_0(1370)$, and the $f_0(1500)$. Another isoscalar, the $f_J(1710)$, may have spin J=0 or 2.

In the quark model, one expects two scalar nonets (1 ${}^{3}P_{0}$) and 2 ${}^{3}P_{0}$) below 2000 MeV. However, the spectrum of scalar $q\bar{q}$ resonances may be strongly distorted by the opening of inelastic thresholds (TORNQVIST 96). For a detailed discussion, see the Note on scalar mesons under the $f_{0}(1370)$.

Several models interpret the $f_0(1500)$ as a supernumerary scalar state due to a glueball mixed with $q\bar{q}$ states in the same mass region (see for example AMSLER 96). This is based on the observation that both the $f_0(1370)$ and the $f_0(1500)$ have similar decay properties (mainly to light quarks), while the quark model expects the heavier resonance to couple strongly to strange quarks. The $f_0(1500)$ has been observed in 4π (ABELE 96), 2π (AMSLER 95B, BERTIN 98), $\eta\eta$ (AMSLER 95C), $\eta\eta'(958)$ (AMSLER 94E), and—weakly—in $K\overline{K}$ decays (ABELE 96B). The $f_0(1500)$ is observed in gluon-rich reactions, such as central production (ALDE 88, BARBERIS 97B), and in radiative $J/\psi(1S)$ decay, while it is not seen in gamma-gamma fusion (ACCIARRI 95J).

The key issue is the identification of the 3P_0 $(s\overline{s})$ -like state in the 1600–2000 MeV mass region. This might be the $f_J(1710)$, if spin 0 is confirmed. In radiative $J/\psi(1S)$ decays, both spin 0 and spin 2 components are found in the $f_J(1710)$ mass region, while the resonance observed in central production has spin 2.

Meson Particle Listings

Non- $q\overline{q}$ Candidates

An $f_0(1710)$ has also been suggested for the ground state scalar glueball (SEXTON 95). See the Note on $f_J(1710)$.

Tensor glueball

The twol 3P_2 $q\bar{q}$ states are very likely the $f_2(1270)$ and $f_2'(1525)$. In the 1800–2400 MeV mass range, one expects three more tensor nonets: the 2 3P_2 and 3 3P_2 radial excitations, and the 1 3F_4 nonet, i.e. six isoscalar 2^{++} resonances. They are all expected to have widths above 100 MeV. There is indeed evidence for several broad resonances in the 1800–2400 MeV region, but the experimental information is too sparse to make a meaningful assignment to $q\bar{q}$ nonets. There is at present no compelling reason to assume that any of these states is a non- $q\bar{q}$ state.

Two states below 2000 MeV, the $f_2(1565)$ and the $f_J(1710)$, are hard to accommodate in the quark model, because their masses are too close to the 1 3P_2 ground state to be members of the 2 3P_2 nonet. The $f_2(1565)$ has only been observed in $p\bar{p}$ annihilation, decaying to $\pi\pi$ (MAY 90, BERTIN 98). The proximity of the $\rho\rho$ and $\omega\omega$ thresholds suggest a possible interpretation as a meson-meson bound state. The $f_J(1710)$ has a well-established 2^{++} component. It is prominently observed in radiative $J/\psi(1S)$ decays, and in central production. It is observed to decay into $K\bar{K}$ (BAI 96C, LONGACRE 86), and its proximity to the $K^*\bar{K}^*$ threshold suggests again a meson-meson bound state.

The narrow $f_2(2220)$ still needs confirmation. There are also still doubts whether it has spin 2 or spin 4. The experimental evidence from $J/\psi(1S)$ radiative decays, πp and Kp scattering is inconclusive. It has not been observed in $p\overline{p}$ annihilation (BARNES 93). If it exists, it couples mainly to strange quark final states, and if spin 2 is confirmed, its prominence in radiative $J/\psi(1S)$ decays and its small width would make it a good glueball candidate.

Pseudoscalar mesons

Four pseudoscalar I = 0 resonances are well established below 1500 MeV: η , $\eta'(958)$, $\eta(1295)$, and $\eta(1440)$. It would be natural to identify the latter two with the $u\overline{u} + d\overline{d}$ and $s\overline{s}$ first radial excitations and $s\bar{s}$ of the 1S_0 ground states. Since the $\pi(1300)$ and the $\eta(1295)$ have nearly the same masses, the $\eta(1295)$ can be assigned to the $(u\overline{u} + d\overline{d})$ 2 ${}^{1}S_{0}$ state. The crucial issue is the identification of the $(s\overline{s})$ 2 ${}^{1}S_{0}$ state. An assignment to the $\eta(1440)$ is not evident. The $\eta(1440)$ is prominently produced in radiative $J/\psi(1S)$ decays and hence expected to have some glueball admixture, and it is mainly produced in $s\bar{s}$ depleted reactions, such as πp scattering, $p\bar{p}$ annihilation, or radiative $J/\psi(1S)$ decays. There is—albeit weak—evidence that the $\eta(1440)$ is made of two resonances with only about 50-100 MeV difference in mass, and with similar widths, the lower mass state decaying to $a_0(980)\pi$ and $\eta\pi\pi$, the higher mass state to $K^*\overline{K}$. It is therefore conceivable that the higher mass state is the $s\bar{s}$ member of the 2 1S_0 nonet (see the Note on $\eta(1440)$).

The $\pi(1800)$ is surprisingly narrow (if interpreted as the second radial excitation of the π). It decays frequently via a pair of S- and P-wave mesons (AMELIN 95B, 96B), which is a signature expected for a hybrid meson.

Axial-vector mesons

The $f_1(1285)$ and $f_1(1420)$ are the two well-established axial-vector resonances. The $f_1(1510)$ still needs confirmation (see the Note on the $f_1(1510)$ under the $\eta(1440)$). The $f_1(1285)$ has the expected properties of the isoscalar $u\bar{u} + d\bar{d}$ member of a ground state 3P_1 nonet. The $f_1(1420)$ has a dominant $K\bar{K}^*$ coupling, as expected for the corresponding $s\bar{s}$ member. In πp scattering, $p\bar{p}$ annihilation at rest from P waves (BERTIN 97) and radiative $J/\psi(1S)$ decays, the $f_1(1420)$ is produced together with the $\eta(1440)$, which gave rise to the former E/ι puzzle. In central production, only the $f_1(1420)$ state is produced (BARBERIS 97C).

Presently, there is no strong evidence for an exotic axial-vector state. However, if the $f_1(1510)$ state is corroborated, the proximity of the $f_1(1420)$ mass to the KK^* threshold suggests a $K\overline{K}^*$ meson-bound state or a threshold enhancement.

Non- $q\overline{q}$ Candidates

p MASS

The mass is known much more precisely in u (atomic mass units) than in MeV; see the footnote. The conversion from u to MeV, 1 $u=931.49432\pm0.00028$ MeV, involves the relatively poorly known electronic charge.

$3.58^{+1.19}_{-1.25}^{+1.03}_{-1.07}$	ZIEGER	92	CNTR	γp Compton scattering
3.3 ±2.2 ±1.3	FEDERSPIEL	91	CNTR	γp Compton scattering

¹⁰ MACGIBBON 95 combine the results of ZIEGER 92, FEDERSPIEL 91, and their own experiment to get a "global average" in which model errors and systematic errors are treated in a consistent way. See MACGIBBON 95 for a discussion.

⁷ This WILKENING 84 value is more cautious than the other and excludes the finite-size effect, which relies on uncertain nuclear integrals.

FEDERSPIEL 91 obtains for the (static) electric polarizability α_p , defined in terms of the induced electric dipole moment by $\mathbf{D}=4\pi\epsilon_0\alpha_p\mathbf{E}$, the value $(7.0\pm2.2\pm1.3)\times10^{-4}\,\mathrm{fm}^3$.

MEAN LIFE

The best limit by far, that of GOLDEN 79, relies, however, on a number of astrophysical assumptions. The other limits come from direct observations of stored antiprotons. See also " \bar{p} Partial Mean Lives" after "p Partial Mean Lives," below.

P DECAY MODES

Below, for N decays, p and n distinguish proton and neutron partial lifetimes. See also the "Note on Nucleon Decay" in our 1994 edition (Phys. Rev. DSO, 1673) for a short review.

The "partial mean life" limits tabulated here are the limits on τ/B_I , where τ is the total mean life and B_I is the branching fraction for the mode in question.

Partial mean life

	Mode	(10 ³⁰ years)	Confidence level

p PARTIAL MEAN LIVES

The "partial mean life" limits tabulated here are the limits on au/B_{I} , where au is the total mean life for the proton and B, is the branching fraction for the mode in question.

Decaying particle: p = proton, n = bound neutron. The same event may appear under more than one partial decay mode. Background estimates may be accurate to a factor of two.

7 PARTIAL MEAN LIVES

The "partial mean life" limits tabulated here are the limits on τ/B_I , where au is the total mean life for the antiproton and B_I is the branching fraction for the mode in question.

 $I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$ Status: ***

We have omitted some results that have been superseded by later experiments. See our earlier editions.

The mass is known much more precisely in u (atomic mass units) than in MeV; see the footnotes. The conversion from u to MeV, 1 u = 931.49432±0.00028 MeV, Involves the relatively poorly known electronic charge. The DIFILIPPO 94 value, in u, is by far the best, but when converted to MeV differs only negligibly from the 1986 CODATA value, which, for consistency, we stick with.

LIMIT ON nn OSCILLATIONS

Mean Time for nn Transition in Vacuum

A test of ΔB =2 baryon number nonconservation. MOHAPATRA 80 and MOHAPATRA 89 discuss the theoretical motivations for looking for $n\bar{n}$ oscillations. DOVER 83 and DOVER 85 give phenomenological analyses. The best limits come from looking for the decay of neutrons bound in nuclei. However, these analyses require model-dependent corrections for nuclear effects. See KABIR 83, DOVER 89, and ALBERICO 91 for discussions. Direct searches for $n \rightarrow \bar{n}$ transitions using reactor neutrons are cleaner but give somewhat poorer limits. We include limits for both free and bound neutrons in the Summary Table.

NOTE ON BARYON DECAY PARAMETERS

Written 1996 by E.D. Commins (University of California, Berkeley).

Baryon semileptonic decays

The typical spin-1/2 baryon semileptonic decay is described by a matrix element, the hadronic part of which may be written

$$\overline{B}_f \left[f_1(q^2) \gamma_{\lambda} + i \ f_2(q^2) \sigma_{\lambda\mu} q^{\mu} + g_1(q^2) \gamma_{\lambda} \gamma_5 + g_3(q^2) \gamma_5 q_{\lambda} \right] B_i.$$

Here B_i and \overline{B}_f are spinors describing the initial and final baryons, and $q=p_i-p_f$, while the terms in f_1 , f_2 , g_1 , and g_3 account for vector, induced tensor ("weak magnetism"), axial vector, and induced pseudoscalar contributions [1]. Second-class current contributions are ignored here. In the limit of zero momentum transfer, f_1 reduces to the vector coupling constant g_V , and g_1 reduces to the axial-vector coupling constant g_A . The latter coefficients are related by Cabibbo's theory [2], generalized to six quarks (and three mixing angles) by Kobayashi and Maskawa [3]. The g_3 term is negligible for transitions in which an e^{\pm} is emitted, and gives a very small correction, which can be estimated by PCAC [4], for μ^{\pm} modes. Recoil effects include weak magnetism, and are taken into account adequately by considering terms of first order in

$$\delta = \frac{m_i - m_f}{m_i + m_f} \; ,$$

where m_i and m_f are the masses of the initial and final baryons.

The experimental quantities of interest are the total decay rate, the lepton-neutrino angular correlation, the asymmetry coefficients in the decay of a polarized initial baryon, and the polarization of the decay baryon in its own rest frame for an unpolarized initial baryon. Formulae for these quantities are derived by standard means [5] and are analogous to formulae for nuclear beta decay [6]. We use the notation of Ref. 6 in the Listings for neutron beta decay. For comparison with experiments at higher q^2 , it is necessary to modify the form factors at $q^2 = 0$ by a "dipole" q^2 dependence, and for high-precision comparisons to apply appropriate radiative corrections [7].

The ratio g_A/g_V may be written as

$$g_A/g_V = |g_A/g_V| e^{i\phi_{AV}}.$$

The presence of a "triple correlation" term in the transition probability, proportional to $\text{Im}(g_A/g_V)$ and of the form

$$\sigma_{i}\cdot(\mathbf{p}_{\ell}\times\mathbf{p}_{\nu})$$

for initial baryon polarization or

See key on page 213

$$\sigma_f \cdot (\mathbf{p}_\ell \times \mathbf{p}_\nu)$$

for final baryon polarization, would indicate failure of timereversal invariance. The phase angle ϕ has been measured precisely only in neutron decay (and in ¹⁹Ne nuclear beta decay), and the results are consistent with T invariance.

Hyperon nonleptonic decays

The amplitude for a spin-1/2 hyperon decaying into a spin-1/2 baryon and a spin-0 meson may be written in the form

$$M = G_F m_{\pi}^2 \cdot \overline{B}_f (A - B\gamma_5) B_i ,$$

where A and B are constants [1]. The transition rate is proportional to

$$R = 1 + \gamma \widehat{\omega}_f \cdot \widehat{\omega}_i + (1 - \gamma)(\widehat{\omega}_f \cdot \widehat{\mathbf{n}})(\widehat{\omega}_i \cdot \widehat{\mathbf{n}}) + \alpha(\widehat{\omega}_f \cdot \widehat{\mathbf{n}} + \widehat{\omega}_i \cdot \widehat{\mathbf{n}}) + \beta \widehat{\mathbf{n}} \cdot (\widehat{\omega}_f \times \widehat{\omega}_i),$$

where $\hat{\mathbf{n}}$ is a unit vector in the direction of the final baryon momentum, and $\hat{\omega}_i$ and $\hat{\omega}_f$ are unit vectors in the directions of the initial and final baryon spins. (The sign of the last term in the above equation was incorrect in our 1988 and 1990 editions.) The parameters α , β , and γ are defined as

$$\begin{split} &\alpha = 2\operatorname{Re}(s^*p)/(\,|\,s\,|^2 + \,|\,p\,|^2)\,\,,\\ &\beta = 2\operatorname{Im}(s^*p)/(\,|\,s\,|^2 + \,|\,p\,|^2)\,\,,\\ &\gamma = (\,|\,s\,|^2 - \,|\,p\,|^2)/(\,|\,s\,|^2 + \,|\,p\,|^2)\,\,, \end{split}$$

where s = A and $p = |\mathbf{p}_f| B/(E_f + m_f)$; here E_f and \mathbf{p}_f are the energy and momentum of the final baryon. The parameters α , β , and γ satisfy

$$\alpha^2 + \beta^2 + \gamma^2 = 1 \ .$$

If the hyperon polarization is \mathbf{P}_Y , the polarization \mathbf{P}_B of the decay baryons is

$$\mathbf{P}_B = \frac{(\alpha + \mathbf{P}_Y \cdot \widehat{\mathbf{n}}) \widehat{\mathbf{n}} + \beta (\mathbf{P}_Y \times \widehat{\mathbf{n}}) + \gamma \widehat{\mathbf{n}} \times (\mathbf{P}_Y \times \widehat{\mathbf{n}})}{1 + \alpha \mathbf{P}_Y \cdot \widehat{\mathbf{n}}} \; .$$

Here P_B is defined in the rest system of the baryon, obtained by a Lorentz transformation along $\hat{\mathbf{n}}$ from the hyperon rest frame, in which $\hat{\mathbf{n}}$ and P_Y are defined.

An additional useful parameter ϕ is defined by

$$\beta = (1 - \alpha^2)^{1/2} \sin \phi .$$

In the Listings, we compile α and ϕ for each decay, since these quantities are most closely related to experiment and are essentially uncorrelated. When necessary, we have changed the signs of reported values to agree with our sign conventions. In the Baryon Summary Table, we give α , ϕ , and Δ (defined below) with errors, and also give the value of γ without error.

Time-reversal invariance requires, in the absence of finalstate interactions, that s and p be relatively real, and therefore that $\beta=0$. However, for the decays discussed here, the finalstate interaction is strong. Thus

$$s = |s| e^{i\delta_s}$$
 and $p = |p| e^{i\delta_p}$,

where δ_s and δ_p are the pion-baryon s- and p-wave strong interaction phase shifts. We then have

$$\beta = \frac{-2|s||p|}{|s|^2 + |p|^2}\sin(\delta_s - \delta_p).$$

One also defines $\Delta = -\tan^{-1}(\beta/\alpha)$. If T invariance holds, $\Delta = \delta_s - \delta_p$. For $\Lambda \to p\pi^-$ decay, the value of Δ may be compared with the s- and p-wave phase shifts in low-energy π^-p scattering, and the results are consistent with T invariance.

Radiative hyperon decays

For the radiative decay of a polarized spin-1/2 hyperon, $B_i \to B_f \gamma$, the angular distribution of the direction \widehat{p} of the final spin-1/2 baryon in the hyperon rest frame is

$$\frac{d\Gamma_{\gamma}}{d\Omega} = \frac{\Gamma_{\gamma}}{4\pi} \left(1 + \alpha_{\gamma} \widehat{p} \cdot \mathbf{P}_{i} \right) ,$$

where \mathbf{P}_i is the hyperon polarization and the asymmetry parameter α_{γ} is

$$lpha_{\gamma} = rac{2 \mathrm{Re} \left[g_1'(0) f_M^*(0)
ight]}{|g_1'(0)|^2 + |f_M(0)|^2} \; .$$

Here $f_M=\frac{(m_i-m_f)}{(m_i+m_f)}\left[(m_i+m_f)f_2'-f_1'\right]$, where $f_1'(q^2)$, $f_2'(q^2)$, and $g_1'(q^2)$ are the $\Delta Q=0$ analogs of the $|\Delta Q|=1$ form factors defined above.

n → pe-v DECAY PARAMETERS

See the above "Note on Baryon Decay Parameters." For discussions of recent results, see the references cited at the beginning of the section on the neutron mean life. For discussions of the values of the weak coupling constants g_A and g_V obtained using the neutron lifetime and asymmetry parameter A, comparisons with other methods of obtaining these constants, and implications for particle physics and for astrophysics, see DUBBERS 91 and WOOLCOCK 91. For tests of the V-A theory of neutron decay, see EROZOLIMSKII 918 and MOSTOVOI 96.

²² EROZOLIMSKII 78 says asymmetric proton losses and nonuniform beam polarization may give a systematic error up to 0.003, thus increasing the EROZOLIMSKII 74 error to 0.005. STEINBERG 74 and STEINBERG 76 estimate these systematic errors to be insignificant in their experiment.

NOTE ON N AND A RESONANCES

Written December 1997 by R.L. Workman (Virginia Polytechnic Institute and State University).

I. Introduction

The excited states of the nucleon have been studied in a large number of formation and production experiments. The conventional (Breit-Wigner) masses, pole positions, widths, and elasticities of the N and Δ resonances in the Baryon Summary Table come almost entirely from partial-wave analyses of πN total, elastic, and charge-exchange scattering data. Partial-wave analyses have also been performed on much smaller data sets to get $N\eta$, ΛK , and ΣK branching fractions. Other branching fractions come from isobar-model analyses of $\pi N \to N\pi\pi$ data. Finally, many $N\gamma$ branching fractions have been determined from photoproduction experiments.

Table 1 lists all the N and Δ entries in the Baryon Listings and gives our evaluation of the status of each, both overall and channel by channel. Only the "established" resonances (overall status 3 or 4 stars) appear in the Baryon Summary Table. We consider a resonance to be established only if it has been seen in at least two independent analyses of elastic scattering and if the relevant partial-wave amplitudes do not behave erratically or have large errors.

Two changes have been made in the Baryon Summary Table: The $\Delta(1900)$ S_{31} state has been downgraded from three stars to two due to its weak signal in speed plots, and thus has been dropped from the Table. More importantly, pole parameters have been added to the Table, as these tend to be less model dependent than parameters found in fits using generalized Breit-Wigner formulas. This point is the subject of the next section.

No new elastic partial-wave analyses have been published since our last *Review*, although some preliminary results were reported at MENU 97 [1], which also contains recent studies of the πN σ term, scattering lengths, and possible isospin-breaking effects.

Several inelastic scattering analyses are now underway [2–5]. Most of them use $\pi N \to N\eta$ data, together with $\pi N \to \pi N$ data, in order to obtain improved values of the properties of the N(1535) S_{11} . The Pittsburgh-ANL [2] and Giessen [3] coupled-channel analyses are similar in scope to that of Manley and Saleski [6], but they differ in theoretical approach and in also using electromagnetic channels.

The interested reader will find further discussions in the proceedings of two recent conferences [7,1], and in two older reviews [8,9].

II. Against Breit-Wigner parameters — a pole-emic

Written December 1997 by G. Höhler (University of Karlsruhe).

(1) All theoretical approaches to the resonance phenomenon have in common that the variation of a partial-wave amplitude T(W), where W is the total c.m. energy, is related to a nearly bound state of the projectile-target system (see e.g., Refs. [1–5]). In πN scattering, this state is an excited state of the nucleon (= isobar). The nearly bound state is described in the framework of S-matrix theory by a pole of the S-matrix element at $W_p = M - i\Gamma/2$ in the lower half of the complex W-plane, close to the real axis; M and Γ are called the mass and width of the resonance. The location of the resonance pole is the same for all reactions to which the resonance couples.

In the inelastic region, a resonance is associated with a cluster of poles on different Riemann sheets. If one of these poles is located near the real axis and sufficiently far from branch points, it will be strongly dominant. If one of the final-state particles itself has a strong decay, one also has to consider branch points in the lower half plane that belong to thresholds for two-particle final states (see e.g., Refs. [6,7]).

- (2) If the formation of an unstable intermediate particle occurs in a scattering process, one expects a time-delay between the arrival of the incident wave packet and its departure from the collision region. Goldberger and Watson [8], starting from earlier work by Wigner, derived for elastic scattering the time-delay Q. Expressed in terms of the amplitude T(W), it is $Q=2\,Sp(W)$, where Sp(W)=|dT/dW| is the speed with which the complex vector T traverses the Argand diagram. If the background can be neglected, a resonance pole leads to a peak of Sp(W) at W=M (see the cited books and Refs. [9-11]).
- (3) It is an old tradition that authors of partial-wave analyses determine conventional resonance parameters from fits to generalized Breit-Wigner formulas. Each group has its own prescription for the treatment of analyticity, the choice of the background, and other details, so the model-dependence is much larger than in the determination of pole parameters. A serious shortcoming is the poor or missing information on inelastic channels. The conventional parameters are the "mass" m, the "width" $\Gamma(W)$ at W=m, and the branching ratios. Following are some problems with these parametrizations.
- (a) The conventional $\Delta(1232)$ parameters come from a fit to the P33 partial wave. It is well known from the Chew-Low plot and dispersion relations [12] that this partial wave

has a large background from the nucleon pole term. The pole position, $1210-50\,i$ MeV, belongs to the Δ -resonance, whereas the conventional parameters, m=1232 MeV and $\Gamma(m)=120$ MeV, belong to the Δ together with the large background in πN scattering.

(b) The N(1535) S_{11} is the only 4-star resonance that does not show a signal in the speed plot. The signal is probably part of the large peak due to the threshold for η production [13]. In this case, poles in other Riemann sheets are expected to give contributions of comparable magnitude. One of these poles produces the threshold cusp [6]. In the 1960's, this problem was treated in many papers (see Ref. 13). In calculations that rely on the conventional mass of 1535 MeV, one cannot see that one has to study a combined resonance plus threshold-cusp phenomenon.

A similar situation of poles in different sheets arises in $\pi\pi$ scattering near the $K\bar{K}$ threshold. See remarks in footnotes to our $f_0(980)$ Listing.

(c) Around 1440 MeV, the VPI group found two poles in the P_{11} amplitude in different Riemann sheets [14]. This was interpreted, by other authors, as evidence for the existence of two nearly degenerate P_{11} resonances, in conflict with the constituent quark model. Cutkosky pointed out that the branch point for $\Delta\pi$ decay is located near the poles, so the poles belong to the same resonance. This was confirmed by a new calculation [15], which also led to conventional parameters of m=1471 MeV and $\Gamma(m)=545$ MeV, which are much different from the pole parameters, 1370-114i and 1360-120i MeV. The speed plot confirms that the formation of the unstable particle N(1440) P_{11} occurs at a considerably lower energy than expected from the conventional parameters.

Conclusion: In contrast to the conventional parameters, the pole positions and speed plots have a well-defined relation to S-matrix theory. They also give more information on the resonances and thresholds and can be used for predictions on other reactions that couple to the excited states.

III. Electromagnetic interactions

Revised December 1997 by R.L. Crawford (University of Glasgow) and R.L. Workman (Virginia Polytechnic Institute and State University).

Nearly all the entries in the Listings concerning electromagnetic properties of the N and Δ resonances are $N\gamma$ couplings. These couplings, the helicity amplitudes $A_{1/2}$ and $A_{3/2}$, have been obtained in partial-wave analyses of single-pion photoproduction, η photoproduction, and Compton scattering. Most photoproduction analyses take the existence, masses, and widths of the resonances from the $\pi N \to \pi N$ analyses, and only determine the $N\gamma$ couplings. A brief description of the various methods of analysis of photoproduction data may be found in our 1992 edition [1].

Our Listings omit a number of analyses that are now obsolete. Most of the older results may be found in our 1982 edition [2]. The errors quoted for the couplings in the Listings are calculated in different ways in different analyses and therefore should be used with care. In general, the systematic differences between the analyses caused by using different parameterization schemes are probably more indicative of the true uncertainties than are the quoted errors.

Probably the most reliable analyses, for most resonances, are ARAI 80, CRAWFORD 80, AWAJI 81, FUJII 81, CRAWFORD 83, and ARNDT 96. The $\Delta(1232)$ and N(1535) are special cases, discussed separately below. The errors we give are a combination of the stated statistical errors on the analyses and the systematic differences between them. The analyses are given equal weight, except ARNDT 96 is weighted, rather arbitrarily, by a factor of two because its data set is at least 50% larger than those of the other analyses and contains many new high-quality measurements. Again, the $\Delta(1232)$ and N(1535) are discussed separately below.

The Baryon Summary Table gives $N\gamma$ branching fractions for those resonances whose couplings are considered to be reasonably well established. The $N\gamma$ partial width Γ_{γ} is given in terms of the helicity amplitudes $A_{1/2}$ and $A_{3/2}$ by

$$\Gamma_{\gamma} = \frac{k^2}{\pi} \frac{2M_N}{(2J+1)M_R} \left[|A_{1/2}|^2 + |A_{3/2}|^2 \right] . \tag{1}$$

Here M_N and M_R are the nucleon and resonance masses, J is the resonance spin, and k is the photon c.m. decay momentum.

New results for $\Delta(1232) \to p\gamma$: Recent measurements of $\gamma p \to N\pi$ and $\gamma p \to \gamma p$ have fueled a number of new analyses

N's and Δ 's

across the first resonance region [3–7]. A central focus has been the E2/M1 ratio, evaluated at the K-matrix and T-matrix poles. The electric quadrupole (E2) and magnetic dipole (M1) amplitudes are related to our helicity amplitudes by

$$A_{1/2} = -\frac{1}{2}(M1 + 3E2)$$
 and $A_{3/2} = -\frac{\sqrt{3}}{2}(M1 - E2)$. (2)

Most recent estimates of the E2/M1 ratio, evaluated at the K-matrix pole, are considerably larger (in magnitude) than the average, $-1.5\pm0.4\%$, quoted in our 1996 Review. This quantity is quite sensitive to the database being fitted. Fits that exclude a few of the older Bonn measurements [8] tend to fall in the range $-2.5\pm0.5\%$. (Some analyses of the recent Mainz and BNL measurements suggest a central value closer to -3% [3,7].) The E2/M1 ratio appears to be relatively stable when evaluated at the T-matrix pole [9]. This ratio of pole residues has been added to the Full Listings [10].

Values of $A_{1/2}$ and $A_{3/2}$ from the RPI [3] and VPI [4] analyses are in reasonable agreement. However, the BNL [7] results are quite different, due to their larger cross sections for $\pi^0 p$ photoproduction. Previous estimates of the E2 and M1 amplitudes, at the K- and T-matrix poles, should be considered obsolete. Pole parameters given for the $\Delta^+(1232)$ in our 1996 Review are also obsolete (see Ref. [11]).

New results for $N(1535) \to p\gamma$: Properties of the N(1535) are difficult to extract from $\pi N \to \pi N$ and $\gamma N \to \pi N$ due to the nearby ηN threshold (see Sec. III). As a result, a number of recent analyses have been based on data from $\pi^- p \to \eta n$ and $\gamma p \to \eta p$. These studies, and those based on coupled-channel analyses including pion photoproduction data, generally find results [12–15] for $A_{1/2}$ that are significantly different from those based on pion photoproduction alone. In particular, $A_{1/2}$ is sensitive to the N(1535) mass and width, and to its interference with the N(1650) [15].

IV. Outlook

Revised November 1997 by D.M. Manley (Kent State University).

In May 1997, a new program in baryon spectroscopy was initiated at the Brookhaven National Laboratory AGS with the Crystal Ball Spectrometer [1]. AGS Expt. E913 measures over most of a 4π solid angle the reactions $\pi^-p \to \gamma n$, $\pi^0 n$, ηn , and $\pi^0\pi^0 n$ at 12 momenta between 285 and 750 MeV/c. These measurements will be completed in 1998, and then AGS Expt. E914 will begin a study of hyperon resonances using the reactions $K^-p \to \text{neutrals}$.

Most of the new generation of experiments to study baryon spectroscopy will use electromagnetic probes. Commissioning experiments were carried out for the CEBAF Large Acceptance Spectrometer, CLAS, during mid 1997, using electron beams with energies of 1.6, 2.4, and 4.0 GeV. The first physics run began in December 1997. Initial measurements of $ep \rightarrow eX$ will be performed with 1.6- and 2.4-GeV electrons. Measurements with 4.0-GeV electrons are scheduled for early 1998. Runs with tagged photons are scheduled for early Spring and Summer, 1998. A number of experiments at CEBAF to study baryon resonances have already been completed, including studies of the $(e, e'K^+)$ reactions on hydrogen and deuterium targets [2], and studies of the $e^-p \rightarrow e^-p\eta$ reaction [3]. The E2/M1 ratio is being investigated using new measurements of the $p(e, e'p)\pi^0$ reaction near the $\Delta(1232)$ resonance, and new measurements of $p(e, e'\vec{p})\pi^0$ at the MIT-Bates Lab [4].

Much work is also underway in European facilities. For example, in 1996, studies of η and K photoproduction commenced at GRAAL in Grenoble [5]. This lab currently provides photon beams with energies up to 1.5 GeV, and may later upgrade to 1.8 GeV. Several reactions are under study there, including $\gamma p \to \gamma p$, ηp , $\pi^0 p$, $\pi^+ n$, and $\pi^0 \pi^0 p$. New meson photoproduction data are also being produced from experiments using the 855-MeV CW electron accelerator MAMI at Mainz, which produces photon beams with energies up to 800 MeV [6]. For example, new experiments of pion photoproduction with linearly polarized photons having energies up to 500 MeV are providing data on the E2/M1 ratio for the $\Delta(1232)$ resonance.

Space does not permit a full discussion of the large amount of experimental work now underway at the labs already mentioned, or at other labs such as Bonn. The new experiments have also inspired many new theoretical and phenomenological efforts to understand this particular aspect of nonperturbative QCD. These efforts include techniques such as lattice gauge

Baryon Particle Listings N's and Δ 's

theory, phenomenological Lagrangians, constituent quark-model calculations, and various unitary multichannel approaches.

V. Non-qqq baryon candidates

The standard quark-model assignments for baryons are outlined in Sec. 13.3, "Baryons: qqq states." Just as with mesons (see the "Note on Non- $q\bar{q}$ mesons"), there have been suggestions that non-qqq baryons might exist, such as hybrid (qqqq) baryons and unstable meson-nucleon bound states [1] (see the "Note on the $\Lambda(1405)$ ").

If non-qqq states exist, they will be more difficult to identify than hybrid mesons: They will not have the clean signature of exotic quantum numbers, and they should also mix with ordinary qqq states. Their identification will depend upon (a) characteristics of their formation and decay, and (b) an over-population of expected qqq states.

Most investigations have focused on the properties of the lightest predicted hybrids. If the first hybrid state lies below 2 GeV, as is suggested by bag-model calculations [2,3,4], it may already exist in our Listings. (However, some estimates put the lightest state well above 2 GeV [5].) At present, there are actually not enough known resonances to fill the known multiplets. If an existing resonance is identified as a hybrid, yet another ordinary qqq state must be found.

The Roper resonance, the N(1440) P_{11} , has been a hybrid candidate based upon its quantum numbers [2] and difficulties with its mass and electromagnetic couplings. If it were a hybrid, our interpretation of the low-lying P_{11} , P_{13} , P_{31} , and P_{33} resonances would change [2,6]. In Ref. 6, both the N(1440) P_{11} and $\Delta(1600)$ P_{33} are hybrid candidates, and N(1540) P_{13} and $\Delta(1550)$ P_{31} states are predicted. One-star P_{13} and P_{31} states were listed in our 1990 Review [7] but were then removed.

Both photoproduction [6,8,9] and electroproduction [9,10] have been considered in the search for a unique hybrid signature. In Ref. 11, QCD counting rules were used to reveal

a characteristic of hybrid electroproduction at high Q^2 . If the N(1440) is a hybrid, its transverse form factor is expected to fall asymptotically $O(1/Q^2)$ faster than for a pure qqq state. However, mixing between qqq and qqqg states will make this identification difficult.

A number of recent experiments have searched for pentaquark $(qqqq\bar{q})$ resonances and H dibaryons (uuddss) states). Narrow structures found in proton-nucleus scattering [12] have been attributed to $qqqs\bar{s}$ states, but these need confirmation. The H-dibaryon experiments, while finding possible candidates [13], have generally quoted upper limits [14] for exotic resonance production. Searches for narrow dibaryons in the nucleon-nucleon interaction are also continuing [15].

Finally, there has been a report [16] of resonances lying below the $\Delta(1232)$. A very weak signal was found using the reaction $pp \to \pi^+ p X^0$. An earlier search [17] for isospin-3/2 states, using $pp \to n X^{++}$, found a null result in the mass range between M_N and $M_N + M_\pi$. At present, there appears to be no evidence for such low-mass states from other reactions.

Note: Signs of couplings from $\pi N \to N\pi\pi$ analyses were changed in the 1986 edition to agree with the baryon-first convention; the overall phase ambiguity is resolved by choosing a negative sign for the $\Delta(1620)$ S_{31} coupling to $\Delta(1232)\pi$.

N(1440) FOOTNOTES

- 1 BAKER 79 finds a coupling of the N(1440) to the N η channel near (but slightly below)
- Threshold. To pole positions are from a search for poles in the unitarized T-matrix; the first (second) value uses, in addition to $\pi N \to N\pi\pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis. The other LONGACRE 77 values are from eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.

 3 From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix
- ARNDT 95 also finds a second-sheet pole with real part = 1383 MeV, -2×imaginary part = 210 MeV, and residue with modulus 92 MeV and phase = -54°.
- ⁵ See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of πN elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams.
- 6 ARNOT 91 (Soln SM90) also finds a second-sheet pole with real part = 1413 MeV, $-2 \times$ Imaginary part = 256 MeV, and residue = (78–153/) MeV.
- ⁷ LONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.
- An alternative which cannot be distinguished from this is to have a P_{13} resonance with M=1530 MeV, $\Gamma=79$ MeV, and elasticity = +0.271. 9 LONGACRE 77 considers this coupling to be well determined.
- 10 WADA 84 is inconsistent with other analyses; see the Note on N and Δ Resonances,
- 11 Converted to our conventions using M= 1486 MeV, $\Gamma=613$ MeV from NOELLE 78.

N(1520) FOOTNOTES

- \$\$ LONGACRE 77 pole positions are from a search for poles in the unitarized T-matrix; the first (second) value uses, in addition to \$\pi N \rightarrow N \pi \pi\$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis. The other LONGACRE 77 values are from eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.
- From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.
- ³ See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of π N elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams.
- All pilotes aim from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.
- 5 LONGACRE 77 considers this coupling to be well determined.
- ⁶ Converted to our conventions using M=1528 MeV, $\Gamma=187$ MeV from NOELLE 78.

N(1535) FOOTNOTES

- ¹LONGACRE 77 pole positions are from a search for poles in the unitarized T-matrix; the first (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis. The other LONGACRE 77 values are from eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.
- ² From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix

- From method II of LONGACKE 73: eyesian instance $N_{\rm B}$ amplitudes.

 3 KRUSCHE 97 fits with the mass fixed at 1544 MeV.

 4 See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of πN elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams.

 5 LONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to $\pi N \to N\pi\pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.

 6 DENIMEDROLICHE 01 uses an effective Lagrangian approach to analyze η photoproduc-
- 6 BENMERROUCHE 91 uses an effective Lagrangian approach to analyze η photoproduc-
- tion data.
 ⁷ Converted to our conventions using M=1548 MeV, $\Gamma=73$ MeV from NOELLE 78.

1/

- $^1\!$ ARNDT 95 finds two distinct states. $^2\!$ BATINIC 95 finds two distinct states. This second resonance was associated with the $N(2090) S_{11}$.
- ³ The two BAKER 77 entries are from an IPWA using the Barrelet-zero method and from
- The two DANCE 77 entires are from a search for poles in the unitarized T-matrix; the first (second) value uses, in addition to $\pi N \to N\pi\pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis. The other LONGACRE 77 values are from eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.
- ⁵ From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix
- From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.
 6 See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of π N elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams. TLONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to π N → Nππ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.
- 8 BAKER 79 fixed this coupling during fitting, but the negative sign relative to the N(1535)
- 9 The overall phase of BAKER 78 couplings has been changed to agree with previous conventions. Superseded by SAXON 80.

 10 The range given for DEANS 75 is from the four best solutions.

 11 LONGACRE 77 considers this coupling to be well determined.

Note: Signs of couplings from $\pi N \to N\pi\pi$ analyses were changed in the 1986 edition to agree with the baryon-first convention; the overall phase ambiguity is resolved by choosing a negative sign for the $\Delta(1620)~S_{31}$ coupling to $\Delta(1232)\pi$.

N(1675) FOOTNOTES

¹LONGACRE 77 pole positions are from a search for poles in the unitarized T-matrix; the first (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saciay (CERN) partial-wave analysis. The other LONGACRE 77 values are from eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.

² From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.

amplitudes.

3 See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of πN elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams. 4 LONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.

⁵ SAXON 80 finds the coupling phase is near 90°.

⁶The range given is from the four best solutions. DEANS 75 disagrees with π^+p \rightarrow $\Sigma^+ K^+$ data of WINNIK 77 around 1920 MeV. 7 LONGACRE 77 considers this coupling to be well determined.

⁸A Breit-Wigner fit to the HERNDON 75 IPWA.

N(1680) FOOTNOTES

- ¹ LONGACRE 77 pole positions are from a search for poles in the unitarized T-matrix; the first (second) value uses, in addition to $\pi N \rightarrow N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis. The other LONGACRE 77 values are from eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.
- ² From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix
- ³ See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of πN elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams.
- ⁴ LONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.
- ⁵ The parametrization used may be double counting.
- The parametrization used may be double counting.

 The range given is from 3 of 4 best solutions; not present in solution 1. DEANS 75 disagrees with π⁺p → Σ⁺K⁺ data of WINNIK 77 around 1920 MeV.

 LONGACRE 77 considers this coupling to be well determined.

 A Breit-Wigner fit to the HERNDON 75 IPWA.

 $N(1700) D_{13}$

 $I(J^P) = \frac{1}{2}(\frac{3}{2})$ Status: ***

Most of the results published before 1975 are now obsolete and have been omitted. They may be found in our 1982 edition, Physics Letters 111B (1982).

The various partial-wave analyses do not agree very well.

N(1700) FOOTNOTES

- ¹ The two BAKER 77 entries are from an IPWA using the Barrelet-zero method and from a conventional energy-dependent analysis.
- a conventional energy-dependent analysis.

 LONGACRE 77 pole positions are from a search for poles in the unitarized T-matrix; the first (second) value uses, in addition to $\pi N \to N\pi\pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis. The other LONGACRE 77 values are from eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.
- any itudes.

 See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of π N elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams.
- SLONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.
- ⁶The overall phase of BAKER 78 couplings has been changed to agree with previous conventions.

 7 The range given is from the four best solutions.

$N(1710) P_{11}$

$$I(J^P) = \frac{1}{2}(\frac{1}{2})$$
 Status: ***

Most of the results published before 1975 are now obsolete and have been omitted. They may be found in our 1982 edition, Physics Letters 111B (1982).

The various partial-wave analyses do not agree very well.

Note: Signs of couplings from $\pi\,N\,\to\,N\,\pi\,\pi$ analyses were changed in the 1986 edition to agree with the baryon-first convention; the overall phase ambiguity is resolved by choosing a negative sign for the $\Delta(1620)$ S_{31} coupling to $\Delta(1232)\pi$.

N(1710) FOOTNOTES

 1 BATINIC 95 finds a second state with a 6 MeV mass difference. 2 The two BAKER 77 entries are from an IPWA using the Barrelet-zero method and from

The two BAKER 77 entires are from an Irvax using the Battelet-Zero method and from a conventional energy-dependent analysis.

LONGACRE 77 pole positions are from a search for poles in the unitarized T-matrix; the first (second) value uses, in addition to $\pi N \to N\pi\pi$ data, elastic amplitudes from Saclay (CERN) partial-wave analysis. The other LONGACRE 77 values are from eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.

⁴ From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix

*From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.

5 See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of π N elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams. 6 LONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to π $N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.

⁷The overall phase of BAKER 78 couplings has been changed to agree with previous

conventions.

8 The range given for DEANS 75 is from the four best solutions.

1 The two BAKER 77 entric		using	the Barr	elet-zero method and from
	tions are from a search in addition to πN — ive analysis. The other	· No	rπ data, IGACRE	he unitarized T-matrix; the elastic amplitudes from a 77 values are from eyeball
³ From method II of LONG/ amplitudes.				gner circles to the T-matrix
⁴ See HOEHLER 93 for a d of N and △ resonances as	determined from Arg of the speeds with wh	gand o lich th	liagrams e amplit	of πN elastic partial-wave udes traverse the diagrams

5 LONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to πN → Nππ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.
 6 The overall phase of BAKER 78 copulings has been changed to agree with previous conventions.
 7 The range given is from the four best solutions. DEANS 75 disagrees with π+p → Σ+K+ data of WINNIK 77 around 1920 MeV.

OMITTED FROM SUMMARY TABLE

There is some evidence for two resonances in this wave between 1800 and 2200 MeV (see CUTKOSKY 80). However, the solution of HOEHLER 79 is quite different.

Most of the results published before 1975 are now obsolete and have been omitted. They may be found in our 1982 edition, Physics Letters 111B (1982).

 $N(\sim 3000)$

$N(\sim 3000 \text{ Region})$ Partial-Wave Analyses

OMITTED FROM SUMMARY TABLE

We list here miscellaneous high-mass candidates for isospin-1/2 resonances found in partial-wave analyses.

Our 1982 edition had an N(3245), an N(3690), and an N(3755), each a narrow peak seen in a production experiment. Since nothing has been heard from them since the 1960's, we declare them to be dead. There was also an N(3030), deduced from total cross-section and 180° elastic cross-section measurements; it is the KOCH 80 $L_{1.15}$ state below.

△(1232) FOOTNOTES

1 Using $\pi^{\pm}d$ as well, PEDRONI 78 determine $(M^{-}-M^{++}) + (M^{0}-M^{+})/3 = 4.6 \pm 0.2$ MeV.
2 See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of π N elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams.
3 This VASAN 76B value is from fits to the coulomb-barrier-corrected CARTER 73 phase shift

shift. 4 This VASAN 76B value is from fits to the CARTER 73 nuclear phase shift without

coulomb barrier corrections. 5 Converted to our conventions using M=1232 MeV, $\Gamma=110$ MeV from NOELLE 78.

⁶ This ARNDT 97 value is very sensitive to the database being fitted. The result is from a fit to the full pion photoproduction database, apart from the BLANPIED 97 cross-section measurements.

△(1600) FOOTNOTES

1 LONGACRE 77 pole positions are from a search for poles in the unitarized T-matrix; the First (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis. The other LONGACRE 77 values are from eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.

2 From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.

From method II of LONGACRE 73: eyeuan its with order region states as amplitudes.

3 See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of π N elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams.

4 LONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.

⁵The range given is from the four best solutions. DEANS 75 disagrees with $\pi^+ p \rightarrow$

 Σ^+K^+ data of WINNIK 77 around 1920 MeV. 6 LONGACRE 77 considers this coupling to be well determined.

 7 WADA 84 is inconsistent with other analyses — see the Note on N and Δ Resonances.

Note: Signs of couplings from $\pi\,N\to N\pi\,\pi$ analyses were changed in the 1986 edition to agree with the baryon-first convention; the overall phase ambiguity is resolved by choosing a negative sign for the $\Delta(1620)~5_{31}$ coupling to $\Delta(1232)\pi$.

△(1620) FOOTNOTES

 $^1\,\mathrm{CHEW}$ 80 reports two S_{31} resonances at somewhat higher masses than other analyses. Problems with this analysis are discussed in section 2.1.11 of HOEHLER 83.

Problems with this analysis are discussed in section 2.1.11 of FIGERLEA 03. **2.LONGACRE 77** pole positions are from a search for poles in the unitarized T-matrix; the first (second) value uses, in addition to $\pi N \rightarrow N\pi\pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis. The other LONGACRE 77 values are from eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.

³ From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.

As See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of π N elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams.

5 LONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.

6 LONGACRE 77 considers this coupling to be well determined.

△(1700) FOOTNOTES

Problems with CHEW 80 are discussed in section 2.1.11 of HOEHLER 83.
²LONGACRE 77 pole positions are from a search for poles in the unitarized T-matrix; the first (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis. The other LONGACRE 77 values are from eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.
³ From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.
⁴ See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of πN elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams.

⁵ LONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.
⁶ The range given is from the four best solutions. DEANS 75 disagrees with $\pi^+ \rho \to \Sigma^+ K^+$ data of WiNNIK 77 around 1920 MeV.
⁷ LONGACRE 77 considers this coupling to be well determined.

Note: Signs of couplings from $\pi\,N\to N\pi\,\pi$ analyses were changed in the 1986 edition to agree with the baryon-first convention; the overall phase ambiguity is resolved by choosing a negative sign for the $\Delta(1620)~S_{31}$ coupling to $\Delta(1232)\pi$.

△(1905) FOOTNOTES

- ¹ From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.
- ² See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of π N elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams.

 ³ LONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to π $N \to N\pi\pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.
- 4 The range given for DEANS 75 is from the four best solutions.
- ⁵ A Breit-Wigner fit to the HERNDON 75 IPWA.
- 6 A Breit-Wigner fit to the NOVOSELLER 78B IPWA.
- ⁷A Breit-Wigner fit to the NOVOSELLER 78B IPWA; the phase is near 90°.

△(1910) FOOTNOTES

- ¹ CHEW 80 reports four resonances in the P_{31} wave see also the Δ (1750). Problems with this analysis are discussed in section 2.1.11 of HOEHLER 83.

 ² LONGACRE 77 pole positions are from a search for poles in the unitarized T-matrix; the first (second) value uses, in addition to $\pi N \to N\pi\pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis. The other LONGACRE 77 values are from eyeball fits with Breit-Wigner circles to the T-matrix amplitudes.

 ³ See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of πN elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams.

 ⁴ The range fixen for DEANS 78 is from the four host evidence.
- The range given for DEANS 75 is from the four best solutions.
- 5 Evidence for this coupling is weak; see NOVOSELLER 78. This coupling assumes the mass is near 1820 MeV.

Δ (1930) FOOTNOTES

¹ See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of πN elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams. ² The range given for DEANS 75 is from the four best solutions.

Note: Signs of couplings from $\pi N \to N \pi \pi$ analyses were changed in the 1986 edition to agree with the baryon-first convention; the overall phase ambiguity is resolved by choosing a negative sign for the $\Delta(1620)$ 5_{31} coupling to $\Delta(1232)\pi$.

△(1950) FOOTNOTES

- 1 From method II of LONGACRE 75: eyeball fits with Breit-Wigner circles to the T-matrix
- ² See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of πN elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams. ³LONGACRE 78 values are from a search for poles in the unitarized T-matrix. The first (second) value uses, in addition to $\pi N \to N \pi \pi$ data, elastic amplitudes from a Saclay (CERN) partial-wave analysis.
- The range given is from the four best solutions. DEANS 75 disagrees with $\pi^+ p \rightarrow \Sigma^+ K^+$ data of WINNIK 77 around 1920 MeV.

 5 A Breit-Wigner fit to the HERNDON 75 IPWA; the phase is near -60° .
- ⁶ A Breit-Wigner fit to the NOVOSELLER 788 IPWA; the phase is near -60°.
- A Breit-Wigner fit to the HERNDON 75 IPWA; the phase is near 120°.
 A Breit-Wigner fit to the NOVOSELLER 78B IPWA; the phase is near 120°.

¹ See HOEHLER 93 for a detailed discussion of the evidence for and the pole parameters of N and Δ resonances as determined from Argand diagrams of π N elastic partial-wave amplitudes and from plots of the speeds with which the amplitudes traverse the diagrams.

$\Delta (\sim 3000 \text{ Region})$ Partial-Wave Analyses

OMITTED FROM SUMMARY TABLE

We list here miscellaneous high-mass candidates for isospin-3/2 resonances found in partial-wave analyses.

Our 1982 edition also had a $\Delta(2850)$ and a $\Delta(3230)$. The evidence for them was deduced from total cross-section and 180° elastic crosssection measurements. The $\Delta(2850)$ has been resolved into the $\Delta(2750)$ $I_{3,13}$ and $\Delta(2950)$ $K_{3,15}$. The $\Delta(3230)$ is perhaps related to the $K_{3,13}$ of HENDRY 78 and to the $L_{3,17}$ of KOCH 80.

BARYON MAGNETIC MOMENTS

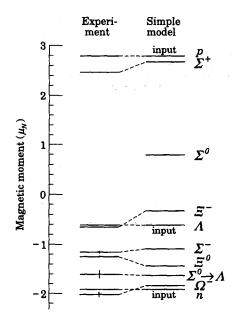

Written 1994 by C.G. Wohl (LBNL).

The figure shows the measured magnetic moments of the stable baryons. It also shows the predictions of the simplest quark model, using the measured p, n, and Λ moments as input. In this model, the moments are [1]

$$\begin{array}{ll} \mu_p = (4\mu_u - \mu_d)/3 & \mu_n = (4\mu_d - \mu_u)/3 \\ \mu_{\Sigma^+} = (4\mu_u - \mu_s)/3 & \mu_{\Sigma^-} = (4\mu_d - \mu_s)/3 \\ \mu_{\Xi^0} = (4\mu_s - \mu_u)/3 & \mu_{\Xi^-} = (4\mu_s - \mu_d)/3 \\ \mu_{\Lambda} = \mu_s & \mu_{\Sigma^0} = (2\mu_u + 2\mu_d - \mu_s)/3 \\ \mu_{\Omega^-} = 3\mu_s \end{array}$$

and the $\Sigma^0 \to \Lambda$ transition moment is

$$\mu_{\varSigma^0\Lambda} = (\mu_d - \mu_u)/\sqrt{3} \ .$$

²The SCHMIDT 65 masses have been reevaluated using our April 1973 proton and K^{\pm} and π^{\pm} masses. P. Schmidt, private communication (1974).

³ The mass has been raised 35 keV to take into account a 46 keV increase in the proton mass and an 11 keV decrease in the π^{\pm} mass (note added Reviews of Modern Physics **39** 1 (1967)).

The quark moments that result from this model are $\mu_u = +1.852 \, \mu_N$, $\mu_d = -0.972 \, \mu_N$, and $\mu_s = -0.613 \, \mu_N$. The corresponding effective quark masses, taking the quarks to be Dirac point particles, where $\mu = q\hbar/2m$, are 338, 322, and 510 MeV. As the figure shows, the model gives a good first approximation to the experimental moments. For efforts to make a better model, we refer to the literature [2].

CONSTRAINED FIT INFORMATION

An overall fit to 5 branching ratios uses 20 measurements and one constraint to determine 5 parameters. The overall fit has a $\chi^2=10.5$ for 16 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to one.

 9 CHAUVAT 85 actually gives $\alpha_+(\overline{\Lambda})/\alpha_-(\Lambda)=-1.04\pm0.29.$ Assumes polarization is same in $\overline{\rho}p\to\overline{\Lambda}X$ and $pp\to\Lambda X$. Tests of this assumption, based on C-invariance and fragmentation, are satisfied by the data.

BA / BV FOR A → pe¬¬¬e

Measurements with fewer than 500 events have been omitted. Where necessary, signs have been changed to agree with our conventions, which are given in the "Note on Baryon Decay Parameters" in the neutron Listings. The measurements all assume that the form factor g₂ = 0. See also the footnote on DWORKIN 90.

¹⁰ The tabulated result assumes the weak-magnetism coupling $w\equiv g_W(0)/g_V(0)$ to be 0.97, as given by the CVC hypothesis and as assumed by the other listed measurements. However, DWORKIN 90 measures w to be 0.15 \pm 0.30, and then $g_A/g_V=-0.731$ \pm 0.016.

^{0.016.} 11 This experiment measures only the absolute value of g_A/g_V .

Baryon Particle Listings Λ 's and Σ 's

Λ AND Σ RESONANCES

Introduction: There are no new results at all on Λ and Σ resonances. The field remains at a standstill and will only be revived if a kaon factory is built. What follows is a much abbreviated version of the note on Λ and Σ Resonances from our 1990 edition. In particular, see that edition for some representative Argand plots from partial-wave analyses.

Table 1 is an attempt to evaluate the status, both overall and channel by channel, of each Λ and Σ resonance in the Particle Listings. The evaluations are of course partly subjective. A blank indicates there is no evidence at all: either the relevant couplings are small or the resonance does not really exist. The main Baryon Summary Table includes only the established resonances (overall status 3 or 4 stars). A number of the 1- and 2-star entries may eventually disappear, but there are certainly many resonances yet to be discovered underlying the established ones.

Sign conventions for resonance couplings: In terms of the isospin-0 and -1 elastic scattering amplitudes A_0 and A_1 , the amplitude for $K^-p \to \overline{K}^0n$ scattering is $\pm (A_1 - A_0)/2$, where the sign depends on conventions used in conjunction with the Clebsch-Gordan coefficients (such as, is the baryon or the meson the "first" particle). If this reaction is partial-wave analyzed and if the overall phase is chosen so that, say, the $\mathcal{L}(1775)D_{15}$ amplitude at resonance points along the positive imaginary axis (points "up"), then any \mathcal{L} at resonance will point "up" and any \mathcal{L} at resonance will point "up" and any \mathcal{L} at resonance determines the isospin. The above ignores background amplitudes in the resonating partial waves.

That is the basic idea. In a similar but somewhat more complicated way, the phases of the $\overline{K}N \to \Lambda\pi$ and $\overline{K}N \to \Sigma\pi$ amplitudes for a resonating wave help determine the SU(3) multiplet to which the resonance belongs. Again, a convention has to be adopted for some overall arbitrary phases: which way is "up"? Our convention is that of Levi-Setti [1] and is shown in Fig. 1, which also compares experimental results with theoretical predictions for the signs of several resonances. In the Listings, a + or - sign in front of a measurement of an inelastic resonance coupling indicates the sign (the absence of a sign means that the sign is not determined, not that it is positive). For more details, see Appendix II of our 1982 edition [2].

Table 1. The status of the Λ and Σ resonances. Only those with an overall status of *** or **** are included in the main Baryon Summary Table.

^{****} Existence is certain, and properties are at least fairly well explored.

*** Existence ranges from very likely to certain, but further confirmation is desirable and/or quantum numbers, branching fractions, etc. are not well determined.

Errors on masses and widths: The errors quoted on resonance parameters from partial-wave analyses are often only statistical, and the parameters can change by more than these errors when a different parametrization of the waves is used.

^{**} Evidence of existence is only fair.

^{*} Evidence of existence is poor

Λ 's and Σ 's, Λ (1405)

Furthermore, the different analyses use more or less the same data, so it is not really appropriate to treat the different determinations of the resonance parameters as independent or to average them together. In any case, the spread of the masses, widths, and branching fractions from the different analyses is certainly a better indication of the uncertainties than are the quoted errors. In the Baryon Summary Table, we usually give a range reflecting the spread of the values rather than a particular value with error.

For three states, the $\Lambda(1520)$, the $\Lambda(1820)$, and the $\Sigma(1775)$, there is enough information to make an overall fit to the various branching fractions. It is then necessary to use the quoted errors, but the errors obtained from the fit should not be taken seriously.

Production experiments: Partial-wave analyses of course separate partial waves, whereas a peak in a cross section or an invariant mass distribution usually cannot be disentangled from background and analyzed for its quantum numbers; and more than one resonance may be contributing to the peak. Results from partial-wave analyses and from production experiments are generally kept separate in the Listings, and in the Baryon Summary Table results from production experiments are used only for the low-mass states. The $\Sigma(1385)$ and $\Lambda(1405)$ of course lie below the $\overline{K}N$ threshold and nearly everything about them is learned from production experiments; and production and formation experiments agree quite well in the case of $\Lambda(1520)$ and results have been combined. There is some disagreement between production and formation experiments in the 1600-1700 MeV region: see the note on the $\Sigma(1670)$.

 $\Lambda(1405) S_{01}$

 $I(J^P) = 0(\frac{1}{2})$ Status: ***

NOTE ON THE $\Lambda(1405)$

Revised March 1998 by R.H. Dalitz (Oxford University).

It is generally accepted that the $\Lambda(1405)$ is a well-established $J^P = 1/2^-$ resonance. It is assigned to the lowest L = 1supermultiplet of the 3-quark system and paired with the $J^P = 3/2^- \Lambda(1520)$. Lying about 30 MeV below the $N\overline{K}$ threshold, the $\Lambda(1405)$ can be observed directly only as a resonance bump in the $(\Sigma\pi)^0$ subsystem in final states of production experiments. It was first reported by ALSTON 61B in the reaction $K^-p \to \Sigma \pi \pi \pi$ at 1.15 GeV/c and has since been seen in at least eight other experiments. However, only two of them had enough events for a detailed analysis: THOMAS 73, with about 400 $\Sigma^{\pm}\pi^{\mp}$ events from $\pi^{-}p \to K^{0}(\Sigma\pi)^{0}$ at 1.69 GeV/c; and HEMINGWAY 85, with 766 $\Sigma^{+}\pi^{-}$ and 1106 $\Sigma^-\pi^+$ events from $K^-p \to (\Sigma\pi\pi)^+\pi^-$ at 4.2 GeV/c, after the selections $1600 \le M(\Sigma \pi \pi)^+ \le 1720$ MeV and momentum transfer $\leq 1.0 \; (\text{GeV}/c)^2$ to purify the $\Lambda(1405) \to (\Sigma \pi)^0$ sample. These experiments agree on a mass of about 1395-1400 MeV and a width of about 60 MeV. (Hemingway's mass of 1391 \pm 1 MeV is from his best, but unacceptably poor, Breit-Wigner fit.)

The Byers-Fenster tests on these data allow any spin and either parity: neither J nor P has yet been determined directly. The early indications for $J^P=1/2^-$ came from finding Re $A_{I=0}$ to be large and negative in a constant-scattering-length analysis of low-energy $N\overline{K}$ reaction data (see KIM 65, SAKITT 65, and earlier references cited therein). The first multichannel energy-dependent K-matrix analysis (KIM 67) strengthened the case for a resonance around 1400–1420 MeV strongly coupled to the I=0 S-wave $N\overline{K}$ system.

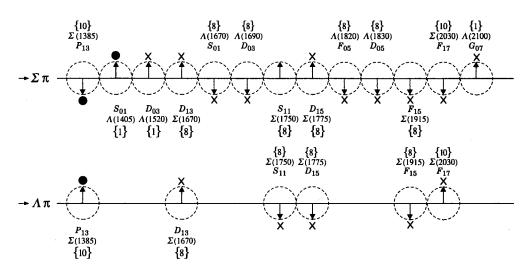

Figure 1. The signs of the imaginary parts of resonating amplitudes in the $\overline{K}N \to \Lambda\pi$ and $\Sigma\pi$ channels. The signs of the $\Sigma(1385)$ and $\Lambda(1405)$, marked with a \bullet , are set by convention, and then the others are determined relative to them. The signs required by the SU(3) assignments of the resonances are shown with an arrow, and the experimentally determined signs are shown with an \times .

Λ(1405)

THOMAS 73 and HEMINGWAY 85 both found the $\Lambda(1405)$ bump to be asymmetric and not well fitted by a Breit-Wigner resonance function with constant parameters. The asymmetry involves a rapid fall in intensity as the $N\overline{K}$ threshold energy is approached from below. This is readily understood as due to a strong coupling of the $\Lambda(1405)$ to the S-wave $N\overline{K}$ channel (see DALITZ 81). This striking S-shaped cusp behavior at a new threshold is characteristic of S-wave coupling; the other below-threshold hyperon, the $\Sigma(1385)$, has no such threshold distortion because its $N\overline{K}$ coupling is P-wave. For the $\Lambda(1405)$, this asymmetry is the sole direct evidence that $J^P=1/2^-$.

Following the early work cited above, a considerable literature has developed on proper procedures for phenomenological extrapolation below the $N\overline{K}$ threshold, partly in order to strengthen the evidence for the spin-parity of the $\Lambda(1405)$, and partly to provide an estimate for the amplitude $f(N\overline{K})$ in the unphysical domain below the $N\overline{K}$ threshold; the latter is needed for the evaluation of the dispersion relation for $N\overline{K}$ and NK forward scattering amplitudes. For recent reviews, see MILLER 84 and BARRETT 89. In most recent work, the $(\Sigma\pi)^0$ production spectrum is included in the data fitted (see, e.g., CHAO 73, MARTIN 81).

It is now accepted that the data can be fitted only with an S-wave pole in the reaction amplitudes below $N\overline{K}$ threshold (see, however, FINK 90), but there is still controversy about the physical origin of this pole (for a review, see DALITZ 81 and DALITZ 82). Two extreme possibilities are: (a) an L=1 SU(3)-singlet uds state coupled with the S-wave meson-baryon systems; or (b) an unstable $N\overline{K}$ bound state, analogous to the (stable) deuteron in the NN system. The problem with (a) is that the $\Lambda(1405)$ mass is so much lower than that of its partner, the $\Lambda(1520)$. This requires, in the QCD-inspired quark model, rather large spin-orbit couplings, whether or not one uses relativistic kinetic energies. CAPSTICK 86 and CAPSTICK 89 conclude that a proper QCD calculation leads only to small energy splittings, whereas LEINWEBER 90, using QCD sum rules, obtains a good fit to this splitting.

On the other hand, the problem with (b) is that then another $J^P=1/2^-\Lambda$ is needed to replace the $\Lambda(1405)$ in the L=1 supermultiplet, and it would have to lie close to the $\Lambda(1520)$, a region already well explored by $N\overline{K}$ experiments without result. Intermediate structures are possible; for example, the cloudy bag model allows the configurations (a) and (b) to mix and finds the intensity of (a) in the $\Lambda(1405)$ to be only 14% (VEIT 84, VEIT 85, JENNINGS 86). Such models naturally predict a second $1/2^-\Lambda$ close to the $\Lambda(1520)$.

The determination of the mass and width of the resonance from $(\Sigma\pi)^0$ data is usually based on the "Watson approximation," which states that the production rate $R(\Sigma\pi)$ of the $(\Sigma\pi)^0$ state has a mass dependence proportional to $(\sin^2\delta_{\Sigma\pi})/q$, q being the $\Sigma\pi$ c.m. momentum, in a $\Sigma\pi$ mass range where $\delta_{\Sigma\pi}$ is not far from $\pi/2$ and only the $\Sigma\pi$ channel is open, i.e., between the $\Sigma\pi$ and the $N\overline{K}$ thresholds. Then $qR(\Sigma\pi)$ is proportional to $\sin^2\delta_{\Sigma\pi}$, and the mass M may be defined as the energy at

which $\sin^2 \delta_{\Sigma\pi} = 1$. The width Γ may be determined from the rate at which $\delta_{\Sigma\pi}$ goes through $\pi/2$, or from the FWHM; this is a matter of convention.

This determination of M and Γ from the data suffers from the following defects:

- (i) The determination of $\sin^2 \delta_{\Sigma\pi}$ requires that $R(\Sigma\pi)$ be scaled to give $\sin^2 \delta_{\Sigma\pi} = 1$ at the peak for the best fit to the data; *i.e.*, the bump must be assumed to arise from a resonance. However, this assumption is supported by the analysis of the low-energy $N\overline{K}$ data and its extrapolation below threshold.
- (ii) Owing to the nearby $N\overline{K}$ threshold, the shape of the best fit to the $M(\Sigma\pi)$ bump is uncertain. For energies below this threshold at $E_{N\overline{K}}$, the general form for $\delta_{\Sigma\pi}$ is

$$q \cot \delta_{\Sigma\pi} = \frac{1 + \kappa\alpha}{\gamma + \kappa(\alpha\gamma - \beta^2)} \ . \tag{1}$$

Here α, β , and γ are the (generally energy-dependent) NN, $N\Sigma$, and $\Sigma\Sigma$ elements of the I=0 S-wave K-matrix for the $(\Sigma\pi, N\overline{K})$ system, and κ is the magnitude of the (imaginary) c.m. momentum k_K for the $N\overline{K}$ system below threshold. The elements α, β, γ are real functions of E; they have no branch cuts at the $\Sigma\pi$ and $N\overline{K}$ thresholds, but they are permitted to have poles in E along the real E axis. The resonance asymmetry arises from the effect of κ on $\delta_{\Sigma\pi}$. We note that $\delta_{\Sigma\pi}=\pi/2$ when $\kappa=-1/\alpha$.

Accepting this close connection of $\delta_{\Sigma\pi}$ with the low-energy $N\overline{K}$ data, it is natural to analyze the two sets of data together (e.g., MARTIN 81), and there is now a large body of accurate $N\overline{K}$ data for laboratory momenta between 100 and 300 MeV/c (see MILLER 84). The two sets of data span c.m. energies from 1370 MeV to 1490 MeV, and the K-matrix elements will not be energy independent over such a broad range. For the I =0 channels, a linear energy dependence for K^{-1} has been adopted routinely ever since the work of KIM 67, and it is essential when fitting the $qR(\Sigma\pi)$ and $N\overline{K}$ data together. However, $qR(\Sigma\pi)$ is not always well fitted in this procedure; the value obtained for the $\Lambda(1405)$ mass M varies a good deal with the type of fit, not a surprising result when the $\Sigma\pi$ mass spectrum below the pK^- threshold contributes only nine data points in a total of about 200. The value of M obtained from an overall fit is not necessarily much better than from one using only the $qR(\Sigma\pi)$ data; and M may be a function of the representation— K-matrix, K⁻¹-matrix, relativistic-separable or nonseparable potentials, etc.— used in fitting over the full energy range. DALITZ 91 fitted the $qR(\Sigma^+\pi^-)$ Hemingway data with each of the first three representations just mentioned, constrained to the I=0 $N\overline{K}$ threshold scattering length from low-energy $N\overline{K}$ data. The (nonseparable) meson-exchange potentials of MÜLLER-GROELING 90, fitted to the low-energy $N\overline{K}$ (and NK) data, predicted an unstable $N\overline{K}$ bound state with mass and width compatible with the $\Lambda(1405)$.

From the measurement of $2p \to 1s$ x rays from kaonic-hydrogen, the energy-level shift ΔE and width Γ of its 1s state can give us two further constraints on the $(\Sigma \pi, N\overline{K})$

Baryon Particle Listings $\Lambda(1405)$

system, at an energy roughly midway between those from the low-energy hydrogen bubble chamber studies and those from $q R(\Sigma \pi)$ observations below the pK^- threshold. IWASAKI 97 have reported the first convincing observation of this x ray, with a good initial estimate:

$$\Delta E - i\Gamma/2 = (-323 \pm 63 \pm 11) - i(204 \pm 104 \pm 50) \text{ eV}$$
. (2)

The errors here encompass about half of the predictions made following the various analyses and/or models for the in-flight K^-p and sub-threshold $q\,R(\varSigma\pi)$ data. Better measurements will be needed to discriminate between the analyses and predictions. Now that ΔE is known with some certainty, we can anticipate much-improved data on kaonic-hydrogen, perhaps from the DA Φ NE storage ring at Frascati, information vital for our quantitative understanding of the $(\varSigma\pi, N\overline{K})$ system in this region. This will lead to better knowledge of kaonic coupling strengths and to more reliable dispersion-theoretic arguments concerning strange-particle processes.

The present status of the $\Lambda(1405)$ thus depends heavily on theoretical arguments, a somewhat unsatisfactory basis for a four-star rating. Nevertheless, there is no known reason to doubt its existence or quantum numbers. The 3-quark model for baryons has been broadly successful in accounting for all of the $L^P = 1^-$ excited baryonic states (CAPSTICK 89), apart from the relatively large mass separation between the $\Lambda(1405)$ and $\Lambda(1520)$. Quark model builders have no reservations about accepting the $\Lambda(1405)$ as a 3-quark state. However, calculations with broken-chiral-symmetric models, which combine internal 3-quark configurations with external meson-baryon states (e.g.,VEIT 85, KAISER 95) end up with descriptions of the $\Lambda(1405)$ dominated by the meson-baryon terms in the wavefunctions. Models using meson-baryon potentials readily fit its mass, and give ΔE negative, as is found empirically. The problem is not so much one of "either (a) or (b)," but rather how to achieve "both (a) and (b)." Theoreticians have not yet been able to deal with the full coupled-channels system, with qqq and $qqqq\overline{q}$ configurations (at the least) being treated on the same footing. On the experimental side, better statistics are needed, both above and below the pK^- threshold. To disentangle the physics, the I = 1 channels also need more attention. For example, low-energy pK_L^0 interactions have not been studied at all in the last 25 years.

$$I(J^P) = O(\frac{3}{2}^-)$$
 Status: ***

Discovered by FERRO-LUZZI 62; the elaboration in WATSON 63 is the classic paper on the Breit-Wigner analysis of a multichannel

The measurements of the mass, width, and elasticity published before 1975 are now obsolete and have been omitted. They were last listed in our 1982 edition Physics Letters 111B (1982).

Production and formation experiments agree quite well, so they are listed together here.

CONSTRAINED FIT INFORMATION

An overall fit to 9 branching ratios uses 24 measurements and one constraint to determine 6 parameters. The overall fit has a $\chi^2=$ 16.5 for 19 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to one.

A(1520) FOOTNOTES

- I From the best-resolution sample of $A\pi\pi$ events only.
- ² The $\vec{K}N \rightarrow \Sigma \pi$ amplitude at resonance is +0.46 ± 0.01.
- ³ Assumes $\Gamma(N\overline{K})/\Gamma_{\text{total}} = 0.46 \pm 0.02$.
- ⁴ Both $\Sigma(1385)\pi$ DS_{03} and $\Sigma(\pi\pi)$ DP_{03} contribute.
- 5 The central bin (1514–1524 MeV) gives 0.74 \pm 0.10; other bins are lower by 2-to-5 standard deviations. 6 Much of the $\Sigma \pi \pi$ decay proceeds via $\Sigma (1385)\pi$.
- ⁷ Assumes $\Gamma(N\overline{K})/\Gamma_{\text{total}} = 0.46$.
- 8 Calculated from $\Gamma(\Lambda\gamma)/\Gamma_{total}$, assuming SU(3). Needed to constrain the sum of all the branching ratios to be unity.

A(1690) DECAY MODES

	Mode	Fraction (Γ_I/Γ)	
$\overline{\Gamma_1}$	NK	20–30 %	
Γ_2	Σπ	20-40 %	
Гз	Λππ	∼ 25 %	
Γ ₅	$\Sigma \pi \pi$ $\Lambda \eta$	~ 20 %	
16	$\Sigma(1385)\pi$, <i>S</i> -wave		

The above branching fractions are our estimates, not fits or averages.

1/(1690) BRANCHING RATIOS

The sum of all the quoted branching ratios is more than 1.0. The two-body ratios are from partial-wave analyses, and thus probably are more reliable than the three-body ratios, which are determined from bumps in cross sections. Of the latter, the $\Sigma\pi\pi$ bump looks more significant. (The error given for the $\Lambda\pi\pi$ ratio looks unreasonably small.) Hardly any of the $\Sigma\pi\pi$ decay can be via Σ (1385), for then seven times as much $\Lambda\pi\pi$ decay would be required. See "Sign conventions for resonance couplings" in the Note on Λ and Σ Resonances.

$$I(J^P) = O(\frac{5}{2}^+)$$
 Status: ***

This resonance is the cornerstone for all partial-wave analyses in this region. Most of the results published before 1973 are now obsolete and have been omitted. They may be found in our 1982 edition Physics Letters 111B (1982).

Most of the quoted errors are statistical only; the systematic errors due to the particular parametrizations used in the partial-wave analyses are not included. For this reason we do not calculate weighted averages for the mass and width.

A(1820) FOOTNOTES

1 The two MARTIN 77 values are from a T-matrix pole and from a Breit-Wigner fit. There is a suggestion of a bump, enough to be consistent with what is expected from $\Sigma(1385) \to \Sigma \pi$ decay.

³ The published sign has been changed to be in accord with the baryon-first convention.

OMITTED FROM SUMMARY TABLE

We list here all the ambiguous resonance possibilities with a mass around 2 GeV. The proposed quantum numbers are D_3 (BARBARO-GALTIERI 70 in $\Sigma\pi$), $D_3+F_5,\,P_3+D_5,$ or P_1+D_3 (BRANDSTETTER 72 in $\Lambda\omega$), and S_1 (CAMERON 78B in $N\overline{K}^*$). The first two of the above analyses should now be considered obsolete. See also NAKKASYAN 75.

OMITTED FROM SUMMARY TABLE

In LITCHFIELD 71, need for the state rests solely on a possibly inconsistent polarization measurement at 1.784 GeV/c. HEMING-WAY 75 does not require this state. GOPAL 77 does not need it in either $N \overline{K}$ or $\Sigma \pi$. With new $K^- n$ angular distributions included, DECLAIS 77 sees it. However, this and other new data are included in GOPAL 80 and the state is not required. BACCARI 77 weakly supports it.

 1 The NAKKASYAN 75 values are from the two best solutions found. Each has the $\Lambda(2100)$ and one additional resonance $(P_3$ or $F_5)$. 2 Note that the three for BACCARI 77 entries are for three different waves. 3 The published sign has been changed to be in accord with the baryon-first convention. The upper limit on the G_3 wave is 0.03.

$\Lambda(2325) D_{03}$

 $I(J^P) = O(\frac{3}{2})$ Status: *

OMITTED FROM SUMMARY TABLE

BACCARI 77 finds this state with either $J^P = 3/2^-$ or $3/2^+$ in a energy-dependent partial-wave analyses of $K^-p \to \Lambda \omega$ from 2070 to 2436 MeV. A subsequent semi-energy-independent analysis from threshold to 2436 MeV selects 3/2". DEBELLEFON 78 (same group) also sees this state in an energy-dependent partial-wave analysis of $K^-p\to \overline{K}\,N$ data, and finds $J^P=3/2^-$ or $3/2^+$. They again prefer $J^P=3/2^-$, but only on the basis of model-dependent considerations.

Λ(2350) H₀₉

$$I(J^P) = O(\frac{9}{2}^+)$$
 Status: ***

DAUM 68 favors $J^{P} = 7/2^{-}$ or $9/2^{+}$. BRICMAN 70 favors $9/2^{+}$. LASINSKI 71 suggests three states in this region using a Pomeron + resonances model. There are now also three formation experiments from the College de France-Saclay group, DEBELLEFON 77, BACCARI 77, and DEBELLEFON 78, which find 9/2+ in energydependent partial-wave analyses of $\overline{K}N \to \Sigma \pi$, $\Lambda \omega$, and $N\overline{K}$.

 $^{^3\,\}mbox{We}$ have increased the CHANG 66 error of 0.018; see our 1970 edition, Reviews of Modern Physics 42 No. 1 (1970).

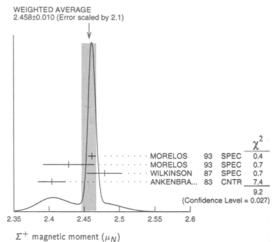

Σ+ MAGNETIC MOMENT

See the "Note on Baryon Magnetic Moments" in the A Listings. Measurements with an error $\geq 0.1 \,\mu_N$ have been omitted.

VALUE	(μ_N)		EVTS		DOCUMENT ID		TECN	COMMENT
2.458	±0.010	OUR AVERAGE	Error		ides scale facto below.	r of	2.1. See	the ideogram
2.4613	±0.0034	±0.0040	250k		MORELOS	93	SPEC	pCu 800 GeV
2.428	± 0.036	±0.007	12k	4	MORELOS	93	SPEC	pCu 800 GeV
2.479	± 0.012	±0.022	137k		WILKINSON	87	SPEC	pBe 400 GeV
2.4040	±0.0198		44k	5	ANKENBRA	83	CNTR	pCu 400 GeV

⁴We assume CPT invariance: this is (minus) the $\overline{\Sigma}^-$ magnetic moment as measured by

MORELOS 93. See below for the moment difference testing CPT. 5 ANKENBRANDT 83 gives the value 2.38 \pm 0.02 μ_N . MORELOS 93 uses the same hyperon magnet and channel and claims to determine the field integral better, leading to the revised value given here.

 $(\mu_{\Sigma^+} + \mu_{\overline{\Sigma}^-}) / |\mu|_{\text{average}}$

A test of CP / Hivariance.			
VALUE	DOCUMENT ID	TECN	COMMENT
0.014±0.015	6 MORELOS 93	SPEC	pCu 800 GeV

⁶This is our calculation from the MORELOS 93 measurements of the Σ^+ and $\overline{\Sigma}^$ magnetic moments given above. The statistical error on $\mu_{\overline{\Sigma}^-}$ dominates the error here.

Σ+ DECAY MODES

	Mode	Fraction (Γ_j/Γ) Confidence level
Γ ₁	$p\pi^0$	(51.57±0.30) %
Γ_2	$n\pi^+$	(48.31±0.30) %
Гз	$p\gamma$	$(1.23\pm0.05)\times10^{-3}$
Γ4	$n\pi^+\gamma$	[a] $(4.5 \pm 0.5) \times 10^{-4}$
Γ ₅	$\Lambda e^+ \nu_e$	$(2.0 \pm 0.5) \times 10^{-5}$

$\Delta S = \Delta Q$ (SQ) violating modes or $\Delta S = 1$ weak neutral current (S1) modes

Γ6	$ne^+\nu_e$	5Q	< 5	× 10 ⁻⁶	90%
Γ ₇	$n\mu^+ u_\mu$	5Q	< 3.0	× 10 ⁻⁵	90%
	pe+ e ^{'-}	51	< 7	× 10 ⁻⁶	

[a] See the Particle Listings below for the pion momentum range used in this measurement.

CONSTRAINED FIT INFORMATION

An overall fit to 2 branching ratios uses 14 measurements and one constraint to determine 3 parameters. The overall fit has a χ^2 7.7 for 12 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ $\Gamma_i/\Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to

$$\begin{array}{c|cccc} x_2 & -100 & \\ x_3 & 12 & -14 \\ \hline & x_1 & x_2 \end{array}$$

Σ⁰ MEAN LIFE

These lifetimes are deduced from measurements of the cross sections for the Primakoff process $\Lambda \to \Sigma^0$ in nuclear Coulomb fields. An alternative expression of the same information is the Σ^0 - Λ transition magnetic moment given in the following section. The relation is $(\mu_{\Sigma} \Lambda/\mu_N)^2 \tau =$ 1.92951×10^{-19} s (see DEVLIN 86).

VALUE (10 ⁻²⁰ s)	DOCUMENT ID		TECN	COMMENT			
7.4±0.7 OUR EVALUATION	Using $\mu_{\sum \Lambda}$ (see the above note).						
$6.5^{+1.7}_{-1.1}$	² DEVLIN	86	SPEC	Primakoff effect

[a] See the Particle Listings below for the pion momentum range used in this measurement.

CONSTRAINED FIT INFORMATION

An overall fit to 3 branching ratios uses 16 measurements and one constraint to determine 4 parameters. The overall fit has a $\chi^2=8.7$ for 13 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left\langle \delta x_i \delta x_j \right\rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to one

Σ^- BRANCHING RATIOS

g_A/g_V FOR Σ⁻ → ne⁻ν_e

Measurements with fewer than 500 events have been omitted. Where necessary, signs have been changed to agree with our conventions, which are given in the "Note on Baryon Decay Parameters" in the neutron Listings. What is actually listed is $|g_1/f_1-0.237g_2/f_1|$. This reduces to $g_A/g_V\equiv g_1(0)/f_1(0)$ on making the usual assumption that $g_2=0$. See also the note on HSUEH 88.

⁶ The sign is, with our conventions, unambiguously positive. The value assumes, as usual, that $g_2=0$. If g_2 is included in the fit, than (with our sign convention) $g_2=-0.56\pm0.37$, with a corresponding reduction of g_A/g_V to $+0.20\pm0.08$.

7 BOURQUIN 83C favors the positive sign by at least 2.6 standard deviations.

 8 TANENBAUM 74 gives 0.435 \pm 0.035, assuming no q^2 dependence in g_A and g_V . The listed result allows q^2 dependence, and is taken from HSUEH 88.

 $f_2(0)/f_1(0)$ FOR $\Sigma^- \to ne^- \overline{\nu}_e$ The signs have been changed to be in accord with our conventions, given in the "Note on Barvon Decay Parameters" in the neutron Listings.

TRIPLE CORRELATION COEFFICIENT D for $\Sigma^- \to ne^- \overline{\nu}_e$

The coefficient D of the term D $P \cdot (P_e \times P_v)$ in the $\Sigma^- \to ne^- v$ decay angular distribution. A nonzero value would indicate a violation of time-reversal invariance.

$\Sigma(1385) P_{13}$

$$I(J^P) = 1(\frac{3}{2}^+)$$
 Status: ***

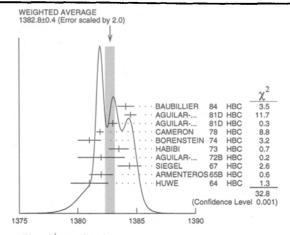

Discovered by ALSTON 60. Early measurements of the mass and width for combined charge states have been omitted. They may be found in our 1984 edition Reviews of Modern Physics **56** No. 2 Pt. II (1984).

We average only the most significant determinations. We do not average results from inclusive experiments with large backgrounds or results which are not accompanied by some discussion of experimental resolution. Nevertheless systematic differences between experiments remain. (See the ideograms in the Listings below.) These differences could arise from interference effects that change with production mechanism and/or beam momentum. They can also be accounted for in part by differences in the parametrizations employed. (See BORENSTEIN 74 for a discussion on this point.) Thus BORENSTEIN 74 uses a Breit-Wigner with energyindependent width, since a P-wave was found to give unsatisfactory fits. CAMERON 78 uses the same form. On the other hand HOLM-GREN 77 obtains a good fit to their $\Lambda\pi$ spectrum with a P-wave Breit-Wigner, but includes the partial width for the $\Sigma\pi$ decay mode in the parametrization. AGUILAR-BENITEZ 81D gives masses and widths for five different Breit-Wigner shapes. The results vary considerably. Only the best-fit S-wave results are given here.

OMITTED FROM SUMMARY TABLE

These are peaks seen in $\Lambda\pi$ and $\Sigma\pi$ spectra in the reaction $\pi^+p\to$ $(Y\pi)K^+$ at 1.7 GeV/c. Also, the Y polarization oscillates in the same region.

MILLER 70 suggests a possible alternate explanation in terms of a reflection of $N(1675) \rightarrow \Lambda K$ decay. However, such an explanation for the $(\Sigma^+ \pi^0) K^+$ channel in terms of $\Delta(1650) \rightarrow \Sigma K$ decay seems unlikely (see PAN 70). In addition such reflections would also have to account for the oscillation of the Y polarization in the 1480 MeV region.

HANSON 71, with less data than PAN 70, can neither confirm nor deny the existence of this state. MAST 75 sees no structure in this region in $K^-p \rightarrow \Lambda \pi^0$.

ENGELEN 80 performs a multichannel analysis of $K^-p \to p \overline{K}{}^0\pi^$ at 4.2 GeV/c. They observe a 3.5 standard-deviation signal at 1480 MeV in $p\overline{K}^0$ which cannot be explained as a reflection of any competing channel.

$\Sigma(1560)$ Bumps

 $I(J^P) = 1(??)$ Status: **

OMITTED FROM SUMMARY TABLE

This entry lists peaks reported in mass spectra around 1560 MeV without implying that they are necessarily related.

DIONISI 78B observes a 6 standard-deviation enhancement at 1553 MeV in the charged $\Lambda/\Sigma\pi$ mass spectra from $K^-p\to$ $(\Lambda/\Sigma)\pi K\overline{K}$ at 4.2 GeV/c. In a CERN ISR experiment, LOCK-MAN 78 reports a narrow 6 standard-deviation enhancement at 1572 MeV in $\Lambda \pi^{\pm}$ from the reaction $pp \to \Lambda \pi^+ \pi^- X$. These enhancements are unlikely to be associated with the $\Sigma(1580)$ (which has not been confirmed by several recent experiments - see the next entry in the Listings).

CARROLL 76 observes a bump at 1550 MeV (as well as one at 1580 MeV) in the isospin-1 $\overline{K}N$ total cross section, but uncertainties in cross section measurements outside the mass range of the experiment preclude estimating its significance.

See also MEADOWS 80 for a review of this state.

$\Sigma(1620)$ Production Experiments

 $I(J^P) = 1(??)$

OMITTED FROM SUMMARY TABLE

Formation experiments are listed separately in the previous entry.

The results of CRENNELL 69B at 3.9 ${
m GeV}/c$ are not confirmed by SABRE 70 at 3.0 GeV/c. However, at 4.5 GeV/c, AMMANN 70 sees a peak at 1642 MeV which on the basis of branching ratios they do not associate with the $\Sigma(1670)$. See MILLER 70 for a review of these conflicts.

THE $\Sigma(1670)$ REGION

Production experiments: The measured $\Sigma \pi / \Sigma \pi \pi$ branching ratio for the $\Sigma(1670)$ produced in the reaction $K^-p \to \pi^- \Sigma (1670)^+$ is strongly dependent on momentum transfer. This was first discovered by EBERHARD 69, who suggested that there exist two Σ resonances with the same mass and quantum numbers: one with a large $\Sigma\pi\pi$ (mainly $\Lambda(1405)\pi$) branching fraction produced peripherally, and the other with a large $\Sigma\pi$ branching fraction produced at larger angles. The experimental results have been confirmed by AGUILAR-BENITEZ 70, ASPELL 74, ESTES 74, and TIMMERMANS 76. If, in fact, there are two resonances, the most likely quantum numbers for both the $\Sigma\pi$ and the $\Lambda(1405)\pi$ states are D_{13} . There is also possibly a third Σ in this region, the $\Sigma(1690)$ in the Listings, the main evidence for which is a large $\Lambda\pi/\Sigma\pi$ branching ratio. These topics have been reviewed by EBERHARD 73 and by MILLER 70.

Formation experiments: Two states are also observed near this mass in formation experiments. One of these, the $\Sigma(1670)D_{13}$, has the same quantum numbers as those observed in production and has a large $\Sigma \pi / \Sigma \pi \pi$ branching ratio; it may well be the $\Sigma(1670)$ produced at larger angles (see TIM-MERMANS 76). The other state, the $\Sigma(1660)P_{11}$, has different quantum numbers, its $\Sigma \pi / \Sigma \pi \pi$ branching ratio is unknown, and its relation to the produced $\Sigma(1670)$ states is obscure.

² The two MARTIN 77 values are from a T-matrix pole and from a Breit-Wigner fit.

³ From solution 1 of BAILLON 75; not present in solution 2.

$\Sigma(1670) D_{13}$

 $I(J^P) = 1(\frac{3}{2}^-)$ Status: ***

Σ(1670) FOOTNOTES

- 1 The two MARTIN 77 values are from a T-matrix pole and from a Breit-Wigner fit.
- ² Results are with and without an S_{11} $\Sigma(1620)$ in the fit.
- ³ SIMS 68 uses only cross-section data. Result used as upper limit only.
- **RMS be uses only cross-section data. Results used to E Γ (1385).

 **Assuming the Λ (1405) π cross-section bump is due only to 3/2 $^-$ resonance.
- ⁶ The CAMERON 77 upper limit on F-wave decay is 0.03.

Baryon Particle Listings Σ (1670) Bumps

Σ (1670) Bumps

 $I(J^P) = 1(??)$

OMITTED FROM SUMMARY TABLE

Formation experiments are listed separately in the preceding entry.

Probably there are two states at the same mass with the same quantum numbers, one decaying to $\Sigma \pi$ and $\Lambda \pi$, the other to $\Lambda(1405)\pi$. See the note in front of the preceding entry.

$J^P=3/2^+$		LEVEQUE	65	HBC		$\Lambda(1405)\pi$

1	Total cross-section	bump with	(J+1/2) Γ _{α1}	/ [total	= 0.23.

 2 Enhancements in $\Sigma\pi$ and $\Sigma\pi\pi$ cross sections. 3 Backward production in the $\Lambda\pi^ K^+$ final state.

Depending on production angle.

APSELL 74, ESTES 74, and TIMMERMANS 76 find strong branching ratio dependence on production angle, as in earlier production experiments.

Σ (1690) FOOTNOTES (PRODUCTION EXPERIMENTS)

 1 From $\pi^+p \to (A\pi^+)K^+$. J > 1/2 is not required by the data. 2 From $\pi^+p \to (A\pi^+)(K\pi)^+$. J > 1/2 is indicated, but large background precludes a definite conclusion. 3 See the $\Sigma(1670)$ Listings. AGUILAR-BENITEZ 70B with three times the data of PRIMER 68 find no evidence for the $\Sigma(1690)$.

⁴ This analysis, which is difficult and requires several assumptions and shows no unambiguous $\Sigma(1690)$ signal, suggests $J^P=5/2^+$. Such a state would lead all previously known Y* trajectories.

 Σ (1750) S_{11}

 $I(J^{P}) = 1(\frac{1}{2})$ Status: ***

For most results published before 1974 (they are now obsolete), see our 1982 edition Physics Letters 111B (1982).

There is evidence for this state in many partial-wave analyses, but with wide variations in the mass, width, and couplings. The latest analyses indicated significant couplings to $N\overline{K}$ and $\Lambda\pi$, as well as to $\Sigma \eta$ whose threshold is at 1746 MeV (JONES 74).

$\overline{\Sigma(1770)} P_{11}$

F(NK)/Frotal

 $I(J^P) = 1(\frac{1}{2}^+)$ Status: *

OMITTED FROM SUMMARY TABLE

Evidence for this state now rests solely on solution 1 of BAILLON 75, (see the footnotes) but the $\Lambda\pi$ partial-wave amplitudes of this solution are in disagreement with amplitudes from most other $\Lambda\pi$ analyses.

Σ(1770) FOOTNOTES

- 1 Required to fit the isospin-1 total cross section of CARROLL 76 in the $\overline{\textit{K}}$ N channel. The addition of new K^-p polarization and K^-n differential cross-section data in GOPAL 80 find it to be more consistent with the Σ (1660) P_{11} .

 From solution 1 of BAILLON 75; not present in solution 2.

 Not required in KANE 74, which supersedes KANE 72.

¹ The two MARTIN 77 values are from a T-matrix pole and from a Brelt-Wigner fit.

 $^{^2}$ A total cross-section bump with (J+1/2) Γ_{el} / Γ_{total} = 0.30.

An S-wave Breit-Wigner fit to the threshold cross section with no background and errors statistical only.

 $I(J^P) = 1(\frac{5}{2}^-)$ Status: ****

Discovered by GALTIERI 63, this resonance plays the same role as cornerstone for isospin-1 analyses in this region as the $\Lambda(1820)$ does in the isospin-0 channel.

For most results published before 1974 (they are now obsolete), see our 1982 edition Physics Letters 111B (1982).

Σ(1775) DECAY MODES

	Mode	Fraction (Γ_I/Γ)	
$\overline{\Gamma_1}$	NK	37-43%	
Γ_2	$\Lambda\pi$	14-20%	
Гз	$\Sigma \pi$	2–5%	
Γ ₄ Γ ₅	$\Sigma(1385)\pi$ $\Sigma(1385)\pi$, <i>D</i> -wave	8–12%	
Γ ₆ Γ ₇	$\Lambda(1520) \pi$ $\Sigma \pi \pi$	17-23%	

The above branching fractions are our estimates, not fits or averages.

CONSTRAINED FIT INFORMATION

An overall fit to 8 branching ratios uses 16 measurements and one constraint to determine 5 parameters. The overall fit has a χ^2 = 63.9 for 12 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ Γ_i/Γ_{total} . The fit constrains the x_i whose labels appear in this array to sum to

Σ(1775) BRANCHING RATIOS

See "Sign conventions for resonance couplings" in the Note on Λ and Σ Resonances. Also, the errors quoted do not include uncertainties due to the parametrization used in the partial-wave analyses and are thus too

Σ(1775) FOOTNOTES

1 The two MARTIN 77 values are from a T-matrix pole and from a Breit-Wigner fit.

2 This rate combines *P*-wave and *F*-wave decays. The CAMERON 77 results for the separate *P*-wave and *F*-wave decays are -0.303 ± 0.010 and -0.037 ± 0.014. The published signs have been changed here to be in accord with the baryon-first convention.

3 The CAMERON 78 upper limit on *G*-wave decay is 0.03.

⁴ For about 3/4 of this, the $\Sigma\pi$ system has I=0 and is almost entirely $\Lambda(1520)$. For the rest, the $\Sigma\pi$ has I=1, which is about what is expected from the known $\Sigma(1775) \to \Sigma(1385)\pi$ rate, as seen in $\Lambda\pi\pi$.

$\Sigma(1880) P_{11}$

 $I(J^P) = 1(\frac{1}{2}^+)$ Status: **

OMITTED FROM SUMMARY TABLE

A P_{11} resonance is suggested by several partial-wave analyses, but with wide variations in the mass and other parameters. We list here all claims which lie well above the P_{11} $\Sigma(1770)$.

Σ(1880) FOOTNOTES

- ¹ The two MARTIN 77 values are from a T-matrix pole and from a Breit-Wigner flt.
 ² From solution 1 of BAILLON 75; not present in solution 2.
 ³ Only unconstrained states from table 1 of LEA 73 are listed.

- ⁴ The published sign has been changed to be in accord with the baryon-first convention.

$\Sigma(1915) F_{15}$

 $I(J^P) = 1(\frac{5}{2}^+)$ Status: ***

Discovered by COOL 66. For results published before 1974 (they are now obsolete), see our 1982 edition Physics Letters 111B (1982).

This entry only includes results from partial-wave analyses. Parameters of peaks seen in cross sections and invariant-mass distributions in this region used to be listed in in a separate entry immediately following. They may be found in our 1986 edition Physics Letters 170B (1986).

Σ(1915) FOOTNOTES

- 1 The two entries for CORDEN 77C are from two different acceptable solutions.
- 2 Preferred solution 3; see CORDEN 76 for other possibilities.

 3 The two MARTIN 77 values are from a T-matrix pole and from a Breit-Wigner fit.
- ⁴ The mass and width are fixed to the GOPAL 77 values due to the low elasticity.
- ⁵ The published sign has been changed to be in accord with the baryon-first convention.

Baryon Particle Listings $\Sigma(1940), \Sigma(2000)$

 $\Sigma(1940) D_{13}$

 $I(J^P) = 1(\frac{3}{2}^-)$ Status: ***

For results published before 1974 (they are now obsolete), see our 1982 edition Physics Letters 111B (1982).

Not all analyses require this state. It is not required by the GOYAL 77 analysis of $K^- n \to (\Sigma \pi)^-$ nor by the GOPAL 80 analysis of $K^- n \rightarrow K^- n$. See also HEMINGWAY 75.

¹ The two MARTIN 77 values are from a T-matrix pole and from a Breit-Wigner fit.

² The published sign has been changed to be in accord with the baryon-first convention. 3 Upper limits on the D_1 and D_3 waves are each 0.03.

 $\Sigma(2030) F_{17}$

 $I(J^P) = 1(\frac{7}{2}^+)$ Status: ***

Discovered by COOL 66 and by WOHL 66. For most results published before 1974 (they are now obsolete), see our 1982 edition Physics Letters 111B (1982).

This entry only includes results from partial-wave analyses. Parameters of peaks seen in cross sections and invariant-mass distributions around 2030 MeV may be found in our 1984 edition, Reviews of Modern Physics **56** No. 2 Pt. II (1984).

72 DPWA $K^-p \rightarrow \Sigma \pi$

708 DPWA $K^-p \rightarrow \Sigma \pi$

OMITTED FROM SUMMARY TABLE

This state suggested by BERTHON 70B finds support in GOPAL 80 with new K^-p polarization and K^-n angular distributions. The very broad state seen in KANE 72 is not required in the later (KANE 74) analysis of $\overline{K}\,N\to\Sigma\pi$.

 Status: ***

Results from partial-wave analyses are too weak to warrant separating them from the production and cross-section experiments. LASINSKI 71 in $\overline{K}N$ using a Pomeron + resonances model, and DEBELLEFON 76, DEBELLEFON 77, and DEBELLEFON 78 in energy-dependent partial-wave analyses of $\overline{K}N \to \Lambda\pi$, $\Sigma\pi$, and $N\overline{K}$, respectively, suggest two resonances around this mass.

CONSTRAINED FIT INFORMATION

An overall fit to 2 branching ratios uses 2 measurements and one constraint to determine 3 parameters. The overall fit has a χ^2 = 0.0 for 0 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ Γ_i/Γ_{total} . The fit constrains the x_i whose labels appear in this array to sum to one.

CONSTRAINED FIT INFORMATION

An overall fit to 4 branching ratios uses 5 measurements and one constraint to determine 5 parameters. The overall fit has a $\chi^2=1.0$ for 1 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to one.

α FOR $\Xi^- \to \Lambda \pi^-$

-0.3

-0.35

WEIGHTED AVERAGE -0.293±0.007 (Error scaled by 1.8)

The above average, $\alpha(\Xi^-)$ $\alpha_-(\Lambda) = -0.293 \pm 0.007$, where the error includes a scale factor of 1.8, divided by our current average $\alpha_{-}(\Lambda)=0.642\pm0.013$, gives the following value for $\alpha(\Xi^+)$.

<u>POCUMENT ID</u>
-0.456±0.014 OUR EVALUATION Error includes scale factor of 1.8.

The errors have been multiplied by 1.2 due to approximations used for the Ξ polarization; see DAUBER 69 for a discussion.

 Ξ 's, Ξ (1530)

E RESONANCES

The accompanying table gives our evaluation of the present status of the Ξ resonances. Not much is known about Ξ resonances. This is because (1) they can only be produced as a part of a final state, and so the analysis is more complicated than if direct formation were possible, (2) the production cross sections are small (typically a few μ b), and (3) the final states are topologically complicated and difficult to study with electronic techniques. Thus early information about Ξ resonances came entirely from bubble chamber experiments, where the numbers of events are small, and only in the 1980's did electronic experiments make any significant contributions. However, there has not been a single new piece of data on Ξ resonances since our 1988 edition.

For a detailed earlier review, see Meadows [1].

Table 1. The status of the Ξ resonances. Only those with an overall status of *** or **** are included in the Baryon Summary Table.

		_			Status	as seen in	
Particle	$L_{2I\cdot 2J}$	Overall status	Ξπ	ΛK	ΣK	$\Xi(1530)\pi$	Other channels
Ξ(1318)	$\overline{P_{11}}$	****					Decays weakly
Ξ(1530)	P_{13}	****	****				
$\Xi(1620)$		*	*				
E(1690)		***		***	**		
三(1820)	D_{13}	***	**	***	**	**	
E(1950)		***	**	**		*	
$\Xi(2030)$	1	***		**	***		
$\Xi(2120)$		*		*			
$\Xi(2250)$		**					3-body decays
$\Xi(2370)$	1	**					3-body decays
E(2500)	_	*		*	*		3-body decays

- **** Existence is certain, and properties are at least fairly well explored.

 *** Existence ranges from very likely to certain, but further confirmation is desirable and/or quantum numbers, branching fractions, etc. are not well determined.
- etc. are not well determined.

 ** Evidence of existence is only fair.
- * Evidence of existence is poor.

Reference

 B.T. Meadows, in Proceedings of the IVth International Conference on Baryon Resonances (Toronto, 1980), ed. N. Isgur, p. 283.

$$I(J^P) = \frac{1}{2}(\frac{3}{2}^+)$$
 Status: ***

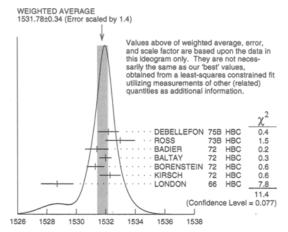

This is the only Ξ resonance whose properties are all reasonably well known. Spin-parity $3/2^+$ is favored by the data.

We use only those determinations of the mass and width that are accompanied by some discussion of systematics and resolution.

 $\Xi(1620)$

 $I(J^P) = \frac{1}{2}(?^?)$ Status: * J, P need confirmation.

OMITTED FROM SUMMARY TABLE

What little evidence there is consists of weak signals in the $\Xi\pi$ channel. A number of other experiments (e.g., BORENSTEIN 72 and HASSALL 81) have looked for but not seen any effect.

Ξ(1690)

 $I(J^P) = \frac{1}{2}(?^?)$ Status: ***

DIONISI 78 sees a threshold enhancement in both the neutral and negatively charged $\Sigma \overline{K}$ mass spectra in $K^- p \to (\Sigma \overline{K}) K \pi$ at 4.2 GeV/c. The data from the ΣK channels alone cannot distinguish between a resonance and a large scattering length. Weaker evidence at the same mass is seen in the corresponding $\Lambda \overline{K}$ channels, and a coupled-channel analysis yields results consistent with a new \varXi .

BIAGI 81 sees an enhancement at 1700 MeV in the diffractively produced ΛK^- system. A peak is also observed in the $\Lambda \overline{K}{}^0$ mass spectrum at 1660 MeV that is consistent with a 1720 MeV resonance decaying to $\Sigma^0\overline{K}^0$, with the γ from the Σ^0 decay not detected.

BIAGI 87 provides further confirmation of this state in diffractive dissociation of Ξ^- into ΛK^- . The significance claimed is 6.7 standard deviations.

 $I(J^P) = \frac{1}{2}(\frac{3}{2}^-)$ Status: ***

The clearest evidence is an 8-standard-deviation peak in ΛK^- seen. by GAY 76. TEODORO 78 favors J=3/2, but cannot make a parity discrimination. BIAGI 87C is consistent with J=3/2 and favors negative parity for this J value.

Ξ(1820) FOOTNOTES

- 1 BIAGI 87 also sees weak signals in the in the $\Xi^-\pi^+\pi^-$ channel at 1782.6 \pm 1.4 MeV ($\Gamma=6.0\pm1.5$ MeV) and 1831.9 \pm 2.8 MeV ($\Gamma=9.6\pm9.9$ MeV).
- 2 BADIER 72 adds all channels and divides the peak into lower and higher mass regions.

 The data can also be fitted with a single Breit-Wigner of mass 1800 MeV and width 150 MeV. ³ From a fit to inclusive $\Xi\pi$, $\Xi\pi\pi$, and ΛK^- spectra.
- ⁴ From a fit to inclusive $\Xi \pi$ and $\Xi \pi \pi$ spectra only.
- ⁵ Including $\Xi \pi \pi$.
- 6 DAUBER 69 uses in part the same data as SMITH 65C. 7 For the decay mode $\Xi^-\pi^+\pi^0$ only. This limit includes $\Xi(1530)\pi$.
- ⁸ Or less. Upper limit for the 3-body decay.

$$I(J^P) = \frac{1}{2}(?^?)$$
 Status: ***

We list here everything reported between 1875 and 2000 MeV. The accumulated evidence for a E near 1950 MeV seems strong enough to include a $\Xi(1950)$ in the main Baryon Table, but not much can be said about its properties. In fact, there may be more than one Ξ near this mass.

Ξ(2030)

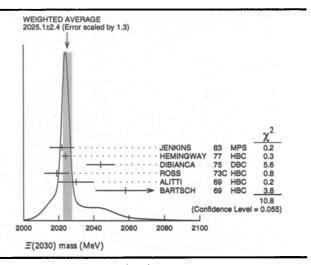

$$I(J^P) = \frac{1}{2} (\geq \frac{5}{2})^{\frac{1}{2}}$$
 tatus: ***

The evidence for this state has been much improved by HEMING-WAY 77, who see an eight standard deviation enhancement in $\Sigma\overline{K}$ and a weaker coupling to $\Lambda\overline{K}$. ALITTI 68 and HEMINGWAY 77 observe no signals in the $\Xi\pi\pi$ (or $\Xi(1530)\pi$) channel, in contrast to DIBIANCA 75. The decay $(\Lambda/\Sigma)\overline{K}\pi$ reported by BARTSCH 69 is also not confirmed by HEMINGWAY 77.

A moments analysis of the HEMINGWAY 77 data indicates at a level of three standard deviations that $J \geq 5/2$.

≡(2120) FOOTNOTES

¹CHLIAPNIKOV 79 does not uniquely identify the K^+ in the $(\overline{A}K^+)$ X final state. It also reports bumps with fewer events at 2240, 2540, and 2830 MeV.

²GAY 76c sees a 4-standard deviation signal. However, HEMINGWAY 77, with more events from the same experiment points out that the signal is greatly reduced if a cut is made on the 4-momentum v. This suggests an anomalous production mechanism if the $\Xi(2120)$ is real.

OMITTED FROM SUMMARY TABLE

The evidence for this state is mixed. BARTSCH 69 sees a bump of not much statistical significance in $\Lambda \overline{K}\pi$, $\Sigma \overline{K}\pi$, and $\Xi \pi \pi$ mass spectra. GOLDWASSER 70 sees a narrower bump in $\Xi \pi \pi$ at a higher mass. Not seen by HASSALL 81 with 45 events/ μ b at 6.5 GeV/c. Seen by JENKINS 83. Perhaps seen by BIAGI 87.

 Ω^-

 $I(J^P) = O(\frac{3}{2}^+)$ Status: ****

The unambiguous discovery in both production and decay was by BARNES 64. The quantum numbers have not actually been measured, but follow from the assignment of the particle to the baryon decuplet. DEUTSCHMANN 78 and BAUBILLIER 78 rule out J=1/2 and find consistency with J=3/2.

We have omitted some results that have been superseded by later experiments. See our earlier editions.

Ω- MASS

The fit assumes the Ω^- and $\overline{\Omega}^+$ masses are the same.

¹ DIBIANCA 75 gives a mass for each event. We quote the average.

 2 The FRY 55 and FRY 558 events were identified as \varOmega^- by ALVAREZ 73. The masses assume decay to ΛK^- at rest. For FRY 558, decay from an atomic orbit could Doppler shift the K^- energy and the resulting \varOmega^- mass by several MeV. This shift is negligible for FRY 55 because the \varOmega decay is approximately perpendicular to its orbital velocity, as is known because the \varLambda strikes the nucleus (L.Alvarez, private communication 1973). We have calculated the error assuming that the orbital n is 4 or larger.

 3 Excluded from the average; the \varOmega^- lifetimes measured by the experiments differ significantly from other measurements.

The EISENBERG 54 mass was calculated for decay in flight. ALVAREZ 73 has shown that the Ω interacted with an Ag nucleus to give $K^- \Xi Ag$.

Ω+ MASS

The fit assumes the \varOmega^- and $\overline{\varOmega}^+$ masses are the same.

OMITTED FROM SUMMARY TABLE

A peak in the $\Omega^-\pi^+\pi^-$ mass spectrum with a signal significance claimed to be at least 5.5 standard deviations. There is no reason to seriously doubt the existence of this state, but unless the evidence is overwhelming we usually wait for confirmation from a second experiment before elevating peaks to the Summary Table.

CHARMED BARYONS (C = +1)

 $\begin{array}{lll} \varLambda_c^+ = u\,d\,c, & \varSigma_c^{++} = u\,u\,c, & \varSigma_c^+ = u\,d\,c, & \varSigma_c^0 = d\,d\,c, \\ \varXi_c^+ = u\,s\,c, & \varXi_c^0 = d\,s\,c, & \varOmega_c^0 = s\,s\,c \end{array}$

CHARMED BARYONS

Figure 1 shows the SU(4) multiplets that have as their lowest levels (a) the SU(3) octet that contains the nucleon, and (b) the SU(3) decuplet that contains the $\Delta(1232)$. All the particles in a given SU(4) multiplet have the same spin and parity. The only known charmed baryons each contain one charmed quark and thus belong to the second level of an SU(4) multiplet. Figure 2 shows this level for the SU(4) multiplet of Fig. 1(a). The level splits apart into two SU(3) multiplets, a $\overline{3}$ that contains the $\Lambda_c(2285)$ and the $\Xi_c(2470)$, both of which decay weakly, and a 6 that contains the $\Sigma_c(2455)$, which decays strongly to $\Lambda_c \pi$, and the $\Omega_c(2710)$, which decays weakly. A second Ξ_c remains to be discovered to fill out the 6, and a host of other baryons with one or more charmed quarks are needed to fill out the full SU(4) multiplets. Furthermore, every N or Δ baryon resonance "starts" another SU(4) multiplet, so the woods are full of charmed baryons, most of which no doubt will forever remain undiscovered. The only candidates so far to belong to more massive multiplets are the $\Lambda_c(2593)$ and the $\Lambda_c(2625)$, and perhaps a $\Xi_c(2645)$; see the Listings.

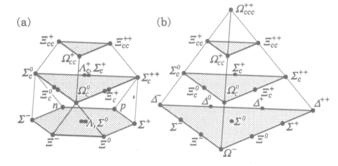

Fig. 1. SU(4) multiplets of baryons made of u, d, s, and c quarks. (a) The 20-plet with an SU(3) octet on the lowest level. (b) The 20-plet with an SU(3) decuplet on the lowest level.

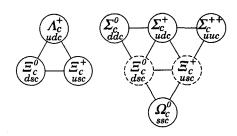

Fig. 2. The SU(3) multiplets on the second level of the SU(4) multiplet of Fig. 1(a). The particles in dashed circles have yet to be discovered.

The states of the $\overline{3}$ multiplet in Fig. 2 are antisymmetric under interchange of the two light quarks (the u, d, and s quarks), whereas the states of the 6 multiplet are symmetric under interchange of these quarks. Actually, there may be some mixing between the pure $\overline{3}$ and 6 Ξ_c states (they have the same I, J, and P quantum numbers) to form the physical Ξ_c states.

It need hardly be said that the flavor symmetries Fig. 1 displays are very badly broken, but the figure is the simplest way to see what charmed baryons should exist.

For a review of theory and experiment, see Ref. 1.

Λ_c^+

A+ DECAY MODES

Nearly all branching fractions of the Λ_c^+ are measured relative to the $\rho\,K^-\pi^+$ mode, but there are no model-independent measurements of this branching fraction. We explain how we arrive at our value of $\mathrm{B}(\Lambda_c^+\to\rho\,K^-\pi^+)$ in a Note at the beginning of the branching-ratio measurements, below. When this branching fraction is eventually well determined, all the other branching fractions will slide up or down proportionally as the true value differs from the value we use here.

F61	$\Sigma^-\mu^+\mu^+$	L	< 7.0	× 10 ⁻⁴	CL=90%

- [a] See the "Note on Λ_c^+ Branching Fractions" below.
- [b] This branching fraction includes all the decay modes of the final-state resonance.
- [c] An ℓ indicates an e or a μ mode, not a sum over these modes.
- [d] The value is for the sum of the charge states of particle/antiparticle states indicated

NOTE ON Λ_{c}^{+} BRANCHING FRACTIONS

Written 1998 by P.R. Burchat (Stanford University).

Most Λ_c^+ branching fractions are measured relative to the decay mode $\Lambda_c^+ \to pK^-\pi^+$. However, there are no model-independent measurements of the absolute branching fraction for $\Lambda_c^+ \to pK^-\pi^+$. Here, we describe the measurements that have been used to extract $B(\Lambda_c^+ \to pK^-\pi^+)$, the model-dependence of the results, and the method we have used to average the results.

ARGUS (ALBRECHT 88C) and CLEO (CRAWFORD 92) measure $B(\overline{B} \to \Lambda_c^+ X) \times B(\Lambda_c^+ \to pK^-\pi^+)$ to be $(0.30 \pm 0.12 \pm 0.06)\%$ and $(0.273 \pm 0.051 \pm 0.039)\%$. Under the assumptions that decays of \overline{B} mesons to baryons are dominated by $\overline{B} \to \Lambda_c^+ X$ and that $\Lambda_c^+ X$ final states other than $\Lambda_c^+ \overline{N} X$ can be neglected, they also measure $B(\overline{B} \to \Lambda_c^+ X)$ to be $(6.8 \pm 0.5 \pm 0.3)\%$ (ALBRECHT 92O) and $(6.4 \pm 0.8 \pm 0.8)\%$ (CRAWFORD 92). Combining these results, we get $B(\Lambda_c^+ \to pK^-\pi^+) = (4.14 \pm 0.91)\%$. However, the assumption that \overline{B} decay modes to baryons other than $\Lambda_c^+ \overline{N} X$ are negligible is not on solid ground experimentally or theoretically. Therefore, the branching fraction for $\Lambda_c^+ \to pK^-\pi^+$ given above may be low by some undetermined amount.

The second type of model-dependent determination of $B(\Lambda_c^+ \to pK^-\pi^+)$ is based on measurements by AR-GUS (ALBRECHT 91G) and CLEO (BERGFELD 94) of $\sigma(e^+e^- \to \Lambda_c^+X) \cdot B(\Lambda_c^+ \to \Lambda \ell^+\nu_\ell) = (4.15 \pm 1.03 \pm 1.18)$ pb and $(4.77 \pm 0.25 \pm 0.66)$ pb. ARGUS (ALBRECHT 96E) and CLEO (AVERY 91) have also measured $\sigma(e^+e^- \to \Lambda_c^+X) \cdot B(\Lambda_c^+ \to pK^-\pi^+)$. The weighted average is (11.2 ± 1.3) pb.

From these measurements, we extract $R \equiv \mathrm{B}(\Lambda_c^+ \to p K^- \pi^+)/\mathrm{B}(\Lambda_c^+ \to \Lambda \ell^+ \nu_\ell) = 2.40 \pm 0.43$. We estimate the $\Lambda_c^+ \to p K^- \pi^+$ branching fraction from the equation

$$B(\Lambda_c^+ \to pK^-\pi^+) = R f F \frac{\Gamma(D \to X\ell^+\nu_{\ell})}{1 + |V_{cd}/V_{cs}|^2} \cdot \tau(\Lambda_c^+) , \quad (1)$$

where $f = B(\Lambda_c^+ \to \Lambda \ell^+ \nu_\ell)/B(\Lambda_c^+ \to X_s \ell^+ \nu_\ell)$ and $F = \Gamma(\Lambda_c^+ \to X_s \ell^+ \nu_\ell)/\Gamma(D^0 \to X_s \ell^+ \nu_\ell)$. When we use

 $1+|V_{cd}/V_{cs}|^2=1.05$ and the world averages $\Gamma(D\to \mathrm{X}\ell^+\nu_\ell)=(0.163\pm0.006)\times10^{-12}~\mathrm{s}^{-1}$ and $\tau(\Lambda_c^+)=(0.206\pm0.012)\times10^{-12}~\mathrm{s},$ we calculate $\mathrm{B}(\Lambda_c^+\to pK^-\pi^+)=(7.7\pm1.5)\%\cdot f\,F.$ Theoretical estimates for f and F are near 1.0 with significant uncertainties.

So, we have two results with significant model-dependence: $\mathrm{B}(\Lambda_c^+ \to pK^-\pi^+) = (4.14\pm0.91)\%$ from \overline{B} decays, and $\mathrm{B}(\Lambda_c^+ \to pK^-\pi^+) = (7.7\pm1.5)\% \cdot f\,F$ from semileptonic Λ_c^+ decays. If we set $f\,F=1.0$ in the second result, and assign an uncertainty of 30% to each result to account for the unknown model-dependence, we get the consistent results $\mathrm{B}(\Lambda_c^+ \to pK^-\pi^+) = (4.14\pm0.91\pm1.24)\%$ and $\mathrm{B}(\Lambda_c^+ \to pK^-\pi^+) = (7.7\pm1.5\pm2.3)\%$. The weighted average of these two results is $\mathrm{B}(\Lambda_c^+ \to pK^-\pi^+) = (5.0\pm1.3)\%$, where the uncertainty contains both the experimental uncertainty and the 30% estimate of model dependence in each result.

This procedure is clearly rather arbitrary, but so is any other procedure until good measurements of the absolute branching fraction are made. Therefore, we have assigned the value $(5.0 \pm 1.3)\%$ to the $\Lambda_c^+ \to p K^- \pi^+$ branching fraction (given as PDG 98 below). As was noted earlier, most of the other modes are measured relative to this mode.

$\Lambda_c(2593)^+$

$$I(J^P) = O(\frac{1}{2}) \text{ Status: } ***$$

Seen in $\Lambda_c^+\pi^+\pi^-$ but not in $\Lambda_c^+\pi^0$, so this is indeed an excited Λ_c^+ rather than a Σ_c^+ . The $\Lambda_c^+\pi^+\pi^-$ mode is largely, and perhaps entirely, $\Sigma_c\pi$, which is just at threshold; thus (assuming, as has not yet been proven, that the Σ_c has $J^P=1/2^+$) the J^P here is almost certainly $1/2^-$. This result is in accord with the theoretical expectation that this is the charm counterpart of the strange A(1405).

$\Lambda_c(2593)^+$ MASS

The mass is obtained from the $m_{\Lambda_c(2593)^+} - m_{\Lambda_c^+}$ mass-difference measurements below.

2459 ± 5 ±30	56	¹ COTEUS	87 S	PEC	nA ≃ 600 GeV
2460 ±25	82	BIAGI	83 S	PEC	Σ - Be 135 GeV

1 Although COTEUS 87 claims to agree well with BIAGI 83 on the mass and width, there appears to be a discrepancy between the two experiments. BIAGI 83 sees a single peak (stated significance about 6 standard deviations) in the $\Lambda K^-\pi^+\pi^+$ mass spectrum. COTEUS 87 sees two peaks in the same spectrum, one at the $\Xi_{\mathbf{c}}^+$ mass, the other 75 MeV lower. The latter is attributed to $\Xi_c^+ \to \Sigma^0 K^- \pi^+ \pi^+ \to (\Lambda \gamma) K^- \pi^+ \pi^+$, with the γ unseen. The *combined* significance of the double peak is stated to be 5.5 standard deviations. But the absence of any trace of a lower peak in BIAGI 83 seems to us to throw into question the interpretation of the lower peak of COTEUS 87.

BOTTOM BARYONS

(B=-1)

 $\Lambda_b^0 = udb$, $\Xi_b^0 = usb$, $\Xi_b^- = dsb$

$$I(J^{p}) = O(\frac{1}{2}^{+})$$
 Status: ***

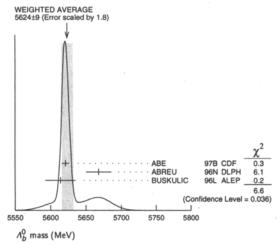

In the quark model, a Λ_b^0 is an isospin-0 udb state. The lowest Λ_b^0 ought to have $J^P = 1/2^+$. None of I, J, or P have actually been measured.

 $^{^1}$ ABE 97B observed 38 events above a background 18 \pm 1.6 events in the mass range 5.60–5.65 GeV/ c^2 , a significance of > 3.4 standard deviations.

 $^{^4}$ ALBAJAR 91E claims 16 \pm 5 events above a background of 9 \pm 1 events, a significance of about 5 standard deviations.

10 MEAN LIFE

These are actually measurements of the average lifetime of weakly decaying b baryons weighted by generally unknown production rates, branching fractions, and detection efficiencies. Presumably, the mix is mainly \varLambda_b^0 , with some Ξ_b^0 and Ξ_b^- .

See b-baryon Admixture section for data on b-baryon mean life average over species of b-baryon particles.

"OUR EVALUATION" is an average of the data listed below performed by the LEP B Lifetimes Working Group as described in our review "Production and Decay of b-flavored Hadrons" in the B^{\pm} Section of the Listings. The averaging procedure takes into account correlations between the measurements and asymmetric lifetime errors.

⁵ Measured using $\Lambda_c \ell^-$ and $\Lambda \ell^+ \ell^-$.						

AD DECAY MODES

These branching fractions are actually an average over weakly decaying b-baryons weighted by their production rates in Z decay (or high-energy $p\bar{p}$), branching ratios, and detection efficiencies. They scale with the LEP Λ_b production fraction $B(b \to \Lambda_b)$ and are evaluated for our value $B(b \to \Lambda_b) = (10.1 + \frac{3.9}{3.1})\%$.

The branching fractions B(b-baryon $\rightarrow \Lambda \ell^- \bar{\nu}_\ell$ anything) and B($\Lambda_b^0 \rightarrow \Lambda_c^+ \ell^- \bar{\nu}_\ell$ anything) are not pure measurements because the underlying measured products of these with B($b \rightarrow \Lambda_b$) were used to determine B($b \rightarrow \Lambda_b$), as described in the note "Production and Decay of b-Flavored Hadrons."

OMITTED FROM SUMMARY TABLE

ABREU 95V observe an excess of same-sign $\Xi^{\mp} \ell^{\mp}$ events in jets, which they interpret as $\Xi_b \to \Xi^- \ell^- \overline{\nu}_\ell X$. They find that the probability for these events to come from non-b-baryon decays is less than 5×10^{-4} and that Λ_b decays can account for less than 10% of these events.

In the quark model, Ξ_b^0 and Ξ_b^- are an isodoublet (usb, dsb) state; the lowest Ξ_b^0 and Ξ_b^- ought to have $J^P=1/2^+$. None of I, J, or P have actually been measured.

E, MEAN LIFE

This is actually a measurement of the average lifetime of *b*-baryons that decay to a jet containing a same-sign $\Xi^\mp \ell^\mp$ pair. Presumably the mix is mainly Ξ_b , with some Λ_b .

"OUR EVALUATION" is an average of the data listed below performed by the LEP B Lifetimes Working Group as described in our review "Production and Decay of b-flavored Hadrons" in the B^\pm Section of the Listings. The averaging procedure takes into account correlations between the measurements and asymmetric lifetime errors.

b-baryon ADMIXTURE $(\Lambda_b, \Xi_b, \Sigma_b, \Omega_b)$

b-baryon ADMIXTURE MEAN LIFE

Each measurement of the b-baryon mean life is an average over an admixture of various b baryons which decay weakly. Different techniques emphasize different admixtures of produced particles, which could result In a different b-baryon mean life.

"OUR EVALUATION" is an average of the data listed below performed by the LEP B Lifetimes Working Group as described in our review "Production and Decay of b-flavored Hadrons" in the B^{\pm} Section of these Listings. The averaging procedure takes into account correlations between the measurements and asymmetric lifetime errors.

b-baryon ADMIXTURE $(\Lambda_b,\Xi_b,\Sigma_b,\Omega_b)$

These branching fractions are actually an average over weakly decaying b-baryons weighted by their production rates in Z decay (or high-energy $p\overline{p}$), branching ratios, and detection efficiencies. They scale with the LEP Λ_b production fraction B($b o \Lambda_b$) and are evaluated for our value B(b o Λ_b) = (10.1 $^{+3.9}_{-3.1}$)%.

The branching fractions B(b-baryon $\rightarrow \Lambda \ell^- \bar{\nu}_{\ell}$ anything) and B($\Lambda_h^0 \rightarrow$ $\Lambda_c^+ \ell^- \overline{\nu}_\ell$ anything) are not pure measurements because the underlying measured products of these with $B(b \rightarrow \Lambda_b)$ were used to determine $B(b \rightarrow \Lambda_b)$, as described in the note "Production and Decay of b-Flavored Hadrons."

	Mode	Fraction (Γ_I/Γ)	
r ₁	$p\mu^-\overline{\nu}$ anything	(4.9± 2.4)%	_
	$\Lambda \ell^- \overline{ u}_\ell$ anything	$(3.1^{+}_{-}1.0^{1})\%$

Magnetic Monopole Searches

MAGNETIC MONOPOLE SEARCHES

Revised December 1997 by D.E. Groom (LBNL).

"At the present time (1975) there is no experimental evidence for the existence of magnetic charges or monopoles, but chiefly because of an early, brilliant theoretical argument by Dirac, the search for monopoles is renewed whenever a new energy region is opened up in high energy physics or a new source of matter, such as rocks from the moon, becomes available [1]." Dirac argued that a monopole anywhere in the universe results in electric charge quantization everywhere, and leads to the prediction of a least magnetic charge $g = e/2\alpha$, the Dirac charge [2]. Recently monopoles have become indispensable in many gauge theories, which endow them with a variety of extraordinarily large masses. The discovery by a candidate event in a single superconducting loop in 1982 [6] stimulated an enormous experimental effort to search for supermassive magnetic monopoles [3,4,5].

Monopole detectors have predominantly used either induction or ionization. Induction experiments measure the monopole magnetic charge and are independent of monopole electric charge, mass, and velocity. Monopole candidate events in single semiconductor loops [6,7] have been detected by this method, but no two-loop coincidence has been observed. Ionization experiments rely on a magnetic charge producing more ionization than an electrical charge with the same velocity. In the case of supermassive monopoles, time-of-flight measurements indicating $v \ll c$ has also been a frequently sought signature.

Cosmic rays are the most likely source of massive monopoles, since accelerator energies are insufficient to produce them. Evidence for such monopoles may also be obtained from astrophysical observations.

Jackson's 1975 assessment remains true. The search is somewhat abated by the lack of success in the 1980's and the decrease of interest in grand unified gauge theories.

⁶ AMBROSIO 97 global MACRO 90%CL is 0.78×10^{-15} at $\beta=1.1\times10^{-4}$, goes through a minimum at 0.61×10^{-15} near $\beta=(1.1-2.7)\times10^{-3}$, then rises to 0.84×10^{-15} at β =0.1. The global limit in this region is below the Parker bound at 10^{-15} . Less stringent limits are established for $4\times 10^{-5}<\beta<1$. Limits set by various triggers in the detector are listed below. All limits assume a catalysis cross section smaller than

7 AMBROSIO 97 "Scintillator D" (low velocity) 90%CL increases from 4.1 \times 10⁻¹⁵ at β =2.7 \times 10⁻³ to 14.6 \times 10⁻¹⁵ at β =0.006.

⁸ AMBROSIO 97 "Scintillator B" 90%CL (single medium-velocity trigger with two analysis criteria).

criteria).

9 AMBROSIO 97 streamer tube 90%CL. Tubes contain helium, and hence trigger is sensitive via the atomic induction mechanism.

10 AMBROSIO 97 CR39 90%CL improves to 4.3×10^{-15} at $\beta = 1.0 \times 10^{-4}$. CR39 is sensitive for $4 \times 10^{-5} < \beta < 1$ except for a window at $0.25 \times 10^{-3} < \beta < 2.1 \times 10^{-3}$. In the middle region other triggers set better limits.

11 AMBROSIO 97 CR39 90%CL falls to 2.7×10^{-15} at $\beta = 1$ and increases at lower velocities. Provides better limit than "Scintillator C" for $0.1 < \beta < 1.0$.

12 AMBROSIO 97 "Scintillator C" 0.0×10^{-15} has do no high absolute energy loss in two

12 AMBROSIO 97 "Scintillator C" 90%CL, based on high absolute energy loss in two scintillator layers.

scintillator layers.

13 AHLEN 94 limit for dyons extends down to β =0.9E-4 and a limit of 1.3E-14 extends to β =0.8E-4. Also see comment by PRICE 94 and reply of BARISH 94. One loophole in the AHLEN 94 result is that in the case of monopoles catalyzing nucleon decay, relativishic particles could veto the events. See AMBROSIO 97 for additional results.

14 Catalysis of nucleon decay; sensitive to assumed catalysis cross section.

15 ORITO 91 limits are functions of velocity. Lowest limits are given here.

16 Used DKMPR mechanism and Penning effect.

17 Assumes monopole attaches fermion nucleus.

** Assumes monopole attacnes termion nuceus.

**B Limit from combining data of CAPLIN 86, BERMON 85, INCANDELA 84, and CABRERA 83. For a discussion of controversy about CAPLIN 86 observed event, see GUY 87.

**Also see SCHOUTEN 87.

**Based on lack of high- energy solar neutrinos from catalysis in the sun.

 20 Anomalous long-range α (4 He) tracks.

 21 CABRERA 82 candidate event has single Dirac charge within $\pm 5\%$.

22 AUAREZ 75, FLEISCHER 75, and FRIEDLANDER 75 explain as fragmenting nucleus. EBERHARD 75 and ROSS 76 discuss conflict with other experiments. HAGSTROM 77 reinterprets as antinucleus. PRICE 78 reassesses.

 23 ADAMS 93 limit based on "survival and growth of a small galactic seed field" is $10^{-16}~(m/10^{17}~{\rm GeV})~{\rm cm}^{-2}~{\rm s}^{-1}~{\rm sr}^{-1}$. Above $10^{17}~{\rm GeV}$, limit $10^{-16}~(10^{17}~{\rm GeV}/m)$ cm⁻² s⁻¹ sr⁻¹ (from requirement that monopole density does not overclose the universe) is more stringent.

24 Catalysis of nucleon decay. 25 Re-evaluates PARKER 70 limit for GUT monopoles.

Supersymmetric Particle Searches

SUPERSYMMETRY

Written October 1997 by Howard E. Haber (Univ. of California, Santa Cruz) Part I, and by M. Schmitt (CERN*) Part II

This review is divided into two parts:

Supersymmetry, Part I (Theory)

- I.1. Introduction
- I.2. Structure of the MSSM
- I.3. Parameters of the MSSM
- I.4. The Higgs sector of the MSSM
- I.5. The supersymmetric-particle sector
- I.6. Reducing the MSSM parameter freedom
- I.7. The constrained MSSMs: mSUGRA, GMSB, and SGUTs
- I.8. The MSSM and precision of electroweak data
- I.9. Beyond the MSSM

Supersymmetry, Part II (Experiment)

- II.1. Introduction
- II.2. Common supersymmetry scenarios
- II.3. Experimental issues
- II.4. Supersymmetry searches in e^+e^- colliders
- II.5. Supersymmetry searches at proton machines
- II.6. Supersymmetry searches at HERA and fixed-target experiment
- II.7. Conclusions

SUPERSYMMETRY, PART I (THEORY)

(by H.E. Haber)

I.1. Introduction: Supersymmetry (SUSY) is a generalization of the space-time symmetries of quantum field theory that transforms fermions into bosons and vice versa. It also provides a framework for the unification of particle physics and gravity [1-3], which is governed by the Planck scale, $M_P \approx 10^{19} \text{ GeV}$ (defined to be the energy scale where the gravitational interactions of elementary particles become comparable to their gauge interactions). If supersymmetry were an exact symmetry of nature, then particles and their superpartners (which differ in spin by half a unit) would be degenerate in mass. Thus, supersymmetry cannot be an exact symmetry of nature, and must be broken. In theories of "low-energy" supersymmetry, the effective scale of supersymmetry breaking is tied to the electroweak scale [4-6], which is characterized by the Standard Model Higgs vacuum expectation value v = 246 GeV. It is thus possible that supersymmetry will ultimately explain the origin of the large hierarchy of energy scales from the W and Z masses to the Planck scale.

At present, there are no unambiguous experimental results that require the existence of low-energy supersymmetry. However, if experimentation at future colliders uncovers evidence for supersymmetry, this would have a profound effect on the study of TeV-scale physics and the development of a more fundamental theory of mass and symmetry-breaking phenomena in particle physics.

Supersymmetric Particle Searches

I.2. Structure of the MSSM: The minimal supersymmetric extension of the Standard Model (MSSM) consists of taking the Standard Model and adding the corresponding supersymmetric partners [7]. In addition, the MSSM contains two hypercharge $Y=\pm 1$ Higgs doublets, which is the minimal structure for the Higgs sector of an anomaly-free supersymmetric extension of the Standard Model. The supersymmetric structure of the theory also requires (at least) two Higgs doublets to generate mass for both "up"-type and "down"-type quarks (and charged leptons) [8,9]. All renormalizable supersymmetric interactions consistent with (global) B-L conservation (B =baryon number and L =lepton number) are included. Finally, the most general soft-supersymmetry-breaking terms are added [10].

If supersymmetry is relevant for explaining the scale of electroweak interactions, then the mass parameters introduced by the soft-supersymmetry-breaking terms must be of order 1 TeV or below [11]. Some bounds on these parameters exist due to the absence of supersymmetric-particle production at current accelerators [12]. Additional constraints arise from limits on the contributions of virtual supersymmetric particle exchange to a variety of Standard Model processes [13,14]. The impact of precision electroweak measurements at LEP and SLC on the MSSM parameter space is discussed briefly in Section I.8.

As a consequence of B-L invariance, the MSSM possesses a multiplicative R-parity invariance, where $R=(-1)^{3(B-L)+2S}$ for a particle of spin S [15]. Note that this formula implies that all the ordinary Standard Model particles have even R-parity, whereas the corresponding supersymmetric partners have odd R-parity. The conservation of R-parity in scattering and decay processes has a crucial impact on supersymmetric phenomenology. For example, starting from an initial state involving ordinary (R-even) particles, it follows that supersymmetric particles must be produced in pairs. In general, these particles are highly unstable and decay quickly into lighter states. However, R-parity invariance also implies that the lightest supersymmetric particle (LSP) is absolutely stable, and must eventually be produced at the end of a decay chain initiated by the decay of a heavy unstable supersymmetric particle.

In order to be consistent with cosmological constraints, a stable LSP is almost certainly electrically and color neutral [16]. Consequently, the LSP in a R-parity-conserving theory is weakly-interacting in ordinary matter, i.e. it behaves like a stable heavy neutrino and will escape detectors without being directly observed. Thus, the canonical signature for conventional R-parity-conserving supersymmetric theories is missing (transverse) energy, due to the escape of the LSP. Moreover, the LSP is a prime candidate for "cold dark matter", a potentially important component of the non-baryonic dark matter that is required in cosmologies with a critical mass density [17].

In the MSSM, supersymmetry breaking is accomplished by including the most general renormalizable soft-supersymmetry-breaking terms consistent with the $SU(3)\times SU(2)\times U(1)$ gauge symmetry and R-parity invariance. These terms parameterize our ignorance of the fundamental mechanism of supersymmetry

breaking. If supersymmetry breaking occurs spontaneously, then a massless Goldstone fermion called the goldstino (\widetilde{G}) must exist. The goldstino would then be the LSP and could play an important role in supersymmetric phenomenology [18]. However, the goldstino is a physical degree of freedom only in models of spontaneously broken global supersymmetry. If the supersymmetry is a local symmetry, then the theory must incorporate gravity; the resulting theory is called supergravity. In models of spontaneously broken supergravity, the goldstino is "absorbed" by the gravitino $(\widetilde{g}_{3/2})$, the spin-3/2 partner of the graviton [19]. By this super-Higgs mechanism, the goldstino is removed from the physical spectrum and the gravitino acquires a mass $(m_{3/2})$.

It is very difficult (perhaps impossible) to construct a model of spontaneously-broken low-energy supersymmetry where the supersymmetry breaking arises solely as a consequence of the interactions of the particles of the MSSM. A more viable scheme posits a theory consisting of at least two distinct sectors: a "hidden" sector consisting of particles that are completely neutral with respect to the Standard Model gauge group, and a "visible" sector consisting of the particles of the MSSM. There are no renormalizable tree-level interactions between particles of the visible and hidden sectors. Supersymmetry breaking is assumed to occur in the hidden sector, and then transmitted to the MSSM by some mechanism. Two theoretical scenarios have been examined in detail: gravity-mediated and gauge-mediated supersymmetry breaking.

All particles feel the gravitational force. In particular, particles of the hidden sector and the visible sector can interact via the exchange of gravitons. Thus, supergravity models provide a natural mechanism for transmitting the supersymmetry breaking of the hidden sector to the particle spectrum of the MSSM. In models of gravity-mediated supersymmetry breaking, gravity is the messenger of supersymmetry breaking [20,21]. In this scenario, the gravitino mass is of order the electroweak-symmetry-breaking scale, while its couplings are roughly gravitational in strength [1,22]. Such a gravitino would play no role in supersymmetric phenomenology at colliders.

In gauge-mediated supersymmetry breaking, supersymmetry breaking is transmitted to the MSSM via gauge forces. The canonical structure of such models involves a hidden sector where supersymmetry is broken, a "messenger sector" consisting of particles (messengers) with SU(3)×SU(2)×U(1) quantum numbers, and the visible sector consisting of the fields of the MSSM [23,24]. The direct coupling of the messengers to the hidden sector generates a supersymmetry breaking spectrum in the messenger sector. Finally, supersymmetry breaking is transmitted to the MSSM via the virtual exchange of the messengers. If this approach is extended to incorporate gravitational phenomena, then supergravity effects will also contribute to supersymmetry breaking. However, in models of gauge-mediated supersymmetry breaking, one usually chooses the model parameters in such a way that the virtual exchange

of the messengers dominates the effects of the direct gravitational interactions between the hidden and visible sectors. In this scenario, the gravitino mass is typically in the eV to keV range, and is therefore the LSP. The helicity $\pm\frac{1}{2}$ components of $\tilde{g}_{3/2}$ behave approximately like the goldstino; its coupling to the particles of the MSSM is significantly stronger than a coupling of gravitational strength.

I.3. Parameters of the MSSM: The parameters of the MSSM are conveniently described by considering separately the supersymmetry-conserving sector and the supersymmetry-breaking sector. A careful discussion of the conventions used in defining the MSSM parameters can be found in Ref. 25. For simplicity, consider the case of one generation of quarks, leptons, and their scalar superpartners. The parameters of the supersymmetry-conserving sector consist of: (i) gauge couplings: g_s , g, and g', corresponding to the Standard Model gauge group $SU(3)\times SU(2)\times U(1)$ respectively; (ii) a supersymmetry-conserving Higgs mass parameter μ ; and (iii) Higgs-fermion Yukawa coupling constants: λ_u , λ_d , and λ_e (corresponding to the coupling of one generation of quarks, leptons, and their superpartners to the Higgs bosons and higgsinos).

The supersymmetry-breaking sector contains the following set of parameters: (i) gaugino Majorana masses M_3 , M_2 and M_1 associated with the SU(3), SU(2), and U(1) subgroups of the Standard Model; (ii) five scalar squared-mass parameters for the squarks and sleptons, $M_{\widetilde{O}}^2$, $M_{\widetilde{U}}^2$, $M_{\widetilde{D}}^2$, $M_{\widetilde{L}}^2$, and $M_{\widetilde{E}}^2$ [corresponding to the five electroweak gauge multiplets, i.e., superpartners of $(u, d)_L$, u_L^c , d_L^c , $(\nu, e^-)_L$, and e_L^c , (iii) Higgssquark-squark and Higgs-slepton-slepton trilinear interaction terms, with coefficients A_u , A_d , and A_e (these are the so-called "A-parameters"); and (iv) three scalar Higgs squared-mass parameters-two of which contribute to the diagonal Higgs squared-masses, given by $m_1^2 + |\mu|^2$ and $m_2^2 + |\mu|^2$, and one offdiagonal Higgs squared-mass term, $m_{12}^2 \equiv B\mu$ (which defines the "B-parameter"). These three squared-mass parameters can be re-expressed in terms of the two Higgs vacuum expectation values, v_d and v_u , and one physical Higgs mass. Here, v_d (v_u) is the vacuum expectation value of the Higgs field which couples exclusively to down-type (up-type) quarks and leptons. (Another notation often employed in the literature is $v_1 \equiv v_d$ and $v_2 \equiv v_u$.) Note that $v_d^2 + v_u^2 = (246 \text{ GeV})^2$ is fixed by the W mass (or equivalently by the Fermi constant G_F), while the $\tan \beta = v_u/v_d$

is a free parameter of the model.

The total number of degrees of freedom of the MSSM is quite large, primarily due to the parameters of the soft-supersymmetry-breaking sector. In particular, in the case of three generations of quarks, leptons, and their superpartners, $M_{\widetilde{Q}}^2$, $M_{\widetilde{D}}^2$, $M_{\widetilde{D}}^2$, $M_{\widetilde{L}}^2$, and $M_{\widetilde{E}}^2$ are hermitian 3×3 matrices, and the A-parameters are complex 3×3 matrices. In addition, M_1 , M_2 , M_3 , B and μ are in general complex. Finally, as in the Standard Model, the Higgs-fermion Yukawa couplings, λ_f (f=u, d, and e), are complex 3×3 matrices which are related to the quark

and lepton mass matrices via: $M_f = \lambda_f v_f / \sqrt{2}$, where $v_e \equiv v_d$ (with v_u and v_d as defined above). However, not all these parameters are physical. Some of the MSSM parameters can be eliminated by expressing interaction eigenstates in terms of the mass eigenstates, with an appropriate redefinition of the MSSM fields to remove unphysical degrees of freedom. The analysis of Ref. 26 shows that the MSSM possesses 124 truly independent parameters. Of these, 18 parameters correspond to Standard Model parameters (including the QCD vacuum angle $\theta_{\rm QCD}$), one corresponds to a Higgs sector parameter (the analogue of the Standard Model Higgs mass), and 105 are genuinely new parameters of the model. The latter include: five real parameters and three CP-violating phases in the gaugino/higgsino sector, 21 squark and slepton masses, 36 new real mixing angles to define the squark and slepton mass eigenstates and 40 new CP-violating phases that can appear in squark and slepton interactions. The most general R-parityconserving minimal supersymmetric extension of the Standard Model (without additional theoretical assumptions) will be denoted henceforth as MSSM-124 [27].

I.4. The Higgs sector of the MSSM: Before describing the supersymmetric-particle sector, let us consider the Higgs sector of the MSSM [8,9,28]. Despite the large number of potential CP-violating phases among the MSSM-124 parameters, one can show that the tree-level MSSM Higgs sector is automatically CP-conserving. That is, unphysical phases can be absorbed into the definition of the Higgs fields such that $\tan \beta$ is a real parameter (conventionally chosen to be positive). Moreover, the physical neutral Higgs scalars are CP eigenstates. There are five physical Higgs particles in this model: a charged Higgs boson pair (H^\pm) , two CP-even neutral Higgs bosons (denoted by H_1^0 and H_2^0 where $m_{H_1^0} \leq m_{H_2^0}$) and one CP-odd neutral Higgs boson (A^0) .

The properties of the Higgs sector are determined by the Higgs potential which is made up of quadratic terms [whose squared-mass coefficients were mentioned above Eq. (1)] and quartic interaction terms. The strengths of the interaction terms are directly related to the gauge couplings by supersymmetry (and are not affected at tree-level by supersymmetry breaking). As a result, $\tan \beta$ [defined in Eq. (1)] and one Higgs mass determine the tree-level Higgs-sector parameters. These include the Higgs masses, an angle α [which measures the component of the original $Y=\pm 1$ Higgs doublet states in the physical CP-even neutral scalars], and the Higgs boson couplings.

When one-loop radiative corrections are incorporated, additional parameters of the supersymmetric model enter via virtual loops. The impact of these corrections can be significant [29,30]. For example, at tree-level, MSSM-124 predicts $m_{H_1^0} \leq m_Z |\cos 2\beta| \leq m_Z$ [8,9]. If this prediction were accurate, it would imply that H_1^0 must be discovered at the LEP-2 collider (running at its maximum energy and luminosity); otherwise MSSM-124 would be ruled out. However, when radiative

Searches Particle Listings

Supersymmetric Particle Searches

corrections are included, the light Higgs-mass upper bound may be significantly increased. For example, in Ref. 29, the following approximate upper bound was obtained for $m_{H_1^0}$ (assuming $m_{A^0} > m_Z$) in the limit of $m_Z \ll m_t \ll M_{\widetilde{t}}$ [where top-squark $(\widetilde{t}_L - \widetilde{t}_R)$ mixing is neglected]

$$m_{H_1^0}^2 \lesssim m_Z^2 + \frac{3g^2 m_Z^4}{16\pi^2 m_W^2} \bigg\{ \bigg[\frac{2m_t^4 - m_t^2 m_Z^2}{m_Z^4} \bigg] \ln \bigg(\frac{M_t^2}{m_t^2} \bigg) + \frac{m_t^2}{3m_Z^2} \bigg\}. \tag{2}$$

More refined computations (which include the effects of top-squark mixing, renormalization group improvement, and the leading two-loop contributions) yield $m_{H^0} \lesssim 125$ GeV for $m_t = 175$ GeV and a top-squark mass of $M_{\tilde{t}} \lesssim 1$ TeV [31]. Clearly, the radiative corrections to the Higgs masses can have a significant impact on the search for the Higgs bosons of the MSSM at LEP [32].

I.5. The supersymmetric-particle sector: Consider the sector of supersymmetric particles (sparticles) in the MSSM. The supersymmetric partners of the gauge and Higgs bosons are fermions, whose names are obtained by appending "ino" at the end of the corresponding Standard Model particle name. The gluino is the color octet Majorana fermion partner of the gluon with mass $M_{\widetilde{g}} = |M_3|$. The supersymmetric partners of the electroweak gauge and Higgs bosons (the gauginos and higgsinos) can mix. As a result, the physical mass eigenstates are model-dependent linear combinations of these states, called charginos and neutralinos, which are obtained by diagonalizing the corresponding mass matrices. The chargino-mass matrix depends on M_2 , μ , tan β and m_W [33].

The corresponding chargino-mass eigenstates are denoted by $\widetilde{\chi}_1^+$ and $\widetilde{\chi}_2^+$, with masses

$$\begin{split} M_{\widetilde{\chi}_{1}^{+},\widetilde{\chi}_{2}^{+}}^{2} &= \frac{1}{2} \left\{ |\mu|^{2} + |M_{2}|^{2} + 2m_{W}^{2} \right. \\ &+ \left[\left(|\mu|^{2} + |M_{2}|^{2} + 2m_{W}^{2} \right)^{2} - 4|\mu|^{2} |M_{2}|^{2} \right. \\ &\left. - 4m_{W}^{4} \sin^{2} 2\beta + 8m_{W}^{2} \sin 2\beta \operatorname{Re}(\mu M_{2}) \right]^{1/2} \right\}, (3) \end{split}$$

where the states are ordered such that $M_{\widetilde{\chi}_1^+} \leq M_{\widetilde{\chi}_2^+}$. If CP-violating effects are ignored (in which case, M_2 and μ are real parameters), then one can choose a convention where $\tan \beta$ and M_2 are positive. (Note that the relative sign of M_2 and μ is meaningful. The sign of μ is convention-dependent; the reader is warned that both sign conventions appear in the literature.) The sign convention for μ implicit in Eq. (3) is used by the LEP collaborations [12] in their plots of exclusion contours in the M_2 vs. μ plane derived from the non-observation of $e^+e^- \to \widetilde{\chi}_1^+\widetilde{\chi}_1^-$.

The neutralino mass matrix depends on M_1 , M_2 , μ , $\tan \beta$, m_Z , and the weak mixing angle θ_W [33]. The corresponding neutralino eigenstates are usually denoted by $\widetilde{\chi}_i^0$ ($i=1,\ldots 4$), according to the convention that $M_{\widetilde{\chi}_1^0} \leq M_{\widetilde{\chi}_2^0} \leq M_{\widetilde{\chi}_3^0} \leq M_{\widetilde{\chi}_3^0}$. If a chargino or neutralino eigenstate approximates a particular

gaugino or Higgsino state, it may be convenient to use the corresponding nomenclature. For example, if M_1 and M_2 are small compared to m_Z (and $|\mu|$), then the lightest neutralino $\widetilde{\chi}_1^0$ will be nearly a pure photino, $\widetilde{\gamma}$ (the supersymmetric partner of the photon).

The supersymmetric partners of the quarks and leptons are spin-zero bosons: the squarks, charged sleptons, and sneutrinos. For simplicity, only the one-generation case is illustrated below (using first-generation notation). For a given fermion f, there are two supersymmetric partners \tilde{f}_L and \tilde{f}_R which are scalar partners of the corresponding left and right-handed fermion. (There is no $\tilde{\nu}_R$ in the MSSM.) However, in general, \tilde{f}_L and \tilde{f}_R are not mass-eigenstates since there is \tilde{f}_L - \tilde{f}_R mixing which is proportional in strength to the corresponding element of the scalar squared-mass matrix [34]

$$M_{LR}^2 = \begin{cases} m_d(A_d - \mu \tan \beta), & \text{for "down"-type } f \\ m_u(A_u - \mu \cot \beta), & \text{for "up"-type } f, \end{cases}$$
(4)

where m_d (m_u) is the mass of the appropriate "down" ("up") type quark or lepton. The signs of the A-parameters are also convention-dependent; see Ref. 25. Due to the appearance of the fermion mass in Eq. (4), one expects M_{LR} to be small compared to the diagonal squark and slepton masses, with the possible exception of the top-squark, since m_t is large, and the bottom-squark and tau-slepton if $\tan \beta \gg 1$.

The (diagonal) L- and R-type squark and slepton squared-masses are given by [2]

$$\begin{split} M_{\widetilde{f}_{L}}^{2} &= M_{\widetilde{F}}^{2} + m_{f}^{2} + (T_{3f} - e_{f} \sin^{2} \theta_{W}) m_{Z}^{2} \cos 2\beta , \\ M_{\widetilde{f}_{R}}^{2} &= M_{\widetilde{R}}^{2} + m_{f}^{2} + e_{f} \sin^{2} \theta_{W} m_{\widetilde{\Phi}}^{2} \cos 2\beta , \end{split}$$
 (5)

where $M_{\widetilde{F}}^2=M_{\widetilde{Q}}^2$ $[M_L^2]$ for \widetilde{u}_L and \widetilde{d}_L $[\widetilde{\nu}_L$ and $\widetilde{e}_L]$, and $M_{\widetilde{R}}^2=M_{\widetilde{U}}^2$, $M_{\widetilde{D}}^2$ and $M_{\widetilde{E}}^2$ for \widetilde{u}_R , \widetilde{d}_R , and \widetilde{e}_R , respectively. In addition, $e_f=\frac{2}{3}$, $-\frac{1}{3}$, 0, -1 for f=u, d, ν , and e, respectively, $T_{3f}=\frac{1}{2}$ $[-\frac{1}{2}]$ for up-type [down-type] squarks and sleptons, and m_f is the corresponding quark or lepton mass. Squark and slepton mass eigenstates, generically called \widetilde{f}_1 and \widetilde{f}_2 (these are linear combinations of \widetilde{f}_L and \widetilde{f}_R) are obtained by diagonalizing the corresponding 2 × 2 squared-mass matrices.

In the case of three generations, the general analysis is more complicated. The scalar squared-masses $[M_{\widetilde{F}}^2$ and $M_{\widetilde{R}}^2$ in Eq. (5)], the fermion masses m_f and the A-parameters are now 3×3 matrices as noted in Section I.3. Thus, to obtain the squark and slepton mass eigenstates, one must diagonalize 6×6 mass matrices. As a result, intergenerational mixing is possible, although there are some constraints from the nonobservation of FCNC's [14]. In practice, because off-diagonal scalar mixing is appreciable only for the third generation, this additional complication can usually be neglected.

It should be noted that all mass formulae quoted in this section are tree-level results. One-loop corrections will modify all these results, and eventually must be included in any precision study of supersymmetric phenomenology.

I.6. Reducing the MSSM parameter freedom: Even in the absence of a fundamental theory of supersymmetry breaking, one is hard-pressed to regard MSSM-124 as a fundamental theory. For example, no fundamental explanation is provided for the origin of electroweak symmetry breaking. Moreover, MSSM-124 is not a phenomenologically viable theory over most of its parameter space. Among the phenomenologically deficiencies are: (i) no conservation of the separate lepton numbers L_e , L_μ , and L_τ ; (ii) unsuppressed FCNC's; and (iii) new sources of CP-violation that are inconsistent with the experimental bounds. As a result, almost the entire MSSM-124 parameter space is ruled out! This theory is viable only at very special "exceptional" points of the full parameter space.

MSSM-124 is also theoretically deficient since it provides no explanation for the origin of the supersymmetry-breaking parameters (and in particular, why these parameters should conform to the exceptional points of the parameter space mentioned above). Moreover, the MSSM contains many new sources of CP violation. For example, some combination of the complex phases of the gaugino-mass parameters, the A-parameters, and μ must be less than of order 10^{-2} – 10^{-3} (for a supersymmetry-breaking scale of 100 GeV) to avoid generating electric dipole moments for the neutron, electron, and atoms in conflict with observed data [35].

There are two general approaches for reducing the parameter freedom of MSSM-124. In the low-energy approach, an attempt is made to elucidate the nature of the exceptional points in the MSSM-124 parameter space that are phenomenologically viable. Consider the following two possible choices. First, one can assume that $M_{\widetilde{Q}}^2$, $M_{\widetilde{U}}^2$, $M_{\widetilde{D}}^2$, $M_{\widetilde{L}}^2$, $M_{\widetilde{E}}^2$ and the matrix A-parameters are generation-independent (horizontal universality [5,26,36]). Alternatively, one can simply require that all the aforementioned matrices are flavor diagonal in a basis where the quark and lepton mass matrices are diagonal (flavor alignment [37]). In either case, L_e , L_μ , and L_τ are separately conserved, while tree-level FCNC's are automatically absent. In both cases, the number of free parameters characterizing the MSSM is substantially less than 124. Both scenarios are phenomenologically viable, although there is no strong theoretical basis for either scenario.

In the high-energy approach, one treats the parameters of the MSSM as running parameters and imposes a particular structure on the soft-supersymmetry-breaking terms at a common high-energy scale [such as the Planck scale (M_P)]. Using the renormalization group equations, one can then derive the low-energy MSSM parameters. The initial conditions (at the appropriate high-energy scale) for the renormalization group equations depend on the mechanism by which supersymmetry breaking is communicated to the effective low energy theory. Examples of this scenario are provided by models of gravity-mediated and gauge-mediated supersymmetry breaking (see Section I.2). One bonus of such an approach is that one of the diagonal Higgs squared-mass parameters is typically driven negative by renormalization group evolution. Thus, electroweak

symmetry breaking is generated radiatively, and the resulting electroweak symmetry-breaking scale is intimately tied to the scale of low-energy supersymmetry breaking.

One of the most common predictions of the high-energy approach is the unification of gaugino mass parameters at some high-energy scale M_X , *i.e.*,

$$M_1(M_X) = M_2(M_X) = M_3(M_X) = m_{1/2}.$$
 (6)

This is a common prediction of both grand unified supergravity models and gauge-mediated supersymmetry-breaking models. Consequently, the effective low-energy gaugino mass parameters (at the electroweak scale) are related:

$$M_3 = (g_s^2/g^2)M_2$$
, $M_1 = (5g'^2/3g^2)M_2 \simeq 0.5M_2$. (7)

In this case, the chargino and neutralino masses and mixing angles depend only on three unknown parameters: the gluino mass, μ , and $\tan \beta$. However, the assumption of gaugino-mass unification could prove false and must eventually be tested experimentally. For example, the phenomenology of neutralinos in a model with $M_1 \simeq M_2$ can differ in some interesting ways from the standard phenomenology based on Eq. (7), as shown in Ref. 38.

1.7. The constrained MSSMs: mSUGRA, GMSB, and SGUTs: One way to guarantee the absence of significant FCNC's mediated by virtual supersymmetric-particle exchange is to posit that the diagonal soft-supersymmetry-breaking scalar squared-masses are universal at some energy scale. In models of gauge-mediated supersymmetry breaking, scalar squared-masses are expected to be flavor independent since gauge forces are flavor-blind. In the minimal supergravity (mSUGRA) framework [1,2], the soft-supersymmetry breaking parameters at the Planck scale take a particularly simple form in which the scalar squared-masses and the A-parameters are flavor diagonal and universal [20]:

$$\begin{split} M_{\widetilde{Q}}^2(M_{\rm P}) &= M_{\widetilde{U}}^2(M_{\rm P}) = M_{\widetilde{D}}^2(M_{\rm P}) = m_0^2 \mathbf{1} \,, \\ M_{\widetilde{L}}^2(M_{\rm P}) &= M_{\widetilde{E}}^2(M_{\rm P}) = m_0^2 \mathbf{1} \,, \\ m_1^2(M_{\rm P}) &= m_2^2(M_{\rm P}) = m_0^2 \,, \\ A_U(M_{\rm P}) &= A_D(M_{\rm P}) = A_L(M_{\rm P}) = A_0 \mathbf{1} \,, \end{split} \tag{8}$$

where 1 is a 3×3 identity matrix in generation space. Renormalization group evolution is then used to derive the values of the supersymmetric parameters at the low-energy (electroweak) scale. For example, to compute squark and slepton masses, one must use the low-energy values for $M_{\widetilde{F}}^2$ and $M_{\widetilde{R}}^2$ in Eq. (5). Through the renormalization group running with boundary conditions specified in Eq. (7) and Eq. (8), one can show that the low-energy values of $M_{\widetilde{F}}^2$ and $M_{\widetilde{R}}^2$ depend primarily on m_0^2 and $m_{1/2}^2$. A number of useful approximate analytic expressions for superpartner masses in terms of the mSUGRA parameters can be found in Ref. 39.

Searches Particle Listings

Supersymmetric Particle Searches

Clearly, in the mSUGRA approach, the MSSM-124 parameter freedom has been sharply reduced. For example, typical mSUGRA models give low-energy values for the scalar mass parameters that satisfy $M_{\widetilde{L}} \approx M_{\widetilde{E}} < M_{\widetilde{Q}} \approx M_{\widetilde{U}} \approx M_{\widetilde{D}}$ with the squark mass parameters somewhere between a factor of 1–3 larger than the slepton mass parameters (e.g., see Ref. 39). More precisely, the low-energy values of the squark mass parameters of the first two generations are roughly degenerate, while $M_{\widetilde{Q}_3}$ and $M_{\widetilde{U}_3}$ are typically reduced by a factor of 1–3 from the values of the first and second generation squark mass parameters because of renormalization effects due to the heavy top quark mass.

As a result, one typically finds that four flavors of squarks (with two squark eigenstates per flavor) and \tilde{b}_R are nearly mass-degenerate. The \tilde{b}_L mass and the diagonal \tilde{t}_L and \tilde{t}_R masses are reduced compared to the common squark mass of the first two generations. (If $\tan \beta \gg 1$, then the pattern of third generation squark masses is somewhat altered; e.g., see Ref. 40.) In addition, there are six flavors of nearly mass-degenerate sleptons (with two slepton eigenstates per flavor for the charged sleptons and one per flavor for the sneutrinos); the sleptons are expected to be somewhat lighter than the mass-degenerate squarks. Finally, third generation squark masses and tau-slepton masses are sensitive to the strength of the respective $\tilde{f}_L - \tilde{f}_R$ mixing as discussed below Eq. (4).

Due to the implicit $m_{1/2}$ dependence in the low-energy values of $M_{\widetilde{Q}}^2$, $M_{\widetilde{U}}^2$ and $M_{\widetilde{D}}^2$, there is a tendency for the gluino in mSUGRA models to be lighter than the first and second generation squarks. Moreover, the LSP is typically the lightest neutralino, $\widetilde{\chi}_1^0$, which tends to be dominated by its gaugino components. However, there are some regions of mSUGRA parameter space where the above conclusions do not hold. For example, one can reject those mSUGRA parameter regimes in which the LSP is a chargino.

One can count the number of independent parameters in the mSUGRA framework. In addition to 18 Standard Model parameters (excluding the Higgs mass), one must specify m_0 , $m_{1/2}$, A_0 , and Planck-scale values for μ and B-parameters (denoted by μ_0 and B_0). In principle, A_0 , B_0 and μ_0 can be complex, although in the mSUGRA approach, these parameters are taken (arbitrarily) to be real. As previously noted, renormalization group evolution is used to compute the low-energy values of the mSUGRA parameters, which then fixes all the parameters of the low-energy MSSM. In particular, the two Higgs vacuum expectation values (or equivalently, m_Z and $\tan \beta$) can be expressed as a function of the Planck-scale supergravity parameters. The simplest procedure is to remove μ_0 and B_0 in favor of m_Z and $\tan \beta$ (the sign of μ_0 is not fixed in this process). In this case, the MSSM spectrum and its interaction strengths are determined by five parameters: m_0 , A_0 , $m_{1/2}$, $\tan \beta$, and the sign of μ_0 , in addition to the 18 parameters of the Standard Model. However, the mSUGRA approach is probably too simplistic. Theoretical considerations suggest that the universality

of Planck-scale soft-supersymmetry-breaking parameters is not generic [41].

In the minimal gauge-mediated supersymmetry-breaking (GMSB) approach, there is one effective mass scale, Λ , that determines all low-energy scalar and gaugino mass parameters through loop-effects (while the resulting Λ -parameters are suppressed). In order that the resulting superpartner masses be of order 1 TeV or less, one must have $\Lambda \sim 100$ TeV. The origin of the μ and B-parameters is quite model dependent and lies somewhat outside the ansatz of gauge-mediated supersymmetry breaking. The simplest models of this type are even more restrictive than mSUGRA, with two fewer degrees of freedom. However, minimal GMSB is not a fully realized model. The sector of supersymmetry-breaking dynamics can be very complex, and it is fair to say that no complete model of gauge-mediated supersymmetry yet exists that is both simple and compelling.

It was noted in Section I.2 that the gravitino is the LSP in GMSB models. Thus, in such models, the next-to-lightest supersymmetric particle (NLSP) plays a crucial role in the phenomenology of supersymmetric particle production and decay. Note that unlike the LSP, the NLSP can be charged. In GMSB models, the most likely candidates for the NLSP are $\widetilde{\chi}_1^0$ and $\widetilde{\tau}_R^{\pm}$. The NLSP will decay into its superpartner plus a gravitino (e.g., $\widetilde{\chi}_1^0 \to \gamma \widetilde{g}_{3/2}$, $\widetilde{\chi}_1^0 \to Z \widetilde{g}_{3/2}$ or $\widetilde{\tau}_R^{\pm} \to \tau^{\pm} \widetilde{g}_{3/2}$), with lifetimes and branching ratios that depend on the model parameters.

Different choices for the identity of the NLSP and its decay rate lead to a variety of distinctive supersymmetric phenomenologies [42]. For example, a long-lived $\widetilde{\chi}_1^0$ -NLSP that decays outside collider detectors leads to supersymmetric decay chains with missing energy in association with leptons and/or hadronic jets (this case is indistinguishable from the canonical phenomenology of the $\widetilde{\chi}_1^0$ -LSP). On the other hand, if $\widetilde{\chi}_1^0 \to \gamma \widetilde{g}_{3/2}$ is the dominant decay mode, and the decay occurs inside the detector, then nearly all supersymmetric particle decay chains would contain a photon. In contrast, the case of a $\widetilde{\tau}_R^\pm$ -NLSP would lead either to a new long-lived charged particle (i.e., the $\widetilde{\tau}_R^+$) or to supersymmetric particle decay chains with τ -leptons.

Finally, grand unification can impose additional constraints on the MSSM parameters. Perhaps one of the most compelling hints for low-energy supersymmetry is the unification of SU(3)×SU(2)×U(1) gauge couplings predicted by models of supersymmetric grand unified theories (SGUTs) [5,43] (with the supersymmetry-breaking scale of order 1 TeV or below). Gauge coupling unification, which takes place at an energy scale of order 10¹⁶ GeV, is quite robust (i.e., the unification depends weakly on the details of the theory at the unification scale). Current low-energy data is in fair agreement with the predictions of supersymmetric grand unification as discussed in Section I.8.

Additional SGUT predictions arise through the unification of the Higgs-fermion Yukawa couplings (λ_f) . There is some

evidence that $\lambda_b = \lambda_\tau$ leads to good low-energy phenomenology [44], and an intriguing possibility that $\lambda_b = \lambda_\tau = \lambda_t$ may be phenomenologically viable [45,40] in the parameter regime where $\tan \beta \simeq m_t/m_b$. Finally, grand unification imposes constraints on the soft-supersymmetry-breaking parameters. For example, gaugino-mass unification leads to the relations given in Eq. (7). Diagonal squark and slepton soft-supersymmetry-breaking scalar masses may also be unified, which is analogous to the unification of Higgs-fermion Yukawa couplings.

In the absence of a fundamental theory of supersymmetry breaking, further progress will require a detailed knowledge of the supersymmetric-particle spectrum in order to determine the nature of the high-energy parameters. Of course, any of the theoretical assumptions described in this section could be wrong and must eventually be tested experimentally.

I.8. The MSSM and precision of electroweak data: The MSSM provides a framework that can be tested by precision electroweak data. The level of accuracy of the measured Z decay observables at LEP and SLC is sufficient to test the structure of the one-loop radiative corrections of the electroweak model [46]. Thus the precision electroweak data is potentially sensitive to the virtual effects of undiscovered particles. Combining the most recent LEP and SLC electroweak results (including the limits obtained from the direct Higgs search at LEP) with the recent top-quark mass measurement at the Tevatron, a preference is found [47,48] for a light Higgs boson mass of order m_Z , which is consistent with the MSSM Higgs mass upper bound discussed in Section I.4. [More precisely, in Ref. 48, the best fit value for the mass of the Standard Model Higgs boson ranges from about 83 to 140 GeV, while the 95% CL upper limit ranges from 287 to 361 GeV, depending on the value used for $\alpha(m_Z)$. (Similar results have been obtained in Ref. 47). Moreover, for Z decay observables, the effects of virtual supersymmetric-particle exchange are suppressed by a factor of $m_Z^2/M_{\rm SUSY}^2$, and therefore decouple in the limit of large supersymmetric-particle masses. It follows that for $M_{\rm SUSY} \gg m_Z$ (in practice, it is sufficient to have all supersymmetric-particle masses above 200 GeV), the MSSM yields an equally good fit to the precision electroweak data as compared to the Standard Model fit.

At present, a global fit of the electroweak data by Erler and Langacker (EL) [48] is in excellent agreement with the predictions of the Standard Model. If some supersymmetric particles are light (say, below 200 GeV but above present experimental bounds deduced from direct searches), then it is possible that the EL fit could be modified in the MSSM. A few years ago, when the rate for $Z \to b\bar{b}$ was four standard deviations above the Standard Model prediction, the possibility that the MSSM could improve the global electroweak fit was taken quite seriously. However, it is hard to imagine that the MSSM could significantly improve the quality of the current EL fit (given that the Standard Model fit is already quite good, and a global fit in the context of the MSSM would

necessarily involve more degrees of freedom). On the other hand, the MSSM could significantly decrease the goodness of the Standard Model fit. This possibility has been explored recently in Ref. 49. Their analysis shows that one can slightly reduce the allowed region of mSUGRA and GMSB model parameter spaces beyond the region already ruled out by the non-observation of direct supersymmetric particle production.

Electroweak observables are also sensitive to the strong coupling constant through the QCD radiative corrections. The EL global fit extracts a value of $\alpha_s(m_Z) = 0.1214 \pm 0.0031$, which is in good agreement with the world average of $\alpha_s(m_Z)$ 0.1191 ± 0.0018 [48]. This result has important implications for the viability of supersymmetric unification. Given the lowenergy values of the electroweak couplings $q(m_Z)$ and $q'(m_Z)$, one can predict $\alpha_s(m_Z)$ by using the MSSM renormalization group equations to extrapolate to higher energies and imposing the unification condition on the three gauge couplings at some high-energy scale, M_X . This procedure (which fixes M_X) can be successful (i.e., three running couplings will meet at a single point) only for a unique value of $\alpha_s(m_Z)$. The extrapolation depends somewhat on the low-energy supersymmetric spectrum (so-called low-energy "threshold effects") and on the SGUT spectrum (high-energy threshold effects), which can somewhat alter the evolution of couplings. For example, allowing for lowenergy threshold effects but neglecting threshold corrections near the unification scale, Ref. 50 finds that SGUT unification in the mSUGRA model predicts that $\alpha_s(m_Z) > 0.126$, which is only in slight disagreement with the results of the EL fit. (Similar results have been obtained in Ref. 51.) Taking SGUT threshold effects into account could either slightly increase or decrease the predicted value of $\alpha_s(m_Z)$, depending on the details of the model. In contrast, the corresponding result for the Standard Model extrapolation, $\alpha_s(m_Z) \simeq 0.073 \pm 0.002$ [52], is many standard deviations away from the experimentally observed result.

1.9. Beyond the MSSM: Non-minimal models of low-energy supersymmetry can also be constructed. One approach is to add new structure beyond the Standard Model at the TeV scale or below. The supersymmetric extension of such a theory would be a non-minimal extension of the MSSM. Possible new structures include: (i) the supersymmetric generalization of the see-saw model of neutrino masses [53,54]; (ii) an enlarged electroweak gauge group beyond $SU(2) \times U(1)$ [55]; (iii) the addition of new, possibly exotic, matter multiplets [e.g., a vector-like color triplet with electric charge $\frac{1}{3}e$; such states sometimes occur as low-energy remnants in E₆ grand unification models]; and/or (iv) the addition of low-energy $SU(3) \times SU(2) \times U(1)$ singlets [56]. A possible theoretical motivation for such new structure arises from the study of phenomenologically viable string theory ground states [57].

A second approach is to retain the minimal particle content of the MSSM but remove the assumption of R-parity invariance. The most general R-parity-violating (RPV) theory

Searches Particle Listings

Supersymmetric Particle Searches

involving the MSSM spectrum introduces many new parameters to both the supersymmetry-conserving and the supersymmetry-breaking sectors. Each new interaction term violates either B or L conservation. For example, consider new scalar-fermion Yukawa couplings derived from the following interactions:

$$(\lambda_L)_{pmn}\widehat{L}_p\widehat{L}_m\widehat{E}_n^c + (\lambda_L')_{pmn}\widehat{L}_p\widehat{Q}_m\widehat{D}_n^c + (\lambda_B)_{pmn}\widehat{U}_p^c\widehat{D}_m^c\widehat{D}_n^c , \tag{9}$$

where $p,\ m$, and n are generation indices, and gauge group indices are suppressed. In the notation above, $\widehat{Q},\ \widehat{U}^c,\ \widehat{D}^c,\ \widehat{L}$, and \widehat{E}^c respectively represent $(u,d)_L,\ u^c_L,\ d^c_L,\ (\nu,\ e^-)_L$, and e^c_L and the corresponding superpartners. The Yukawa interactions are obtained from Eq. (9) by taking all possible combinations involving two fermions and one scalar superpartner. Note that the term in Eq. (9) proportional to λ_B violates B, while the other two terms violate L.

Phenomenological constraints on various low-energy B- and L-violating processes yield limits on each of the coefficients $(\lambda_L)_{pmn}$, $(\lambda_L')_{pmn}$ and $(\lambda_B)_{pmn}$ taken one at a time [58]. If more than one coefficient is simultaneously non-zero, then the limits are in general more complicated. All possible RPV terms cannot be simultaneously present and unsuppressed; otherwise the proton decay rate would be many orders of magnitude larger than the present experimental bound. One way to avoid proton decay is to impose B- or L-invariance (either one alone would suffice). Otherwise, one must accept the requirement that certain RPV coefficients must be extremely suppressed.

If R-parity is not conserved, supersymmetric phenomenology exhibits features that are quite distinct from that of the MSSM. The LSP is no longer stable, which implies that not all supersymmetric decay chains must yield missing-energy events at colliders. Both $\Delta L = 1$ and $\Delta L = 2$ phenomena are allowed (if L is violated), leading to neutrino masses and mixing [59], neutrinoless double beta decay [60], sneutrino-antisneutrino mixing [54,61], and s-channel resonant production of the sneutrino in e^+e^- collisions [62]. Since the distinction between the Higgs and matter multiplets is lost, R-parity violation permits the mixing of sleptons and Higgs bosons, the mixing of neutrinos and neutralinos, and the mixing of charged leptons and charginos, leading to more complicated mass matrices and mass eigenstates than in the MSSM.

Squarks can be regarded as leptoquarks since if $\lambda_L' \neq 0$, the following processes are allowed: $e^+\overline{u}_m \to \overline{\tilde{d}}_n \to e^+\overline{u}_m$, $\overline{\nu}\overline{d}_m$ and $e^+d_m \to \widetilde{u}_n \to e^+d_m$. (As above, m and n are generation labels, so that $d_2=s$, $d_3=b$, etc.) These processes have received much attention during the past year as a possible explanation for the HERA high Q^2 anomaly [63].

The theory and phenomenology of alternative low-energy supersymmetric models (such as models with R-parity violation) and its consequences for collider physics have only recently begun to attract significant attention. Experimental and theoretical constraints place some restrictions on these approaches, although no comprehensive treatment has yet appeared in the literature.

SUPERSYMMETRY, PART II (EXPERIMENT) (by M. Schmitt)

II.1. Introduction: The theoretical strong points of supersymmetry (SUSY) have motivated many searches for supersymmetric particles. Most of these have been guided by the MSSM and are based on the canonical missing-energy signature caused by the escape of the LSP's ('lightest supersymmetric particles'). More recently, other scenarios have received considerable attention from experimenters, widening the range of topologies in which new physics might be found.

Unfortunately, no convincing evidence for the production of supersymmetric particles has been found. The most far reaching laboratory searches have been performed at the Tevatron and at LEP, and these are the main topic of this review. In addition, there are a few special opportunities exploited by HERA and certain fixed-target experiments.

In order to keep this review as current as possible, the most recent results have been used, including selected preliminary results reported at the High Energy Conference of the European Physical Society, held in Jerusalem during August 1997.

Theoretical aspects of supersymmetry have been covered in Part I of this review by H.E. Haber (see also Ref. 1, 2); we use his notations and terminology.

II.2. Common supersymmetry scenarios: In the 'canonical' scenario [1], supersymmetric particles are pair-produced and decay directly or via cascades to the LSP. For most typical choices of model parameters, the lightest neutralino is the LSP. Conservation of R-parity is assumed, so the LSP's do not decay and escape detection, causing an apparent transverse momentum imbalance, $p_T^{\rm miss}$ (also referred to as missing transverse energy, E_T), and missing energy, $E^{\rm miss}$. There are always two LSP's per event. The searches demand significant $p_T^{\rm miss}$ as the main discriminant against Standard Model (SM) processes; collimated jets, isolated leptons or photons, and appropriate kinematic cuts provide additional handles to reduce backgrounds.

The conservation of R-parity is not required in supersymmetry, however, and in some searches it is assumed that supersymmetric particles decay via interactions which violate R-parity (RPV), and hence, lepton and/or baryon number. For the most part the production of superpartners is unchanged, but in general the missing-energy signature is lost. Depending on the choice of the R-parity-breaking interaction, SUSY events are characterized by excess leptons or hadronic jets, and in many cases it is relatively easy to suppress SM backgrounds [3]. In this scenario the pair-production of LSP's, which need not be $\widetilde{\chi}_1^0$'s or $\widetilde{\nu}$'s, is a significant SUSY signal.

In models assuming gauge-mediated supersymmetry breaking (GMSB) [4], the gravitino $\tilde{g}_{3/2}$ is a weakly-interacting fermion with a mass so small that it can be neglected when considering the event kinematics. It is the LSP, and the lightest neutralino decays to it radiatively, possibly with a very long lifetime. For the most part the decays and production of other superpartners are the same as in the canonical scenario, so when the $\tilde{\chi}_1^0$ lifetime is not too long, the event topologies are augmented by the presence of photons which can be energetic and isolated. If the $\tilde{\chi}_1^0$ lifetime is so long that it decays outside of the detector, the event topologies are the same as in the canonical scenario. In some variants of this theory the right-sleptons are lighter than the lightest neutralino, and they decay to a lepton and a gravitino. This decay might occur after the slepton exits the apparatus, depending on model parameters.

Finally, in another scenario the gluino \tilde{g} is assumed to be very light $(M_{\tilde{g}} < 5 \text{ GeV}/c^2)$ [5]. It is a color-octet fermion which can saturate the decays of charginos and neutralinos. In this scenario the decay of the gluino to the lightest neutralino is

kinematically suppressed, so long-lived supersymmetric hadrons $(\tilde{g} + g)$ bound states called R^0 's) are formed [6]. These will produce hadronic showers in the calorimeters, thus spoiling the canonical missing-energy signature on which most SUSY searches rely. The exclusion of a light gluino is not settled (see the Listings), however, given recent experimental and theoretical developments, this issue may well be settled in the near future.

II.3. Experimental issues: Before describing the results of the searches, a few words about the issues facing the experimenters are in order.

Given no signal for supersymmetric particles, experimenters are forced to derive limits on their production. The most general formulation of supersymmetry is so flexible that few universal bounds can be obtained. Often more restricted forms of the theory are evoked for which predictions are more definite—and exclusions more constraining. The most popular of these is minimal supergravity ('mSUGRA'). As explained in the Part I of this review, parameter freedom is drastically reduced by requiring related parameters to be equal at the unification scale. Thus, the gaugino masses are equal with value $m_{1/2}$, and the slepton, squark, and Higgs masses depend on a common scalar mass parameter, m_0 . In the individual experimental analyses, only some of these assumptions are necessary. For example, the gluon and squark searches at proton machines constrain mainly M_3 and a scalar mass parameter m_0 for the squark masses, while the chargino, neutralino, and slepton searches at e^+e^- colliders constrain M_2 and a scalar mass parameter m_0 for the slepton masses. In addition, results from the Higgs searches can be used to constrain $m_{1/2}$ and m_0 as a function of $\tan \beta$. (The full analysis involves large radiative corrections coming from squark mixing, which is where the dependence on $m_{1/2}$ and m_0 enter.) In the mSUGRA framework, all the scalar mass parameters m_0 are the same and the three gaugino mass parameters are proportional to $m_{1/2}$, so limits from squarks, sleptons, charginos, gluinos, and Higgs all can be used to constrain the parameter space.

While the mSUGRA framework is convenient, it is based on several theoretical assumptions which are highly specific, so limits presented in this framework cannot easily be applied to other supersymmetric models. Serious attempts to reduce the model dependence of experimental exclusions have been made recently. When model-independent results are impossible, the underlying assumptions and their consequences are carefully delineated. This is easier to achieve at e^+e^- colliders than at proton machines.

The least model-dependent result from any experiment is the upper limit on the cross section. It requires only the number N of candidate events, the integrated luminosity \mathcal{L} , the expected backgrounds b, and the acceptance ϵ for a given signal. The upper limit on the number of signal events for a

given confidence level N^{upper} is computed from N and b (see review of Statistics). The experimental bound is simply

$$\epsilon \cdot \sigma < N^{\text{upper}}/\mathcal{L}.$$
 (1)

This information is nearly always reported, but some care is needed to understand how the acceptance was estimated, since it is often sensitive to assumptions about masses and branching ratios. Also, in the more complicated analyses, $N^{\rm upper}$ also changes as a result of the optimization for a variety of possible signals.

The theoretical parameter space is constrained by computing $\epsilon \cdot \sigma$ of Eq. (1) in terms of the relevant parameters while $N^{\text{upper}}/\mathcal{L}$ is fixed by experiment. Even after the theoretical scenario and assumptions have been specified, some choice remains about how to present the constraints. The quantity $\epsilon \cdot \sigma$ may depend on three or more parameters, yet in a printed page one usually can display limits only in a two-dimensional space. Three rather different tactics are employed by experimenters:

- Select "typical" values for the parameters not shown. These may be suggested by theory, or values giving more conservative—or more powerful results may be selected. Although the values are usually specified, one sometimes has to work to understand the possible 'loopholes.'
- Scan the parameters not shown. The lowest value for $\epsilon \cdot \sigma$ is used in Eq. (1), thereby giving the weakest limit for the parameters shown. As a consequence, the limit applies for all values of the parameters not shown.
- Scan parameters to find the lowest acceptance ε and
 use it as a constant in Eq. (1). The limits are then
 safe from theoretical uncertainties but may be overconservative, hiding powerful constraints existing in
 more typical cases.

Judgement is exercised: the second option is the most correct but may be impractical or uninteresting; most often representative cases are presented. These latter become standard, allowing a direct comparison of experiments, and also the opportunity to combine results.

Limits reported here are derived for 95% C.L. unless noted otherwise.

II.4. Supersymmetry searches in e^+e^- colliders: The center-of-mass energy of the large electron-positron collider (LEP) at CERN has been raised well above the Z peak in recent years. After collecting approximately 150 pb⁻¹ at LEP 1, each experiment (ALEPH, DELPHI, L3, OPAL) has accumulated the first data at LEP 2: about 5.7 pb⁻¹ at $\sqrt{s} \sim 133$ GeV (1995) [7], 10 pb⁻¹ at 161 GeV and 11 pb⁻¹ at 172 GeV (1996). This review emphasizes the most recent LEP 2 results.

At LEP experiments and SLD at SLAC excluded all visible supersymmetric particles up to about half the Z mass (see the Listings for details). These limits come mainly from the

Supersymmetric Particle Searches

comparison of the measured Z widths to the SM expectations, and depend less on the details of the SUSY particle decays than do the results of direct searches [8]. The new data taken at higher energies allow much stronger limits to be set, although the complex interplay of masses, cross sections, and branching ratios makes simple general limits impossible to specify.

The main signals come from SUSY particles with charge, weak isospin, or large Yukawa couplings. The gauge fermions (charginos and neutralinos) generally are produced with large cross sections, while the scalar particles (sleptons and squarks) are suppressed near threshold by kinematic factors.

Charginos are produced via γ^* , Z^* , and $\widetilde{\nu}_e$ exchange. Cross sections are in the 1–10 pb range, but can be an order of magnitude smaller when $M_{\widetilde{\nu}_e}$ is less than 100 GeV/ c^2 due to the destructive interference between s- and t-channel amplitudes. Under the same circumstances, neutralino production is enhanced, as the t-channel \widetilde{e} exchange completely dominates the s-channel Z^* exchange. When Higgsino components dominate the field content of charginos and neutralinos, cross sections are large and insensitive to slepton masses.

Sleptons and squarks are produced via γ^* and Z^* exchange; for selectrons there is an important additional contribution from t-channel neutralino exchange which generally increases the cross section substantially. Although the Tevatron experiments have placed general limits on squark masses far beyond the reach of LEP, a light top squark (stop) could still be found since the flavor eigenstates can mix to give a large splitting between the mass eigenstates. The coupling of the lightest stop to the Z^* will vary with the mixing angle, however, and for certain values, even vanish, so the limits on squarks from LEP depend on the mixing angle assumed.

The various SUSY particles considered at LEP usually decay directly to SM particles and LSP's, so signatures commonly consist of some combination of jets, leptons, possibly photons, and missing energy. Consequently the search criteria are geared toward a few distinct topologies. Although they may be optimized for one specific signal, they are often efficient for others. For example, acoplanar jets are expected in both $\widetilde{t_1} \widetilde{t_1}$ and $\widetilde{\chi}^0_1 \widetilde{\chi}^0_2$ production, and acoplanar leptons for both $\widetilde{\ell}^+ \widetilde{\ell}^-$ and $\widetilde{\chi}^+ \widetilde{\chi}^-$.

The major backgrounds come from three sources. First, there are the so-called 'two-photon interactions,' in which the beam electrons emit photons which combine to produce a low mass hadronic or leptonic system leaving little visible energy in the detector. Since the electrons are seldom deflected through large angles, $p_T^{\rm miss}$ is low. Second, there is difermion production, usually accompanied by a large initial-state radiation induced by the Z pole, which gives events that are well balanced with respect to the beam direction. Finally, there is four-fermion production through states with one or two resonating bosons $(W^+W^-, ZZ, We\nu, Ze^+e^-, \text{etc.})$ which can give events with large $E^{\rm miss}$ and $p_T^{\rm miss}$ due to neutrinos and electrons lost down the beam pipe.

In the canonical case, E^{miss} and p_T^{miss} are large enough to eliminate most of these backgrounds. The e^+e^- initial state is

well defined so searches utilize both transverse and longitudinal momentum components. It is possible to measure the missing mass $(M_{\rm miss} = \{(\sqrt{s} - E_{\rm vis})^2 - \vec{p}^{\;2}_{\rm vis}\}^{1/2})$ which is small if $p_T^{\rm miss}$ is caused by a single neutrino or undetected electron or photon, and can be large when there are two massive LSP's. The four-fermion processes cannot be entirely eliminated, however, and a non-negligible irreducible background is expected. Fortunately, the uncertainties for these backgrounds are not large.

High efficiencies are easily achieved when the mass of the LSP is lighter than the parent particle by at least $10~{\rm GeV}/c^2$ and greater than about $10~{\rm GeV}/c^2$. Difficulties arise when the mass difference ΔM between the produced particle and the LSP is smaller than $10~{\rm GeV}/c^2$ as the signal resembles background from two-photon interactions. A very light LSP is challenging also since, kinematically speaking, it plays a role similar to a neutrino, so that, for example, a signal for charginos of mass $80~{\rm GeV}/c^2$ is difficult to distinguish from the production of W^+W^- pairs.

Since the start of LEP 2, experimenters have made special efforts to cover a wide range of mass differences. Also, since virtual superpartners exchanged in decays can heavily influence branching ratios to SM particles, care has been taken to ensure that the search efficiencies are not strongly dependent on the final state. This ability to cover a wide range of topologies has driven the push for bounds with a minimum of model dependence.

Charginos have been excluded up to 86 GeV/ c^2 [9] except in cases of low acceptance ($\Delta M = M_{\widetilde{\chi}^\pm} - M_{\widetilde{\chi}^0_1} \lesssim 5 \text{ GeV}/c^2$) or low cross section ($M_{\widetilde{\nu}_e} \lesssim M_W$). When $|\mu| \ll M_2$, the Higgsino components are large for charginos and neutralinos. In this case the associated production of neutralino pairs $\widetilde{\chi}_1^0 \widetilde{\chi}_2^0$ is large and the problem of small mass differences ($M_{\widetilde{\chi}^0_2} - M_{\widetilde{\chi}^0_1}$) less severe. Experimental sensitivity now extends down to mass differences of 4 GeV/ c^2 , corresponding to M_2 well above 1 TeV/ c^2 . The strong variation of the efficiency with ΔM makes it difficult to derive absolute bounds on the masses of charginos and neutralinos. The problem of low cross sections will be less severe after higher integrated luminosities have been delivered.

The limits from chargino and neutralino production are most often used to constrain M_2 and μ for fixed $\tan \beta$. An example from the OPAL Collaboration is shown in Fig. 1, where excluded regions in the (μ, M_2) plane are shown for $\tan \beta = 1.5$ and 35 for $\sqrt{s} = 172$ GeV. The case of heavy sneutrinos is illustrated by the plots with $m_0 = 1$ TeV/ c^2 . The plots also provide a gluino mass scale, valid assuming gaugino mass unification, which implies that the mass of gluinos hypothetically produced in proton machines is proportional to the mass of charginos with a large gaugino component.

When the sleptons are light, two important effects must be considered for charginos: the cross section is significantly reduced and the branching ratio to leptons is enhanced, especially to τ 's via $\tilde{\tau}$'s which can have non-negligible mixing. These effects are greatest when the chargino has a large gaugino component. The weakest bounds are found for $\mu \sim -70~{\rm GeV}/c^2$

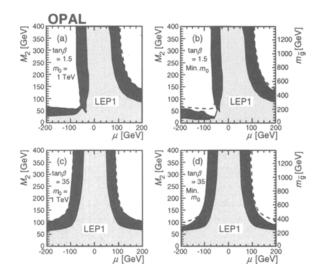

Figure 1: Regions in the (μ, M_2) plane excluded by chargino and neutralino searches performed by the OPAL Collaboration, for two values of $\tan \beta$ [9]. The light shaded region shows the limits derived from the Z width, while the dark region shows the additional exclusion obtained by the direct searches at LEP 2. The dashed line shows the kinematic bound for charginos; exclusions beyond this come from the searches for neutralinos. m_0 is the universal mass parameter for sleptons and sneutrinos, so when $m_0 = 1 \text{ TeV}/c^2$ the sneutrino is very heavy and cross sections are as large as possible. The curves labeled 'minimal m_0 ' give an indication of how much the exclusions weaken when light sneutrinos are considered. The gluino scale is shown for comparison to Tevatron results; it is valid assuming the unification of gaugino masses.

and $\tan \beta < 2$, as the cross section is reduced with respect to larger $|\mu|$, the impact of $\tilde{\tau}$ mixing can be large, and the efficiency is not optimal because ΔM is large. The erosion in the bounds when sneutrinos are light is illustrated clearly by the so-called 'minimal m_0 ' case (Fig. 1). Here m_0 is a universal mass for sleptons and sneutrinos at the GUT scale; for this analysis the smallest value of m_0 consistent with OPAL slepton limits has been taken.

If the sneutrino is lighter than the chargino, then two-body decays $\widetilde{\chi}^+ \to \ell^+ \widetilde{\nu}$ dominate, and in the 'corridor' $0 < M_{\widetilde{\chi}^\pm} - M_{\widetilde{\nu}} \lesssim 3 \text{ GeV}/c^2$ the acceptance is so low that no exclusion is possible [10]. An example of this is shown in Fig. 2, from the ALEPH Collaboration. Since the chargino cross-section and field content varies with μ , two values were tested: in both cases the corridor $M_{\widetilde{\chi}^\pm} \lesssim M_{\widetilde{\nu}}$ persists, and strictly speaking the lower limit on $M_{\widetilde{\chi}^\pm}$ is the one from LEP 1. Searches for charged sleptons can be used to cover this corridor, as shown in the figure, but this coverage is effective only for low $\tan \beta$. The

searches for neutralinos alleviate the problem in some regions of parameter space, but they cannot close the corridor.

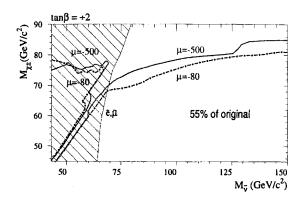

Figure 2: Limit on a gaugino-like chargino as a function of the sneutrino mass, from the ALEPH Collaboration [9]. The open corridor $0 < M_{\widetilde{\chi}^{\pm}} - M_{\widetilde{\nu}} \lesssim 3 \text{ GeV}/c^2$ is evident. $\tan \beta = \sqrt{2}$ is fixed and two values of μ are shown. The hatched region is excluded by slepton searches, but at higher $\tan \beta$ this exclusion is much weaker.

The limits on slepton masses [11] are well below the kinematic limit due to a strong p-wave phase space suppression near threshold. A variety of limits have been derived, considering right-sleptons only (which is conservative), or degenerate right/left-sleptons (which is optimistic), or relying on a universal slepton mass m_0 (which is model-dependent). For individual experiments, the limits on selectrons reach 80 GeV/c^2 due to contributions from t-channel neutralino exchange; they depend slightly on μ and an eta. For the extreme case $M_{\widetilde{\mathcal{V}}^0} o 0$, the AMY Collaboration at TRISTAN obtained a result which reaches 79 GeV/ c^2 for degenerate selectrons at 90% CL [12]. Limits on smuons reach approximately 60 GeV/c^2 , and staus, 55 GeV/c^2 . For selectrons and smuons the dependence on $\Delta M = M_{\widetilde{\ell}} - M_{\widetilde{\Sigma}^0}$ is weak for $\Delta M \gtrsim 10~{
m GeV}/c^2$ unless parameters are chosen which lead to a large branching ratio for $\widetilde{\ell}_R \to \ell \widetilde{\chi}^0_2$, possible when $M_{\widetilde{\chi}^0_1}$ is very small. Preliminary results from the combination of the four LEP experiments have been derived, leading to significantly stronger bounds [13]: $M_{\widetilde{e}_R} > 80 \text{ GeV}/c^2$ and $M_{\widetilde{\mu}_R} > 74 \text{ GeV}/c^2$ for $M_{\widetilde{\chi}_1^0} = 45 \text{ GeV}/c^2$. Bounds on the parameters M_2 and m_0 also have been derived.

In some GMSB models, sleptons may decay to $\ell^{\pm} \, \widetilde{g}_{3/2}$ outside the detector, so the experimental signature is a pair of colinear, heavily ionizing tracks. Searches for such events [14] have placed mass limits of 66 GeV/ c^2 (combined: 68 GeV/ c^2 [13]) for $\widetilde{\mu}_R$ and $\widetilde{\tau}_R$.

Limits on stop and sbottom masses [15], like the slepton mass limits, do not extend to the kinematic limit. The stop

Supersymmetric Particle Searches

decay $\tilde{t}_1 \to c \widetilde{\chi}_1^0$ proceeds through loops, giving a lifetime long enough to allow the top squark to form supersymmetric hadrons which provide a pair of jets and missing energy. If sneutrinos are light the decay $\tilde{t}_1 \to b \ell \tilde{\nu}$ dominates, giving two leptons in addition to the jets. Access to very small ΔM is possible due to the visibility of the decay products of the c and b quarks. Limits vary from 75 GeV/ c^2 for an unrealistic pure \tilde{t}_L state to 60 GeV/ c^2 if the coupling of \tilde{t}_1 to the Z vanishes. The DELPHI result is shown in Fig. 3 as an example. The combination of results from all four experiments, shown in Fig. 4, is significantly stronger: for example, $M_{\tilde{t}} > 75$ GeV/ c^2 is obtained for $\Delta M > 10$ GeV/ c^2 and any mixing [13]. Limits on sbottoms are weaker due to their smaller electric charge.

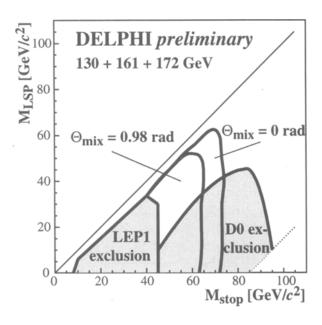

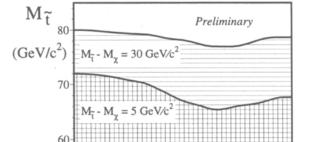

Figure 3: Ranges of excluded stop and neutralino masses reported by the DELPHI Collaboration [15]. Two values of mixing angle are shown: $\theta_{\text{mix}} = 0$ gives pure \tilde{t}_L and $\theta_{\text{mix}} = 0.98$ rad gives a stop with no coupling to the Z. The range excluded by DØ is also shown.

In canonical SUSY scenarios the lightest neutralino leaves no signal in the detector. Nonetheless, the tight correspondences among the neutralino and chargino masses allow an indirect limit on $M_{\widetilde{\chi}_1^0}$ to be derived [9,10]. The key assumption is that the gaugino mass parameters M_1 and M_2 unify at the GUT scale, which leads to a definite relation between them at the electroweak scale: $M_1 = \frac{5}{3} \tan^2 \theta_W M_2$. Assuming slepton masses to be at least 200 GeV/ c^2 , the bound on $M_{\widetilde{\chi}_1^0}$ is derived from the results of chargino and neutralino searches and certain bounds from LEP 1, as illustrated in Fig. 5, from DELPHI. The various contours change as $\tan \beta$ is increased, with the result that the lower limit on $M_{\widetilde{\chi}_1^0}$ increases also.

95% C.L. Exclusion OPAL, ALEPH, and DELPHI

Figure 4: Lower bound on the stop mass as a function of the mixing angle for two values of $\Delta M = M_{\widetilde{t}} - M_{\widetilde{\chi}_1^0}$, derived from the combined results of the LEP experiments. These results are preliminary [13].

 $\Theta_{\widetilde{t}}$

(Degrees)

When sleptons are lighter than 80 GeV/ c^2 , all the effects of light sneutrinos on both the production and decay of charginos and heavier neutralinos must be taken into account. Although the bounds from charginos are weakened substantially, useful additional constraints from the slepton searches rule out the possibility of a massless neutralino. The current preliminary limit, shown in Fig. 6, is $M_{\widetilde{\chi}_1^0} > 25~{\rm GeV}/c^2$ for $\tan\beta > 1$ and $M_{\widetilde{\nu}} > 200~{\rm GeV}/c^2$ (effectively, $m_0 \gtrsim 200~{\rm GeV}/c^2$). Allowing the universal slepton mass m_0 to have any value, the limit is $M_{\widetilde{\chi}_1^0} > 14~{\rm GeV}/c^2$ [10]. These bounds can be evaded by dropping gaugino mass unification or R-parity conservation, or by assuming the gluino is very light.

If R-parity is not conserved, the lightest neutralino decays to SM particles and is visible inside the detector. Searches for supersymmetry with R-parity violation [16] usually assume that one of three possible interaction terms $(LL\overline{E}, LQ\overline{D}, \overline{U}\,\overline{D}\,\overline{D})$ dominates. The relevant term can cause R-parity violation directly in the decay of the produced particle, or it can be manifested indirectly in the decay of the LSP, which need no longer be neutral or colorless. Rather exotic topologies can occur, such as six-lepton final states in slepton production with $LL\overline{E}$ dominating, or ten-jet final states in chargino production with $\overline{U}\,\overline{D}\,\overline{D}$ dominating; and, for the most part, entirely new search criteria keyed to an excess of leptons and/or jets must be devised. Although not all possibilities have been tested yet, searches with a wide scope have found no evidence for supersymmetry with R-parity violation, and limits are usually

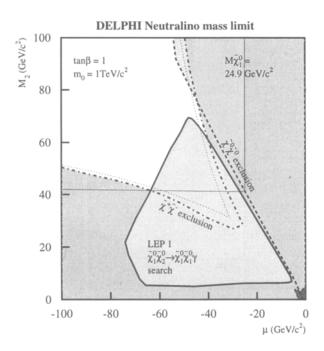

Figure 5: Excluded regions in the (μ, M_2) plane obtained by the DELPHI Collaboration, for $\tan \beta = 1$ and $m_0 = 1 \text{ TeV}/c^2$ [9]. (This very high value for m_0 is tantamount to setting all slepton masses to 1 TeV/c^2 .) The combination of LEP 2 chargino search (dotdash line) and the neutralino search (dashed line) with the single-photon limits from LEP 1 (thick solid line) give the limit on $M_{\widetilde{\chi}_1^0}$. The thin solid line shows the values of μ and M_2 giving $M_{\widetilde{\chi}_1^0} = 24.9 \text{ GeV}/c^2$, and the dotted line gives the kinematic limit for charginos at $\sqrt{s} = 172 \text{ GeV}$.

as constraining as in the canonical scenario. In fact, the direct exclusion of pair-produced $\tilde{\chi}_1^0$'s rules out some parameter space not accessible in the canonical case.

R-parity violation can lead to new production processes, such as s-channel sneutrino production, which also are being investigated [17].

Visible signals from the lightest neutralino are also realized in special cases of GMSB which predict $\widetilde{\chi}_1^0 \to \gamma \, \widetilde{g}_{3/2}$ with a lifetime short enough for the decay to occur inside the detector. The most promising topology consists of two energetic photons and missing energy resulting from $e^+e^- \to \widetilde{\chi}_1^0 \widetilde{\chi}_1^0$. (In the canonical scenario, such events also would appear for $e^+e^- \to \widetilde{\chi}_2^0 \widetilde{\chi}_2^0$ followed by $\widetilde{\chi}_2^0 \to \gamma \widetilde{\chi}_1^0$ which can be expected in certain regions of parameter space.) The LEP experiments have observed no excess over the expected number of background events [18], leading to a bound on the neutralino mass of about 70 GeV/ c^2 . As an example, the L3 upper limit on the number of signal events is plotted as a function of neutralino mass

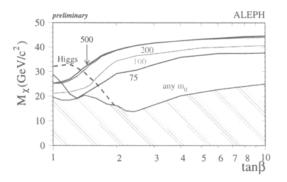

Figure 6: Lower limit on the mass of the lightest neutralino, derived by the ALEPH Collaboration using constraints from chargino, neutralino, and slepton searches [10]. The values $500, \ldots, 75$ show the bound obtained when fixing the universal scalar mass and taking slepton bounds into account; including also limits from Higgs for $m_0 = 75 \text{ GeV}/c^2$ gives the dashed line. Allowing m_0 to vary freely independently of $\tan \beta$ gives the curve labelled 'any m_0 .'

in Fig. 7. When the results are combined [13], the limit is $M_{\widetilde{\chi}_1^0} > 75~{\rm GeV}/c^2$. Single-photon production has been used to constrain the process $e^+e^- \to \widetilde{g}_{3/2}\widetilde{\chi}_1^0$.

At the time of this writing, LEP was colliding beams at $\sqrt{s}=183$ GeV. No signals for supersymmetry were reported in conferences; rather, preliminary limits $M_{\widetilde{\chi}^{\pm}} \gtrsim 91$ GeV/ c^2 were shown [19]. In coming years the center of mass energy will be increased in steps up to a maximum of 200 GeV.

II.5. Supersymmetry searches at proton machines: Although the LEP experiments can investigate a wide range of scenarios and cover obscure corners of parameter space, they cannot match the mass reach of the Tevatron experiments (CDF and $D\emptyset$). Each experiment has logged approximately 110 pb⁻¹ of data at $\sqrt{s} = 1.8$ TeV—ten times the energy of LEP 2. Although the full energy is never available for annihilation, the cross sections for supersymmetric particle production are large due to color factors and the strong coupling.

The main source of signals for supersymmetry are squarks (scalar partners of quarks) and gluinos (fermionic partners of gluons), in contradistinction to LEP. Pairs of squarks or gluinos are produced in s, t and u-channel processes, which decay directly or via cascades to at least two LSP's. The key distinction in the experimental signature is whether the gluino is heavier or lighter than the squarks, with the latter occurring naturally in mSUGRA models. The u, d, s, c, and b squarks are assumed to have similar masses; the search results are reported in terms of their average mass $M_{\widetilde{q}}$ and the gluino mass $M_{\widetilde{q}}$.

The classic searches [20] rely on large missing transverse energy E_T caused by the escaping neutralinos. Jets with high

Supersymmetric Particle Searches

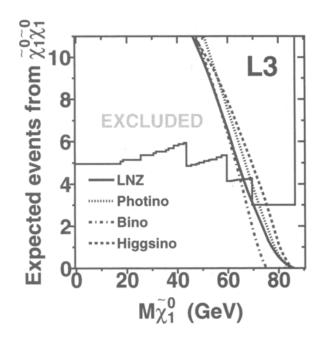

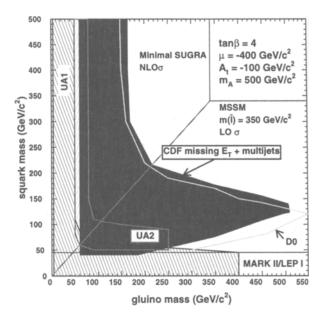

Figure 7: Upper limit on the number of acoplanar photon events as a function of the neutralino mass, from the L3 Collaboration [18]. The theoretical cross section depends on the field content of the neutralino, shown here for pure photinos, binos, and Higgsinos. 'LNZ' refers to a particular model [4].

transverse energy are also required as evidence of a hard interaction; care is taken to distinguish genuine E_T from fluctuations in the jet energy measurement. Backgrounds from W, Z and top production are reduced by rejecting events with identified leptons. Uncertainties in the rates of these processes are minimized by normalizing related samples, such as events with two jets and one or more leptons. The tails of more ordinary hard-scattering processes accompanied by multiple gluon emission are estimated directly from the data.

The bounds are displayed in the $(M_{\widetilde{g}},M_{\widetilde{q}})$ plane and have steadily improved with the integrated luminosity. The latest result from the CDF Collaboration is shown in Fig. 8, which also shows a recent result from DØ. If the squarks are heavier than the gluino, then $M_{\widetilde{g}} \gtrsim 180~{\rm GeV}/c^2$. If they all have the same mass, then that mass is at least 260 ${\rm GeV}/c^2$, according to the DØ analysis. If the squarks are much lighter than the gluin (in which case they decay via $\widetilde{q} \to q \widetilde{\chi}_1^0$), the bounds from UA1 and UA2 [21] play a role giving $M_{\widetilde{g}} \gtrsim 300~{\rm GeV}/c^2$. All of these bounds assume there is no gluino lighter than 5 ${\rm GeV}/c^2$.

Since these results are expressed in terms of the physical masses relevant to the production process and experimental signature, the excluded region depends primarily on the assumption of nearly equal squark masses with only a small dependence on other parameters such as μ and $\tan \beta$. Direct constraints on

the theoretical parameters m_0 and $m_{1/2}\approx 0.34\,M_3$, shown in Fig. 9, have been obtained by the DØ Collaboration assuming the mass relations of the mSUGRA model. In particular, m_0 is keyed to the squark mass and $m_{1/2}$ to the gluino mass, while for the LEP results these parameters usually relate to slepton and chargino masses.

Charginos and neutralinos may be produced directly by annihilation $(q\overline{q} \to \widetilde{\chi}_i^{\pm} \widetilde{\chi}_j^0)$ or in the decays of heavier squarks $(\widetilde{q} \to q' \widetilde{\chi}_i^{\pm}, q \widetilde{\chi}_j^0)$. They decay to energetic leptons (for example, $\widetilde{\chi}^{\pm} \to \ell \nu \widetilde{\chi}_1^0$ and $\widetilde{\chi}_2^0 \to \ell^+ \ell^- \widetilde{\chi}_1^0$) and the branching ratio can be high for some parameter choices. The presence of energetic leptons has been exploited in two ways: the 'trilepton' signature and the 'dilepton' signature.

The search for trileptons is most effective for the associated production of $\widetilde{\chi}_1^{\pm}\widetilde{\chi}_2^0$ [22]. The requirement of three energetic leptons reduces backgrounds to a very small level, but is efficient for the signal only in special cases. The results reported to date are not competitive with the LEP bounds.

The dilepton signal is geared more for the production of charginos in gluino and squark cascades [23]. Jets are required as expected from the rest of the decay chain; the leptons should be well separated from the jets in order to avoid backgrounds from heavy quark decays. Drell-Yan events are rejected with simple cuts on the relative azimuthal angles of the leptons and their transverse momentum. In some analyses the Majorana nature of the gluino is exploited by requiring two leptons with

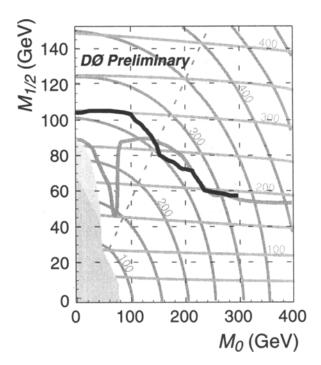

Figure 9: Bounds in the $(m_0, m_{1/2})$ plane obtained by the DØ Collaboration from their searches for squarks and gluinos [20]. The dark solid line shows the result from the jets+ E_T selection, and the grey solid line shows the result from the dielectron selection. The radial contours give the squark mass in this plane, and the nearly horizontal lines give the gluino mass. Parameter values in the shaded region lead to unphysical conditions.

the same charge, thereby greatly reducing the background. In this scenario limits on squarks and gluinos are almost as stringent as in the classic jets+ E_T case.

It should be noted that the dilepton search complements the multijet+ E_T search in that the acceptance for the latter is reduced when charginos and neutralinos are produced in the decay cascades—exactly the situation in which the dilepton signature is most effective.

A loophole in the squark-gluino bounds has recently been addressed using dijet mass distributions [24]. If gluinos are lighter than about 5 GeV/c^2 , E_T is very small and the classic jets+ E_T searches are no longer effective. Resonant production of squarks would have a large cross section, however, and if the squarks are not very heavy, broad peaks in the dijet mass distributions are expected. Comparison of the observed spectrum with theoretical estimates rules out light gluinos if squarks are lighter than about 600 GeV/c^2 .

The top squark is different from the other squarks because its SM partner is so massive: large off-diagonal terms in the squared-mass matrix lead to large mixing effects and a possible light mass eigenstate, $M_{\widetilde{t}_1} \ll M_{\widetilde{q}}$. Analyses designed to find

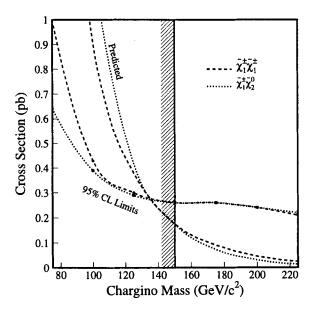

Figure 10: Comparison of the DØ upper limits on chargino and neutralino cross sections with theory in a GMSB scenario, plotted as a function of the chargino mass [28]. The vertical line shows the result obtained from the combined chargino and neutralino exclusions. It corresponds to $M_{\widetilde{\chi}_1^0} \gtrsim 75 \text{ GeV/}c^2$.

light stops have been performed by DØ [25]. The first of these was based on the jets+ E_T signature expected when the the stop is lighter than the chargino. A powerful limit $M_{\widetilde{t}} \gtrsim 90~{\rm GeV/c^2}$ was obtained, provided the neutralino was at least 30 ${\rm GeV/c^2}$ lighter than the stop as depicted in Fig. 3. (These searches are sensitive to the $c\widetilde{\chi}_1^0$ channel which does not apply below the dotted line.) More recently a search for the pair-production of light stops decaying to $b\widetilde{\chi}_1^\pm$ was performed. The presence of two energetic electrons was required; backgrounds from W's were greatly reduced. Regrettably this experimental bound does not yet improve existing bounds on stop masses.

An anomalous event observed by the CDF Collaboration [26] sparked much theoretical speculation [27]. It contains two energetic electrons, two energetic photons, large E_T , and little else. Since it is difficult to explain this event with SM processes, theorists have turned to SUSY. While some models are based on canonical MSSM scenarios (without gaugino mass unification), others are based on GMSB models with selectron production followed by $\tilde{e} \to e \tilde{\chi}^0_1$ and $\tilde{\chi}^0_1 \to \gamma \tilde{g}_{3/2}$. These models predict large inclusive signals for $p\bar{p} \to \gamma\gamma + X$ given kinematic constraints derived from the properties of the CDF event. The Tevatron experiments have looked for such events, and have found none [28], aside from the one anomalous event. These results have been translated into the bound $M_{\tilde{\chi}^0_1} > 75 \text{ GeV}/c^2$, as shown in Fig. 10 from the DØ Collaboration. This bound is

as good as that derived from the combination of the four LEP experiments.

II.6. Supersymmetry searches at HERA and fixed-target experiments: The electron-proton collider (HERA) at DESY runs at $\sqrt{s} = 310$ GeV and, due to its unique beam types, can be used to probe certain channels more effectively than LEP or the Tevatron.

The first of these is associated selectron-squark production [29] through t-channel neutralino exchange. Assuming the conservation of R-parity, the signal consists of an energetic isolated electron, a jet, and missing transverse momentum. No signal was observed in 20 pb⁻¹ of data and limits were placed on the sum $\frac{1}{2}(M_{\widetilde{e}}+M_{\widetilde{q}})$. They are weaker than the latest ones from LEP.

A more interesting opportunity comes in SUSY models with R-parity violation, in particular, with a dominant $LQ\overline{D}$ interaction [30]. Squarks would be produced directly in the s-channel, decaying either directly to a lepton and a quark via R-parity violation or to a pair of fermions and a chargino or neutralino, with the latter possibly decaying via R-parity violation. Less than 3 pb⁻¹ were used to look for a squark resonance above SM backgrounds. All possible topologies were

considered, so model-independent bounds on the R-parity-violating parameter λ'_{111} could be derived as a function of the squark mass. The special case of a light \widetilde{t}_1 was also considered, and limits derived on λ'_{131} as a function of $M_{\widetilde{t}}$. These were improved by considering also the pair-production of stops via photon-gluon fusion (see the Listings for more information).

Limits from SUSY searches in fixed-target or beam-dump experiments were surpassed long ago by the colliders. An important exception is the search for the light gluino, materializing as a long-lived supersymmetric hadron called the R^0 [6]. These could be produced in fixed-target experiments with hadron beams and observed via their decay in flight to a low mass hadronic state: $R^0 \to \pi^+\pi^-\widetilde{\chi}^0_1$ or $\eta\widetilde{\chi}^0_1$. The KTeV Collaboration at Fermilab have searched for R^0 's in their neutral-kaon data and found no evidence for this particle in the $\pi^+\pi^-\widetilde{\chi}^0_1$ channel, deriving strong limits on its mass and lifetime [31], as shown in Fig. 11. A complementary search for supersymmetric baryons was performed by the E761 Collaboration with a charged hyperon beam [32].

II.7. Conclusions: A huge variety of searches for supersymmetry have been carried out at LEP, the Tevatron, and HERA. Despite all the effort, no signal has been found, forcing the

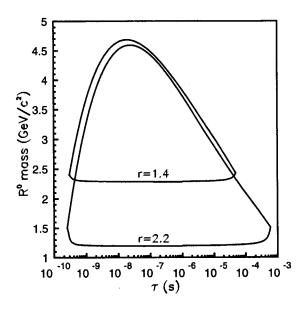

Figure 11: Ranges of R^0 mass and lifetime excluded at 90% CL by the KTeV Collaboration [31]. The ratio of the R^0 to the $\tilde{\chi}_1^0$ mass is r

experimenters to derive limits. We have tried to summarize the interesting cases in Table 1. At the present time there is little room for SUSY particles lighter than M_W . The LEP collaborations will analyze more data taken at higher energies, and the Tevatron collaborations will begin a high luminosity run in a couple of years. If still no sign of supersymmetry appears, definitive tests will be made at the LHC.

MINIMAL SUPERSYMMETRIC STANDARD MODEL ASSUMPTIONS

All results shown below (except where stated otherwise) are based on the Minimal Supersymmetric Standard Model (MSSM) as described in the Note on Supersymmetry. This includes the assumption that R-parity is conserved. In addition the following assumptions are made in most cases:

- 1) The $\tilde{\chi}_1^0$ (or $\tilde{\gamma}$) is the lightest supersymmetric particle (LSP).
- 2) $m_{\widetilde f_L}=m_{\widetilde f_R}$ where $\widetilde f_L$ and $\widetilde f_R$ refer to the scalar partners of left-and right-handed fermions.

Limits involving different assumptions either are identified with comments or are in the miscellaneous section.

When needed, specific assumptions of the eigenstate content of neutralinos and charginos are indicated (use of the notation $\widetilde{\gamma}$ (photino), \widetilde{H} (Higgsino), \widetilde{W} (w-ino), and \widetilde{Z} (z-ino) indicates the approximation of a pure state was made).

$\widetilde{\chi}_1^0$ (Lightest Neutralino) MASS LIMIT

 $\widetilde{\chi}_1^0$ is likely to be the lightest supersymmetric particle (LSP). See also the $\widetilde{\chi}_2^0$, $\widetilde{\chi}_3^0$, $\widetilde{\chi}_4^0$ section below.

We have divided the $\widetilde{\chi}_1^0$ listings below into three sections: 1) Accelerator limits for $\widetilde{\chi}_1^0$, 2) Bounds on $\widetilde{\chi}_1^0$ from dark matter searches, and 3) Other bounds on $\widetilde{\chi}_1^0$ from astrophysics and cosmology.

Accelerator limits for $\tilde{\chi}_1^0$

These papers generally exclude regions in the $M_2-\mu$ parameter plane based on accelerator experiments. Unless otherwise stated, these papers assume minimal supersymmetry and GUT relations (gaugino-mass unification condition). $\Delta m_0=m_{\widetilde{\chi}_0^0}-m_{\widetilde{\chi}_0^0}-m_{\widetilde{\chi}_0^0}$

- 1 ABREU 98 bound combines the chargino and neutralino searches at $\sqrt{s}{=}161,\,172$ GeV with single-photon-production results at LEP-1 from ABREU 97J. The limit is based on the same assumptions as ALEXANDER 96J except $m_0{=}1$ TeV.
- ² ACCIARRI 98F evaluates production cross sections and decay branching ratios within the MSSM, and includes in the analysis the effects of gaugino cascade decays. The limit is obtained for $0 < M_2 < 2000$, $|\mu| < 500$, and $1 < \tan \beta < 40$, but remains valid outside this domain. No dependence on the trilinear-coupling parameter A is found. The limit holds for all values of m_0 consistent with scalar lepton contraints. It improves to 24.6 GeV for $m_{\widetilde{\nu}} > 200$ GeV. Data taken at $\sqrt{s} = 130$ –172 GeV.
- 3 ACKERSTAFF 98L evaluates production cross sections and decay branching ratios within the MSSM, and includes in the analysis the effects of gaugino cascade decays. The bound is determined indirectly from the $\tilde{\chi}_1^+$ and $\tilde{\chi}_2^0$ searches within the MSSM. The limit is obtained for $0 < M_2 < 1500$, $|\mu| < 500$ and $\tan\beta > 1$, but remains valid outside this domain. The limit holds for the smallest value of m_0 consistent with scalar lepton constraints (ACKERSTAFF 97H). It improves to 24.7 GeV for $m_0{=}1$ TeV. Data taken at $\sqrt{s}{=}130{-}172$ GeV.
- ⁴ ALEXANDER 96L bound for $tan \beta = 35$ is 26.0 GeV.
- ⁵ BUSKULIC 96A puts a lower limit on $m_{\widetilde{\chi}_1^0}$ from the negative search for neutralinos,
- tharginos. The bound holds for $m_{\widetilde{\nu}} > 200^{\circ}$ GeV. A small region of (μ, M_2) still allows $m_{\widetilde{\lambda}0} = 0$ if sneutrino is lighter. This analysis combines data from e^+e^- collisions at $\frac{1}{\sqrt{3}} = 91.2$ and at 130–136 GeV.
- 6 ACCIARRI 95E limit for $an\!eta$ >2 is 20 GeV, and the bound disappears if $an\!eta$ \sim 1.
- 7 ELLIS 97c uses constraints on X^\pm , X^0 , and $\tilde{\ell}$ production obtained by the LEP experiments from e^+e^- collisions at $\sqrt{s}=130$ –172 GeV. It assumes a universal mass m_0 for scalar leptons at the grand unification scale.
- ABREU 960 searches for possible final states of neutralino pairs produced in e^+e^- collisions at $\sqrt{s}=130$ –140 GeV. See their Fig. 3 for excluded regions in the (μ,M_2) plane.
- plane.

 9 ACCIARRI 96F searches for possible final states of neutralino pairs produced in e^+e^- collisions at \sqrt{s} = 130–140 GeV. See their Fig. 5 for excluded regions in the (μ, M_2) plane.
- 10 ALEXANDER 96) bound is determined indirectly from the $\widetilde{\chi}_1^{\pm}$ and $\widetilde{\chi}_2^0$ searches within MSSM. A universal scalar mass m_0 at the grand unification scale is assumed. The bound is for the smallest possible value of m_0 allowed by the LEP $\overline{\ell},\,\widetilde{\nu}$ mass limits. Branching fractions are calculated using minimal supergravity. The bound is for $m_{\widetilde{\chi}_2^0} m_{\widetilde{\chi}_2^0} > 10$

GeV. The limit improves to 21.4 GeV for m_0 =1 TeV. Data taken at \sqrt{s} = 130-136

- GeV. ACKERSTAFF 96C, using data from $\sqrt{s}=$ 161 GeV, improves the limit for $m_0=$
- 11 FRANKE 94 reanalyzed the LEP constraints on the neutralinos in the MSSM with an additional singlet.
- ¹² DECAMP 92 limit for $\tan \beta > 2$ is m>13 GeV.
- 13 HEARTY 89 assumed pure $\widetilde{\gamma}$ eigenstate and $m_{\widetilde{e}_L}=m_{\widetilde{e}_R}$. There is no limit for $m_{\widetilde{e}}>$ 58 GeV. Uses $e^+e^- \to \gamma \tilde{\gamma} \tilde{\gamma}$. No GUT relation assumptions are made.

Bounds on $\widetilde{\chi}_1^0$ from dark matter searches

These papers generally exclude regions in the $M_2-\mu$ parameter plane assuming that $\widetilde{\chi}^0_1$ is the dominant form of dark matter in the galactic halo. These limits are based on the lack of detection in laboratory experiments or by the absence of a signal in underground neturino detectors. The latter signal is expected if $\tilde{\chi}_1^0$ accumiates in the Sun or the Earth and annihilates into high-energy ν 's.

- 14 BOTTINO 97 points out that the current data from the dark-matter detection experiment DAMA are sensitive to neutralinos in domains of parameter space not excluded by terrestrial laboratory searches.
- ¹⁵LOSECCO 95 reanalyzed the IMB data and places lower limit on $m_{\widetilde{\chi}_1^0}$ of 18 GeV if the LSP is a photino and 10 GeV if the LSP is a higgsino based on LSP annihilation in the sun producing high-enery neutrinos and the limits on neutrino fluxes from the IMB
- 16 MORI 93 excludes some region in M_2 - μ parameter space depending on $\tan\beta$ and lightest scalar Higgs mass for neutralino dark matter $m_{\widetilde{\chi}0} > m_W$, using limits on upgoing muons produced by energetic neutrinos from neutralino annihilation in the Sun and the Earth.
- Produced by energetic neutrinos from neutralino diministron in the son and the Latin.

 18 OTTINO 92 excludes some region M₂-μ parameter space assuming that the lightest neutralino is the dark matter, using upgoing muons at Kamiokande, direct searches by Ge detectors, and by LEP experiments. The analysis includes top radiative corrections on Higgs parameters and employs two different hypotheses for nucleon-Higgs coupling. Effects of rescaling in the local neutralino density according to the neutralino relic abundance are taken into account.

 18 DOTTINO 31 excluded 3 region in M₂-μ plane using upgoing muon data from Kamioka
- 18 BOTTINO 91 excluded a region in $M_2-\mu$ plane using upgoing muon data from Kamloka experiment, assuming that the dark matter surrounding us is composed of neutralinos and that the Higgs boson is not too heavy.
- 19 GELMINI 91 exclude a region in $M_2-\mu$ plane using dark matter searches
- 20 KAMIONKOWSKI 91 excludes a region in the M_2 - μ plane using IMB limit on upgoing muons originated by energetic neutrinos from neutralino annihilation in the sun, assuming that the dark matter is composed of neutralinos and that $m_{H_1^0}\lesssim$ 50 GeV. See Fig. 8
- 21 MORI 91B exclude a part of the region in the M_2 – μ plane with $m_{\widetilde{\chi}^0_1}\lesssim 80$ GeV using a limit on upgoing muons originated by energetic neutrinos from neutralino annihilation in the earth, assuming that the dark matter surrounding us is composed of neutralinos and that $m_{H_1^0} \lesssim 80 \text{ GeV}$.
- 22 OLIVE 88 result assumes that photinos make up the dark matter in the galactic halo. Limit is based on annihilations in the sun and is due to an absence of high energy neutrinos detected in underground experiments. The limit is model dependent.

Other bounds on $\tilde{\chi}_1^0$ from astrophysics and cosmology

Most of these papers generally exclude regions in the $M_2-\mu$ parameter plane by requiring that the $\widetilde{\chi}_1^0$ contribution to the overall cosmological density is less than some maximal value to avoid overclosure of the Universe. Those not based on the cosmological density are indicated. Many of these papers also include LEP and/or other bounds.

- 23 ELLIS 97C uses in addition to cosmological constraints, data from e^+e^- collisions at 170–172 GeV. It assumes a universal scalar mass for both the Higgs and scalar leptons, as well as radiative supersymmetry breaking with universal gaugino masses. ELLIS 97c also uses the absence of Higgs detection (with the assumptions listed above) to set a limit on $\tan\beta > 1.7$ for $\mu < 0$ and $\tan\beta > 1.4$ for $\mu > 0$. This paper updates ELLIS 96B. ²⁴ ELLIS 96B uses, in addition to cosmological constraints, data from BUSKULIC 96K and
- SUGIMOTO 96. It assumes a universal scalar mass m_0 and radiative Supersymmetry breaking, with universal gaugino masses.
- 25 Mass of the bino (=LSP) is limited to $m_{\widetilde{B}} \lesssim 350$ GeV for $m_{\widetilde{t}} = 174$ GeV.
- ²⁶ Mass of the bino (=LSP) is limited to $m_{\widetilde{B}}\lesssim 350$ GeV for $m_t\leq 200$ GeV. Mass of the higgsino (=LSP) is limited to $m_{\widetilde{H}}\lesssim 1$ TeV for $m_t\leq 200$ GeV.
- 27 Mass of the bino (=LSP) is limited to $m_{\widetilde{B}} \lesssim$ 550 GeV. Mass of the higgsino (=LSP) is limited to $m_{\widetilde{H}} \lesssim$ 3.2 TeV.
- 28 GRIFOLS 90 argues that SN1987A data exclude a light photino ($\lesssim 1$ MeV) if $m_{\widetilde{q}} < 1.1$ TeV, $m_{\widetilde{\mu}} < 0.83$ TeV.
- ²⁹ ELLIS 88b argues that the observed neutrino flux from SN 1987A is inconsistent with a light photino if 60 GeV $\lesssim m_{\widetilde{q}} \lesssim 2.5$ TeV. If m(higgsino) is O(100 eV) the same argument leads to limits on the ratio of the two Higgs v.e.v.'s. LAU 93 discusses possible relations of ELLIS 88b bounds.
- 30 KRAUSS 83 finds $m_{\widetilde{\gamma}}$ not 30 eV to 2.5 GeV. KRAUSS 83 takes into account the gravitino decay. Find that limits depend strongly on reheated temperature. For example a new allowed region $m_{\widetilde{\gamma}}=$ 4–20 MeV exists if $m_{\rm gravitino}$ <40 TeV. See figure 2.

$\tilde{\chi}_{2}^{0}$, $\tilde{\chi}_{3}^{0}$, $\tilde{\chi}_{4}^{0}$ (Neutralinos) MASS LIMITS

CL%

VALUE (GeV)

Neutralinos are unknown mixtures of photinos, z-inos, and neutral higgsinos (the supersymmetric partners of photons and of Z and Higgs bosons). The limits here apply only to $\widetilde{\chi}_{0}^{0}$, $\widetilde{\chi}_{0}^{0}$, and $\widetilde{\chi}_{0}^{0}$, $\widetilde{\chi}_{0}^{0}$ is the lightest supersymmetric particle (LSP); see $\widetilde{\chi}_{0}^{0}$ Mass Limits. It is not possible to quote rigorous mass limits because they are extremely model dependent; i.e. they depend on branching ratios of various $\widetilde{\chi}^{0}$ decay modes, on the masses of decay products $(\tilde{e},\,\tilde{\gamma},\,\tilde{q},\,\tilde{g})$, and on the \tilde{e} mass exchanged in $e^+e^- ou \tilde{\chi}^0_1\tilde{\chi}^0_2$. Often limits are given as contour plots in the $m_{\tilde{\chi}^0_1}-m_{\tilde{e}}$ plane vs other parameters. When specific assumptions are made, e.g., the neutralino is a pure photino $(\widetilde{\gamma})$, pure z-ino (\widetilde{Z}) , or pure neutral higgsino (\widetilde{H}^0) , the neutralinos will be labelled as such.

 31 ACKERSTAFF 98L is obtained from direct searches in the $e^+\,e^-\,\to\,\widetilde\chi^0_1\widetilde\chi^0_{2,3}$ production channels, and Indirectly from $\tilde{\chi}^{\pm}_{1}$ and $\tilde{\chi}^{0}_{1}$ searches within the MSSM. See footnote to ACKERSTAFF 98L in the chargino Section for further details on the assumptions. Data taken at $\sqrt{s}=130-172$ GeV.

 32 ACCIARRI 95E limits go down to 0 GeV $(\tilde{\chi}_2^0)$, 60 GeV $(\tilde{\chi}_3^0)$, and 90 GeV $(\tilde{\chi}_4^0)$ for $\tan\beta=1$.

³³ ACCIARRI 98F is obtained from direct searches in the $e^+e^- \to \tilde{\chi}_{1,2}^0 \dot{\tilde{\chi}}_2^0$ production channels, and indirectly from $\widetilde{\chi}_1^\pm$ and $\widetilde{\chi}_1^0$ searches within the MSSM. See footone to ACCIARRI 98F in the chargino Section for futher details on the assumptions. Data taken at $\sqrt{s} = 130-172$ GeV.

at $\sqrt{s}=130-1/2$ GeV. 34 ABACHI 96 searches for 3-lepton final states. Efficiencies are calculated using mass relations and branching ratios in the Minimal Supergravity scenario. Results are presented as lower bounds on $\sigma(\widetilde{\chi}_1^{\pm}\widetilde{\chi}_2^0) \times \mathrm{B}(\widetilde{\chi}_1^{\pm} \to \ell \nu_\ell \widetilde{\chi}_1^0) \times \mathrm{B}(\widetilde{\chi}_2^0 \to \ell^+ \ell^- \widetilde{\chi}_1^0)$ as a function of $m_{\widetilde{\chi}_1^0}$. Limits range from 3.1 pb $(m_{\widetilde{\chi}_1^0}=45~\mathrm{GeV})$ to 0.6 pb $(m_{\widetilde{\chi}_1^0}=100~\mathrm{GeV})$.

³⁵ ABE 96K looked for tripleton events from chargino-neutralino production. They obtained lower bounds on $m_{\widetilde{\chi}^0_2}$ as a function of μ . The lower bounds are in the 45–50 GeV range

for gaugino-dominant $\widetilde{\chi}_2^0$ with negative μ , if aneta <10. See paper for more details of the assumptions.

³⁶ ACCIARRI 96F looked for associated production $e^+e^- \rightarrow \tilde{\chi}_1^0 \tilde{\chi}_2^0$. See the paper for upper bounds on the cross section. Data taken at $\sqrt{s} = 130-136$ GeV.

 37 ACKERSTAFF 96C is obtained from direct searches in the $e^+e^-
ightarrow \, \widetilde{\chi}^0_1 \, \widetilde{\chi}^0_{2.3}$ production channel, and indirectly from $\widetilde{\chi}_1^\pm$ searches within MSSM. Data from $\sqrt{s}=130,136,$ and 161 GeV are combined. The same assumptions and constraints of ALEXANDER 961 apply. The limit improves to 94.3 GeV for $m_0=1$ TeV. 38 ALEXANDER 961 looked for associated $e^+e^- \to \widetilde{\chi}_0^0\widetilde{\chi}_0^0$. A universal scalar mass m_0 at

the grand unification scale is assumed. The bound is for the smallest possible value of m_0 alowed by the LEP $\tilde{\ell},\,\tilde{\nu}$ mass limits, 1.5 < $an\!eta$ <35. Branching fractions are calculated using minimal supergravity. The bound is for $m_{\widetilde{\chi}0} > 10$ GeV. The limit improves to 47.5 GeV for $m_0=1$ TeV. Data taken at $\sqrt{s}=130$ –136 GeV. ACKERSTAFF 96c, using data from $\sqrt{s}=161$ GeV, improves the limit for $m_0=1$ TeV to 51.9 GeV.

³⁹ ALEXANDER 96L bound for $\tan\beta$ =35 is 51.5 GeV. ⁴⁰ BUSKULIC 96K looked for associated $e^+e^- \rightarrow \widetilde{\chi}_1^0\widetilde{\chi}_2^0$ and assumed the dominance of off-shell Z-exchange in the $\overline{\chi}_2^0$ decay. The bound is for $m_{\widetilde{\chi}_2^0} - m_{\widetilde{\chi}_1^0} > 9$ GeV. Data taken at $\sqrt{s} = 130-136$ GeV.

41 For $\tan \beta > 2$ the limit is >40 GeV; and it disappears for $\tan \beta < 1.6$. 42 ABREU 90G exclude $B(Z \to \widetilde{\chi}_1^0 \widetilde{\chi}_2^0) \ge 10^{-3}$ and $B(Z \to \widetilde{\chi}_2^0 \widetilde{\chi}_2^0) \ge 2 \times 10^{-3}$ assuming $\tilde{\chi}_2^0 \to \tilde{\chi}_1^0$ f \tilde{f} via virtual Z. These exclude certain regions in model parameter space, see their Fig. 5.

space, see time rig. 3. 43 AKRAWY 90N exclude B($Z \to \tilde{\chi}_1^0 \tilde{\chi}_2^0$) $\gtrsim 3-5 \times 10^{-4}$ assuming $\tilde{\chi}_2^0 \to \tilde{\chi}_1^0 f \tilde{r}$ or $\tilde{\chi}_1^0 f$ for most accessible masses. These exclude certain regions in model parameter space, see

 44 BAER 90 is independent of decay modes. Limit from analysis of supersymmetric parameter space restrictions implied by $\Delta\Gamma(Z)<120$ MeV. These result from decays of Z to all combinations of $\tilde{\chi}_I^\pm$ and $\tilde{\chi}_I^0$. Minimal supersymmetry with $\tan\!\beta > 1$ is assumed.

 $^{45}\,\mathrm{See}$ Figs. 4, 5 in BARKLOW 90 for the excluded regions.

46 DECAMP 90K exclude certain regions in model parameter space, see their figures.

47 SAKAI 90 assume $m_{\widetilde{H}_1^0}=0$. The limit is for $m_{\widetilde{H}_2^0}$.

48 Pure $\tilde{\gamma}$ and pure \tilde{Z} eigenstates. B($\tilde{Z} \rightarrow q \bar{q} \tilde{\gamma}$) = 0.60 and B($\tilde{Z} \rightarrow e^+ e^- \tilde{\gamma}$) = 0.13. $m_{\widetilde{e}_L} = m_{\widetilde{e}_R} < 70 \text{ GeV. } m_{\widetilde{\gamma}} < 10 \text{ GeV.}$

⁴⁹ Pure $\widetilde{\gamma}$ and pure \widetilde{Z} eigenstates. B($\widetilde{Z} \to q \overline{q} \widetilde{g}) = 1$. $m_{\widetilde{e}_L} = m_{\widetilde{e}_R} < 70$ GeV. $m_{\widetilde{\gamma}} = 0$.

⁵⁰ Pure higgsino. The LSP is the other higgsino and is taken massless. Limit degraded if

 $\tilde{\chi}^{Q}$ not pure higgsino or if LSP not massless. 51 Pure $\tilde{\gamma}$ and pure \tilde{Z} eigenstates. B($\tilde{Z} \rightarrow \tilde{\nu}\nu$) = 1. $m_{\tilde{e}_L} = m_{\tilde{e}_R} = 26$ GeV. $m_{\tilde{\gamma}} = 10$ GeV. No excluded region remains for $m_{\widetilde{e}} >$ 30 GeV.

52 AKERLOF 85 is e+e-monojet search motivated by UA1 monojet events. Observed only one event consistent with $e^+e^- \to \widetilde{\gamma} + \widetilde{\chi}^0$ where $\widetilde{\chi}^0 \to \text{monojet}$. Assuming that missing- $p_{\widetilde{X}}$ is due to $\widetilde{\gamma}$, and monojet due to $\widetilde{\widetilde{\chi}}{}^0$, limits dependent on the mixing and $m_{\widetilde{e}}$ are given, see their figure 4.

53 BARTEL 85L assume $m_{\widetilde{H}_1^0}=$ 0, $\Gamma(Z\to\widetilde{H}_1^0\widetilde{H}_2^0)\gtrsim \frac{1}{2}$ $\Gamma(Z\to \nu_e\overline{\nu}_e)$. The limit is

for $m_{\widetilde{H}_2^0}$.

⁵⁴BEHREND 85 find no monojet at $E_{
m cm}=$ 40–46 GeV. Consider $ilde{\chi}^0$ pair production via Z^0 . One is assumed as massless and escapes detector. Limit is for the heavier one, decaying into a jet and massless $\widetilde{\chi}^0$. Both $\widetilde{\chi}^0$'s are assumed to be pure higgsino. For these very model-dependent results, BEHREND 85 excludes m=1.5–19.5 GeV. 55 ADEVA 84B observed no events with signature of acoplanar lepton pair with missing energy. Above example limit is for $m_{\widetilde{\gamma}}$ <2 GeV and $m_{\widetilde{e}}$ <40 GeV, and assumes $B(\tilde{Z} \to \mu^+ \mu^- \tilde{\gamma}) = B(\tilde{Z} \to e^+ e^- \tilde{\gamma}) = 0.10$. BR = 0.05 gives 33.5 GeV limit.

56 BARTEL 84C search for $e^+e^- \rightarrow \tilde{Z} + \tilde{\gamma}$ with $\tilde{Z} \rightarrow \tilde{\gamma} + e^+e^-$, $\mu^+\mu^-$, $q\overline{q}$, etc. They see no acoplanar events with missing- p_T due to two $\tilde{\gamma}$'s. Above example limit is for $m_{\widetilde{e}}$ = 40 GeV and for light stable $\tilde{\gamma}$ with $B(\tilde{Z} \rightarrow e^+e^-\tilde{\gamma}) = 0.1$.

⁵⁷ ELLIS 84 find if lightest neutralino is stable, then $m_{\widetilde{\chi}0}$ not 100 eV - 2 GeV (for $m_{\widetilde{q}}$ = 40 GeV). The upper limit depends on $m_{\widetilde{q}}$ (similar to the $\widetilde{\gamma}$ limit) and on nature of $\widetilde{\widetilde{\chi}}^0$. For pure higgsino the higher limit is 5 GeV.

Unstable $\widetilde{\chi}_1^0$ (Lightest Neutralino) MASS LIMIT

Unless stated otherwise, the limits below assume that the $\tilde{\gamma}$ decays either into γ \tilde{G} (goldstino) or into $\gamma \widetilde{H}^0$ (Higgsino).

⁵⁸ABBOTT 98 studied the chargino and neutralino production, where the lightest neutralino in their decay products further decays into $\gamma \, \widetilde{G}$. The limit assumes the gaugino nass unification.

⁵⁹ ABREU 98 uses data at \sqrt{s} =161 and 172 GeV. Upper bounds on $\gamma\gamma E$ cross section are obtained. Similar limits on γE are also given, relevant for ${
m e}^+ \, {
m e}^- \to \, \widetilde{\chi}_1^0 \, \widetilde{{
m G}}$ production,

 60 ACKERSTAFF 98J looked for $\gamma\gamma E$ final states at \sqrt{s} =161–172 GeV. They set limits on $\sigma(e^+e^- o ilde{\chi}_1^0 ilde{\chi}_1^0)$ In the range 0.22–0.50 pb for $m_{\widetilde{\chi}_1^0}$ in the range 45–86 GeV. Mass limits for explicit models from the literature are given in Fig. 19 of their paper. Similar limits on $\gamma+$ missing energy are also given, relevant for $\widetilde{\chi}_1^0$ \widetilde{G} production.

⁶¹ ACCIARRI 97V looked for $\gamma\gamma E$ final states at \sqrt{s} =161 and 172 GeV. They set limits on $\sigma(e^+e^- \to \tilde{\chi}_1^0 \tilde{\chi}_1^0)$ In the range 0.25–0.50 pb for masses in the range 45–85 GeV. The lower limits on $m_{\tilde{\chi}_1^0}$ vary in the range of 64.8 GeV (pure bino with 90 GeV slepton) to 75.3 GeV (pure higgsino). There is no limit for pure zino case.

 62 ELLIS 97 reanalyzed the LEP2 (\sqrt{s} =161 GeV) limits of $\sigma(\gamma\gamma + E_{miss})$ < 0.2 pb to exclude $m_{\widetilde{\chi}_1^0} <$ 63 GeV if $m_{\widetilde{e}_L} = m_{\widetilde{e}_R} <$ 150 GeV and $\widetilde{\chi}_1^0$ decays to γ \widetilde{G} inside detector.

 63 BUSKULIC 960 extended the search for $e^+e^- \rightarrow \widetilde{\chi}_1^0 \widetilde{\chi}_1^0$ in BUSKULIC 95E under

the same assumptions. See their Fig. 5 for excluded region in the neutralino-chargino parameter space. Data taken at $\sqrt{s}=130-136$ GeV. ⁶⁴ BUSKULIC 95E looked for $e^+e^- \rightarrow \widetilde{\chi}_1^0\widetilde{\chi}_1^0$, where $\widetilde{\chi}_1^0$ decays via *R*-parity violating interaction into one neutrino and two opposite-charge leptons. The bound applies provided that $B(Z \rightarrow \widetilde{\chi}_1^0\widetilde{\chi}_1^0) > 3 \times 10^{-5}\beta^3$, β being the final state $\widetilde{\chi}_1^0$ velocity.

65 BUSKULIC 95E looked for $e^+e^- \to \widetilde{\gamma}\widetilde{\gamma}$, where $\widetilde{\gamma}$ decays via R-parity violating interaction into one neutrino and two opposite-charge leptons. They extend the domain in the $(m_{\widetilde{e}}, m_{\widetilde{\gamma}})$ plane excluded by ACTON 93G to $m_{\widetilde{e}} >$ 220 GeV/ c^2 (for $m_{\widetilde{\gamma}} =$ 15 GeV/ c^2) and to $m_{\widetilde{\gamma}} > 2 \text{ GeV}/c^2$ (for $m_{\widetilde{e}} < 220 \text{ GeV}/c^2$).

66 ACTON 93G assume R-parity violation and decays $\tilde{\gamma} \to \tau^{\pm} \ell^{\mp} \nu_{\ell}$ ($\ell = e$ or μ). They exclude $m_{\tilde{\gamma}} = 4$ -43 GeV for $m_{\widetilde{e}_{\ell}} <$ 42 GeV, and $m_{\tilde{\gamma}} = 7$ -30 GeV for $m_{\widetilde{e}_{\ell}} <$ 100 GeV (95% CL). Assumes \tilde{e}_{R} much heavier than \tilde{e}_{ℓ} , and lepton family number violation but L_e - L_μ conservation.

 67 ABE 891 exclude $m_{\widetilde{\gamma}}=0.15$ –25 GeV (95%CL) for $d=(100~{
m GeV})^2$ and $m_{\widetilde{e}}=40~{
m GeV}$ In the case $\tilde{\gamma} \to \gamma \tilde{G}$, and $m_{\tilde{\gamma}}$ up to 23 GeV for $m_{\tilde{e}} =$ 40 GeV in the case $\tilde{\gamma} \to \gamma \tilde{H}^0$.

⁶⁸ BEHREND 87B limit is for unstable photinos only. Assumes B($\tilde{\gamma} \rightarrow \gamma(\tilde{G} \text{ or } \tilde{H}^0)$) =1, $m_{\tilde{G} \text{ or } \tilde{H}^0} \ll m_{\tilde{\gamma}}$ and pure $\tilde{\gamma}$ eigenstate. $m_{\tilde{e}_L} = m_{\tilde{e}_R} < 100 \text{ GeV}$.

⁶⁹ ADEVA 85 is sensitive to $\tilde{\gamma}$ decay path <5 cm. With $m_{\tilde{e}}=50$ GeV, limit (CL = 90%) is $m_{\tilde{\gamma}}>$ >20.5 GeV. Assume $\tilde{\gamma}$ decays to photon + goldstino and search for acoplanar photons with large missing p_T .

70 BALL 84 is FNAL beam dump experiment. Observed no $\tilde{\gamma}$ decay, where $\tilde{\gamma}$'s are expected to come from \tilde{g} 's produced at the target. Three possible $\tilde{\gamma}$ lifetimes are considered.

Gluino decay to goldstino + gluon is also considered 71 BEHREND 83 and BARTEL 84B look for 2γ events from $\widetilde{\gamma}$ pair production. With supersymmetric breaking parameter d = $(100~{\rm GeV})^2$ and $m_{\widetilde{e}}=40~{\rm GeV}$ the excluded regions at CL = 95% would be $m_{\widetilde{\gamma}}=$ 100 MeV - 13 GeV for BEHREND 83 $m_{\widetilde{\gamma}}=$ 80 MeV - 18 GeV for BARTEL 84B. Limit is also applicable if the $\widetilde{\gamma}$ decays radiatively within the detector.

within the detector. Within the detector $\tilde{\gamma} \rightarrow \gamma +$ goldstino. Photino must be either light enough (<30 eV) to satisfy cosmology bound, or heavy enough (>0.3 MeV) to have disappeared at early universe.

$\tilde{\chi}_1^{\pm}$, $\tilde{\chi}_2^{\pm}$ (Charginos) MASS LIMITS

Charginos $(\widetilde{X}^{\pm}$'s) are unknown mixtures of w-inos and charged higgsinos (the supersymmetric partners of W and Higgs bosons). Mass limits are relatively model dependent, so assumptions concerning branching ratios need to be specified. When specific assumptions are made, e.g. the chargino is a pure w-ino (\widetilde{W}) or pure charged higgsino (\widetilde{H}^{\pm}) , the charginos will be labelled as such.

In the Listing below, we use $\Delta m_+ = m_{\widetilde{\chi}^\pm_1} - m_{\widetilde{\chi}^0_1} \Delta m_{\nu} = m_{\widetilde{\chi}^\pm_1} - m_{\widetilde{\nu}^*}$ or simply Δm to indicate that the constraint applies to both Δm_+ and Δm_{ν} .

 73 ABREU 98 uses data at $\sqrt{s}{=}161$ and 172 GeV. The universal scalar mass at the GUT scale is assumed to compute branching fractions and mass spectrum. The limit is for 41 $<\!m_{\widetilde{\nu}}<100$ GeV, and $\tan\beta\!=\!1{-}35$. The limit improves to 84.3 GeV for $m_{\widetilde{\nu}}>300$ GeV. For Δm_+ below 10 GeV, the limit is independent of $m_{\widetilde{\nu}}$, and is given by 80.3 GeV for $\Delta m_+=5$ GeV, and by 52.4 GeV for $\Delta m_+=3$ GeV.

74 ACCIARRI 98F evaluates production cross sections and decay branching ratios within the MSSM, and includes in the analysis the effects of gaugino cascade decays. The limit is obtained for $0 < M_2 < 2000$, $\tan \beta < 1.41$, $\tan \mu = -200$ GeV, and holds for all values of m_0 . No dependence on the trillinear-coupling parameter A is found. It improves to 84 GeV for large sneutrino mass, at μ =-200 GeV. See the paper for limits obtained with specific assumptions on the gaugino/higgsino composition of the state. Data taken at \sqrt{s} = 130-172 GeV.

 75 ACKERSTAFF 98L evaluates production cross sections and decay branching ratios within the MSSM, and includes in the analysis the effects of gaugino cascade decays. The limit is obtained for 0 c M_2 c 1500, $|\mu|$ < 500 and $\tan\beta$ > 1, but remains valid outside this domain. The dependence on the trilinear-coupling parameter A is studied, and found neglibible. The limit holds for the smallest value of m_0 consistent with scalar lepton constraints (ACKERSTAFF 97H) and for all values of m_0 where the condition $\Delta m_{\widetilde{\nu}} > 2.0$ GeV is satisfied. $\Delta m_{\nu} > 10$ GeV if $\widetilde{x}^{\pm} \rightarrow \ell \widetilde{\nu}_{\ell}$. The limit improves to 84.5 GeV for $m_0 = 1$ TeV. Data taken at $\sqrt{s} = 130 - 172$ GeV.

76 ABREU 96L assumes the dominance of off-shell W-exchange in the chargino decay and $\Delta(m)>10$ GeV. The bound is for the smallest $\tilde{\ell},\,\tilde{\nu}$ mass allowed by LEP, provided either $m_{\widetilde{\nu}}>m_{\widetilde{\chi}\pm}$ or $m_{\widetilde{\chi}\pm}-m_{\widetilde{\nu}}>10$ GeV. $1<\tan\beta<35$. For a mostly higgsino $\tilde{\chi}^+$ ($m_{\widetilde{\chi}\pm}-m_{\widetilde{\chi}0}=5$ GeV) the limit is 63.8 GeV, independently of the $\tilde{\ell}$ masses. Data taken at $\sqrt{s}=130-136$ GeV.

- 77 ACCIARRI 96F assume $m_{\widetilde{\nu}} >$ 200 GeV and $m_{\widetilde{\chi}_{1}^{\pm}} < m_{\widetilde{\chi}_{0}^{0}}$. See their Fig. 4 for excluded regions in the $(m_{\widetilde{\chi}_{2}^{\pm}}, m_{\widetilde{\chi}_{0}^{0}})$ plane. Data taken at $\sqrt{s} = 130$ –136 GeV.
- 78 ABBOTT 98 studied the chargino and neutralino production, where the lightest neutralino in their decay products further decays into γ \tilde{G} . The limit assumes the gaugino mass unification.
- 79 Mass unincation. 79 Mass unincation. The Mass unincation of the Mass unincation of the Mass are calculated using mass relations and branching ratios in the Minimal Supergravity scenario. Results are presented in Fig. 1 of their paper as lower bounds on $\sigma(p\overline{p} \to \widetilde{\chi}^{\pm}\widetilde{\chi}^{0}_{2}) \times B(3\ell)$. Limits range from 0.66 pb $(m_{\widetilde{\chi}^{\pm}_{1}}=45 \text{ GeV})$ to 0.10 pb $(m_{\widetilde{\chi}^{\pm}_{1}}=124 \text{ GeV})$.
- 80 ABREU 98 uses data at \sqrt{s} =161 and 172 GeV. The universal scalar mass at the GUT scale is assumed to compute branching fractions and mass spectrum, and the radiative decay of the lightest neutralino into gravitino is assumed. The limit is for $\Delta m > 10$ GeV, at $4 < m_{\widetilde{\nu}} < 100$ GeV, and $4 < m_{\widetilde{\nu}} < 100$ GeV, and $4 < m_{\widetilde{\nu}} < 100$ GeV and $4 < m_{\widetilde{\nu}} < 100$ GeV. and $4 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is for $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}} < 100$ GeV. The second of the limit is $2 < m_{\widetilde{\nu}$
- 81 ACKERSTAFF 98K looked for dilepton+ E_T final states at \sqrt{s} =130-172 GeV. Limits on $\sigma(e^+e^- \to \widetilde{\chi}_1^+\widetilde{\chi}_1^-) \times B^2(\ell)$, with B(ℓ)=B($\chi^+ \to \ell^+ \nu_\ell \chi_1^0$) (B(ℓ)=B($\chi^+ \to \ell^+ \widetilde{\nu}_\ell$)), are given in Fig. 16 (Fig. 17).
- 82 CARENA 97 studied the constraints on chargino and sneutrino masses from muon g-2. The bound can be important for large $\tan \beta$.
- 83 KALINOWSKI 97 studies the constraints on the chargino-neutralino parameter space from limits on $\Gamma(W \to \widetilde{\chi}_1^\pm \widetilde{\chi}_1^0)$ achievable at LEP2. This is relevant when $\widetilde{\chi}_1^\pm$ is "invisible," i.e., if $\widetilde{\chi}_1^\pm$ dominantly decays into $\widetilde{\nu}_\ell \ell^\pm$ with little energy for the lepton. Small otherwise allowed regions could be excluded.
- 84 ABE 96K looked for tripleton events from chargino-neutralino production. The bound on $m_{\widetilde{\chi}^{\pm}_1}$ can reach up to 47 GeV for specific choices of parameters. The limits on the combined production cross section times 3-lepton branching ratios range between 1.4 and 0.4 pb, for $45 < m_{\widetilde{\chi}^{\pm}_1} (\text{GeV}) < 100$. See the paper for more details on the parameter dependence of the results.
- 85 ACKERSTAFF 96c assumes the dominance of off-shell W-exchange in the chargino decay and applies for $\Delta m > 10$ GeV in the region of parameter space defined by: $M_2 < 1500$ GeV, $|\mu| < 500$ GeV and $\tan \beta > 1.5$. The bound is for the smallest $\tilde{\ell}, \tilde{\nu}$ mass allowed by LEP, with the efficiency for $\tilde{\chi}^{\pm} \rightarrow \tilde{\nu} \nu$ decays set to zero. The limit improves to 78.5 GeV for $m_0 = 1$ TeV. Data taken at $\sqrt{s} = 130,136$, and 161 GeV.
- ⁸⁶ ALEXANDER 96J assumes a universal scalar mass m_0 at the grand unification scale. The bound is for the smallest possible value of m_0 alowed by the LEP $\tilde{\ell},\,\tilde{\nu}$ mass limits. 1.5 <tan/ β <35. Branching fractions are calculated using minimal supergravity. The bound is for $\Delta(m)$ >10 GeV. The limit improves to 65.4 GeV for m_0 =1 TeV. Data taken at $\sqrt{s}=130$ -136 GeV.
- 87 BUSKULIC 96K assumes the dominance of off-shell W-exchange in the chargino decay and applies throughout the (M_2,μ) plane for 1.41 <tan β <35 provided either $m_{\widetilde{\nu}} > m_{\widetilde{\chi}\pm}$ and $m_{\widetilde{\chi}\pm} m_{\widetilde{\chi}0}^{2} >$ 4 GeV, or $m_{\widetilde{\chi}\pm} m_{\widetilde{\nu}} >$ 4 GeV. The limit improves to 67.8 GeV for
 - a pure gaugino $\vec{\hat{\chi}}^{\pm}$ and $m_{\widetilde{\nu}} > 200$ GeV. Data taken at $\sqrt{s} = 130$ –136 GeV.
- 88 BUSKULIC 960 searched for pair-produced charginos which decay into $\widetilde{\chi}^0_1$ with either leptons or hadrons, where $\widetilde{\chi}^0_1$ further decays leptonically via *R*-parity violating interactions. See their Fig. 5 for excluded region in the neutralino-chargino parameter space. Data taken at $\sqrt{s}=130\text{-}136$ GeV.
- ⁸⁹ ADRIANI 93M limit from $\Delta\Gamma(Z)$ < 35.1 MeV. For pure wino, the limit is 45.5 GeV.
- ⁹⁰ DECAMP 92 limit is for a general $\tilde{\chi}^{\pm}$ (all contents).
- 91 HIDAKA 91 limit obtained from LEP and preliminary CDF limits on the gluino mass (as analyzed in BAER 91).
- 92 ABREU 90G limit is for a general $\widetilde{\chi}^{\pm}$. They assume charginos have a three-body decay such as $\ell^{+}\nu\widetilde{\gamma}$.
- 93 AKESSON 908 assume $\widetilde{W}\to e\widetilde{\nu}$ with B > 20% and $m_{\widetilde{\nu}}=$ 0. The limit disappears if $m_{\widetilde{\nu}}>$ 30 GeV.
- 94 AKRAWY 90D assume charginos have three-body decay such as $\ell^+ \nu \widetilde{\gamma}$ (i.e. $m_{\widetilde{\nu}} > m_{\widetilde{\chi}+}$). A two-body decay, $\widetilde{\chi}^+ \to \ell \widetilde{\nu}$ would have been seen by their search for acoplanar leptons. The result is independent of the hadronic branching ratio. They search for acoplanar electromagnetic clusters and quark jets.
- electromagnetic cubsters and quain jets. 95 BARKLOW 90 assume 100% $\widetilde{W} \to W^* \widetilde{\chi}_1^0$. Valid up to $m_{\widetilde{\chi}_1^0} \lesssim [m_{\widetilde{W}} 5 \text{ GeV}]$.
- ⁹⁶ BARKLOW 90 assume 100% $\widetilde{H} \to H^* \widetilde{\chi}_1^0$. Valid up to $m_{\widetilde{\chi}_1^0} \lesssim [m_{\widetilde{H}} 8 \text{ GeV}]$.
- 97 DECAMP 90C assume charginos have three-body decay such as $\ell^+ \nu \widetilde{\gamma}$ (i.e. $m_{\widetilde{\nu}} > m_{\widetilde{\chi}^+}$), and branching ratio to each lepton is 11%. They search for acoplanar dimuons, dielectrons, and μe events. Limit valid for $m_{\widetilde{\gamma}} <$ 28 GeV.
- 98 ADACHI 89 assume only single photon annihilation in the production. The limit applies for arbitrary decay branching ratios with $\mathrm{B}(\widetilde{\chi} \to e \nu \widetilde{\gamma}) + \mathrm{B}(\widetilde{\chi} \to \mu \nu \widetilde{\gamma}) + \mathrm{B}(\widetilde{\chi} \to \nu \widetilde{\gamma}) + \mathrm{B}(\widetilde{\chi} \to \mu \nu \widetilde{\gamma$
- 99 ADEVA 898 assume for $\ell \nu \tilde{\gamma}$ ($\ell \tilde{\nu}$) mode that B(e) = B(μ) = B(τ) = 11% (33%) and search for acoplanar dimuons, dielectrons, and μe events. Also assume $m_{\tilde{\gamma}} <$ 20 GeV and for $\ell \tilde{\nu}$ mode that $m_{\tilde{\nu}} =$ 10 GeV.
- 100 ANSARI 87D looks for high p_T e^+e^- pair with large missing p_T at the CERN $p\widetilde{p}$ collider at $E_{\rm CM}=546-630$ GeV. The limit is valid when $m_{\widetilde{\nu}}\lesssim 20$ GeV, ${\sf B}(\widetilde{W}\to e\widetilde{\nu}_e)=1/3$, and ${\sf B}(Z\to \widetilde{W}^+\widetilde{W}^-)$ is calculated by assuming pure gaugino eigenstate. See their Fig. 3(b) for excluded region in the $m_{\widetilde{W}}-m_{\widetilde{\nu}}$ plane.

Supersymmetric Particle Searches

Long-lived \tilde{X}^{\pm}	(Chargino)	MASS	LIMITS
------------------------------	------------	------	--------

Limits on charginos which leave the detector before decaying. VALUE (GeV) CL% DOCUMENT ID TECN • • • We do not use the following data for averages, fits, limits, etc. • • • 101 ABREU >80 95 970 DLPH 102 BARATE >83 95 97k ALEP >45 ABREU 90G DLPH 95 >28.2 **ADACHI** 90c TOPZ 101 ABREU 97D bound applies only to masses above 45 GeV. Data collected in e^+ collisions at \sqrt{s} =130–172 GeV. The limit improves to 84 GeV for $m_{\widetilde{\nu}} >$ 200 GeV. 102 BARATE 97k uses e^+e^- data collected at $\sqrt{s}=130$ –172 GeV. Limit valid for $\tan\beta=\sqrt{2}$ and $m_{\widetilde{\nu}}>100$ GeV. The limit improves to 86 GeV for $m_{\widetilde{\nu}}>250$ GeV.

ν̃ (Sneutrino) MASS LIMIT

The limit depends on the number, $N(\tilde{\nu})$, of sneutrinos assumed to be degenerate in mass. Only $\tilde{\nu}_{\ell}$ (not $\tilde{\nu}_{R}$) exist. It is possible that $\tilde{\nu}$ could be the lightest supersymmetric particle (LSP).

114 ADEVA

95

95

> 31.4

> 39.4

- 105 DECAMP 92 limit is from $\Gamma({\rm invisible})/\Gamma(\ell\ell)=5.91\pm0.15$ (N $_{\nu}=2.97\pm0.07$).
- 106 ABREU 91F limit (>32 GeV) is independent of sneutrino decay mode.
- 107 ALEXANDER 91F limit is for one species of $\tilde{\nu}$ and is derived from $\Gamma(\text{invisible, new})/\Gamma(\ell\ell)$
- < 0.38. 108 ACCIARRI 970 studied the effect of the s-channel tau-sneutrino exchange in $e^+e^$ e⁺e⁻ at $\sqrt{s}=m_Z$ and $\sqrt{s}=130-172$ GeV, via the *R*-parity violating coupling $\lambda_{131} L_1 L_1 e_1$. The limits quoted here hold for $\lambda_{131}>0.05$. Similar limits were studied in e⁺e⁻ $\rightarrow \mu^+\mu^-$ together with $\lambda_{232} L_2 L_3 e_2$ coupling.
- 109 CARENA 97 studled the constraints on chargino and sneutrino masses from muon g = 2. The bound can be important for large tanβ.
- 110 BUSKULIC 95E looked for $Z \to \widetilde{\nu} \overline{\widetilde{\nu}}$, where $\widetilde{\nu} \to \nu \chi_1^0$ and χ_1^0 decays via *R*-parity
- violating interactions into two leptons and a neutrino. 111 BECK 94 limit can be inferred from limit on Dirac neutrino using $\sigma(\tilde{\nu})=4\sigma(\nu)$. Also private communication with H.V. Klapdor-Kleingrothaus.
- ¹¹²FALK 94 puts an upper bound on $m_{\widetilde{
 u}}$ when $\widetilde{
 u}$ is LSP by requiring its relic density does ot overclose the Universe.
- 113 SATO 91 search for high-energy neutrinos from the sun produced by annihilation of sneutrinos in the sun. Sneutrinos are assumed to be stable and to constitute dark matter in our galaxy. SATO 91 follow the analysis of NG 87, OLIVE 88, and GAISSER 86.
- $^{114} \, \rm ADEVA$ 90: limit is from $\Delta \textit{N}_{\nu}~<~0.19$.

ẽ (Selectron) MASS LIMIT

Limits assume $m_{\widetilde{e}_l}=m_{\widetilde{e}_R}$ unless otherwise stated. When the assumption of a universal scalar mass parameter m_0 for \tilde{e}_l and \tilde{e}_R is mentioned, the relation between $m_{\widetilde{e}_l}$ and $m_{\widetilde{e}_l}$ can be found in the "Note on Supersymmetry."

In the Listings below, we use $\Delta m = m_{\widetilde{e}} - m_{\widetilde{\chi}_1^0}$.

 115 ACCIARRI 98F looked for acoplanar dielectron+ E_T final states at \sqrt{s} =130–172 GeV. The limit assumes $\mu=-200$ GeV, and zero efficiecny for decays other than $\tilde{e}_R \to e \tilde{\chi}_1^0$. See their Fig. 6 for the dependence of the limit on Δm .

116 ACKERSTAFF 98K looked for dielectron+ E_T final states at \sqrt{s} =130–172 GeV. The limit assumes $\mu < -100$ GeV, aneta = 35, and zero efficiency for decays other than $\tilde{e}_R \to$ $e\widetilde{\chi}_1^0$. The limit improves to 66.5 GeV for $\tan\!eta\!=\!1.5$.

 117 ACKERSTAFF 97H searched for acoplanar e^+e^- , assuming the MSSM with universal scalar mass and $an\!eta\!=\!1.5$ but conservatively did not take the possible $ilde{e}_L$ production into account. The limit improves to 68 GeV for the lightest allowed $\widetilde{\chi}_1^0$, while it disappears for $\Delta(m) < 3$ GeV. The study includes data from e^+e^- collisions at \sqrt{s} =161 GeV, as well as 130–136 GeV (ALEXANDER 97B).

118 BARATE 97N uses e^+e^- data collected at \sqrt{s} =161 and 172 GeV. The limit is for $\tan\beta$ =2. It improves to 75 GeV if $\Delta(m)$ >35 GeV.

BARATE 97N limit from ALCARAZ 96 limit on Z Invisible-decay width and N_{ν} =3, independent of decay mode. Limit improves to 41 GeV for degenerate right-handed

120 ABREU 960 bound assumes $|\mu|>$ 200 GeV. The limit on $m_{\widetilde{e}_R}$ obtained by assuming a heavy \tilde{e}_L reduces to below 48 GeV. Data taken at $\sqrt{s} = 130-136$ GeV.

121 ACCIARRI 96F searched for acoplanar electron pairs. The limit is on $m_{\widetilde{e}_R}$, under the assumption of a universal scalar mass in the range 0 < m < 100 GeV. It assumes 0 < M < 200 GeV, $-200 < \mu < 0$ GeV, $\tan \beta = 1.5$. The corresponding limit for for $m_{\widetilde{e}_L}$ is 64 GeV. The bound on $m_{\widetilde{e}_R}$ ($m_{\widetilde{e}_L}$) improves to 58 GeV (70 GeV) for $m_{\widetilde{\chi}_1^0} = 0$. Data taken at $\sqrt{s} = 130-136$ GeV.

122 AID 96C used electron+jet events with missing energy and momentum to look for $eq \rightarrow \tilde{eq}$ via neutralino exchange with decays into $(e\tilde{\chi}_1^0)(q\tilde{\chi}_1^0)$. See the paper for dependences

123 BUSKULIC 1 96K searched for acoplanar electron pairs. The bound disappears for $\Delta(m)$ <10 GeV, while it improves to 59 GeV for $m_{\widetilde{\chi}0}^{-}$ =0. If μ is small and the LSP

hlggsino-dominated, no bound beyond $m_Z/2$ exists. Data taken at $\sqrt{\tilde{s}}=130$ –136 GeV. 124 SUGIMOTO 96 looked for single photon production from e^+e^- annihilation at \sqrt{s} = 57.8 GeV. The lower bound improves to 65.5 GeV for a massless photino.

125 SUGIMOTO 96 combined FORD 86, BEHREND 88B, HEARTY 89, HOSODA 94, ABE 95A, and SUGIMOTO 96 results. The lower bound improves to 79.3 GeV for a massless photino.

 126 ABE 95A looked for single photon production from e^+e^- annihilation at $\sqrt{s}=$ 58 GeV. The lower bound improves to 47.2 GeV for a massless photino.

127 BUSKULIC 95E looked for $Z \to \overline{e_R^+} \overline{e_R^-}$ where $\overline{e_R} \to e \chi_1^0$ and χ_1^0 decays via R-parity violating interactions into two leptons and a neutrino.

128 ADRIANI 93M used acolinear di-lepton events.

129 DECAMP 92 limit improves for equal masses. They looked for acoplanar electrons.

 $^{130}\,\mathrm{AKESSON}$ 90B assume $m_{\widetilde{\gamma}}=0.$ Very similar limits hold for $m_{\widetilde{\gamma}}\lesssim$ 20 GeV.

131 AKRAWY 90D look for acoplanar electrons. For $m_{\widetilde{e}_L} \gg m_{\widetilde{e}_R}$, limit is 41.5 GeV, for m_{\approx} < 30 GeV.

132 BAER 90 limit from $\Delta\Gamma(Z)$ (nonhadronic) < 53 MeV. Independent of decay modes. Mininal supersymmetry and $\tan\beta>1$ assumed.

133 DECAMP 90C look for acoplanar electrons. For $m_{\widetilde{e}_L} \gg m_{\widetilde{e}_R}$ limit is 42 GeV, for $m_{\widetilde{\gamma}}$ < 33 GeV.

134 ZHUKOVSKII 90 set limit by saying the luminosity of a magnetized neutron star due to massiess photino emission by electrons be small compared with its neutrino luminosity.

135 ADACHI 89 assume only photon and photino exchange and $m_{\widetilde{e}_L}=m_{\widetilde{e}_R}$. The limit for the nondegenerate case is 26 GeV.

136 ADEVA 89B look for acoplanar electrons.

- 137 ALBAJAR 89 limit applies for \tilde{e}_L when $m_{\tilde{e}_L}=m_{\tilde{\nu}_L}$ and $m_{\tilde{\gamma}}=0$. See their Fig. 55 for the 90% CL excluded region in the $m_{\widetilde e_L}-m_{\widetilde
 u_L}$ plane. For $m_{\widetilde
 u}=m_{\widetilde \gamma}=$ 0, limit is 50 138 ${\mbox{GeV}}$. ALBAJAR 89 assume $m_{\widetilde{\gamma}}=0.$
- 139 HEARTY 89 assume $m_{\widetilde{\gamma}}^{'}=$ 0. The limit is very sensitive to $m_{\widetilde{\gamma}}$; no limit can be placed for $m_{\widetilde{\gamma}} \gtrsim$ 13 GeV.
- $^{140}\mathrm{The}$ limit is reduced to 43 GeV if only one \tilde{e} state is produced (\tilde{e}_L or \tilde{e}_R very heavy).
- 141 BEHREND 888 limits assume pure photino eigenstate and $m_{\widetilde{e}_L}=m_{\widetilde{e}_R}$. 142 The 95% CL limit for BEHREND 888 is 47.5 GeV for $m_{\widetilde{\gamma}}=0$. The limit for $m_{\widetilde{e}_L}\gg$ $m_{\widetilde{e}_R}$ is 40 GeV at 90% CL.

$\tilde{\mu}$ (Smuon) MASS LIMIT

Limits assume $m_{\widetilde{\mu}_L} = m_{\widetilde{\mu}_R}$ unless otherwise stated.

In the Listings below, we use $\Delta(m)=m_{\widetilde{\mu}}-m_{\widetilde{\chi}0}$. When limits on $m_{\widetilde{\mu}_R}$ are quoted, it is understood that limits on $m_{\widetilde{\mu}_L}$ are usually at least as strong.

 143 ACCIARRI 98F looked for dimuon+ E_T final states at \sqrt{s} =130–172 GeV. The limit assumes $\mu=-$ 200 GeV, and zero efficiecny for decays other than $\widetilde{\mu}_R \to ~\mu \widetilde{\chi}_1^0$. See their Fig. 6 for the dependence of the limit on Δm .

144 ACKERSTAFF 98k looked for dimuon+ E_T final states at \sqrt{s} =130–172 GeV. The limit assumes $\mu < -100$ GeV, $\tan \beta$ =1.5, and zero efficiency for decays other than $\widetilde{\mu}_R \to$ $\mu\widetilde{\chi}_1^0$. The limit improves to 62.7 GeV for B($\widetilde{\mu}_R \to \mu\widetilde{\chi}_1^0$)=1.

¹⁴⁵BARATE 97N uses e^+e^- data collected at \sqrt{s} =161 and 172 GeV. The limit assumes $B(\widetilde{\mu} \to \mu \widetilde{\chi}_1^0) = 1.$

 $^{146}\,\mathrm{ACKERSTAFF}$ 97H limit is for $m_{\widetilde{\chi}_1^0}$ >12 GeV allowed by their chargino, neutralino search, and for $an\!eta\geq 1.5$ and $|\mu|>200$ GeV. The study includes data from e^+e^-

collisions at \sqrt{s} =161 GeV, as well as at 130-136 GeV (ALEXANDER 97B). ¹⁴⁷BARATE 97N limit from ALCARAZ 96 limit on Z invisible-decay width and N_{ν} =3, independent of decay mode. Limit improves to 41 GeV for degenerate right-handed

¹⁴⁸ Data taken at $\sqrt{s} = 130-136$ GeV.

149 BUSKULIC 95E looked for $Z \to \widetilde{\mu}_R^+ \widetilde{\mu}_R^-$, where $\widetilde{\mu}_R \to \mu \chi_1^0$ and χ_1^0 decays via *R*-parity violating interactions into two leptons and a neutrino.

150 AKRAWY 90D look for acoplanar muons. For $m_{\widetilde{\mu}_L} \gg m_{\widetilde{\mu}_R}$, limit is 41.0 GeV, for m_{\approx} < 30 GeV.

151 BAER 90 limit from $\Delta\Gamma(Z)$ (nonhadronic) < 53 MeV. Independent of decay modes. Mininal supersymmetry and $\tan\beta>1$ assumed. 152 DECAMP 90C look for acoplanar muons. For $m_{\widetilde{\mu}_L}\gg m_{\widetilde{\mu}_R}$ limit is 40 GeV, for $m_{\widetilde{\gamma}}<$

153 GeV. 153 ADACHI 89 assume only photon exchange, which gives a conservative limit. $m_{\widetilde{\mu}_L}$ $m_{\widetilde{\mu}_R}$ assumed. The limit for nondegenerate case is 22 GeV.

154 ADEVA 898 look for acoplanar muons.

$\tilde{\tau}$ (Stau) MASS LIMIT

Limits assume $m_{\widetilde{ au}_L} = m_{\widetilde{ au}_R}$ unless otherwise stated.

In the Listings below, we use $\Delta(m)=m_{\widetilde{\tau}}-m_{\widetilde{\chi}_{\bullet}^0}$. The limits depend on the potentially large mixing angle of the lightest mass eigenstate $\tilde{\tau}_1 = \tilde{\tau}_R \sin\!\theta_{ au} + \tilde{\tau}_L \sin\!\theta_{ au}$. The coupling to the Z vanishes for $\theta_{\tau}=0.82$.

 156 BARATE 97N limit from ALCARAZ 96 limit on Z invisible-decay width and $N_{\nu}=3$, Independent of decay mode. Limit improves to 41 GeV for degenerate right-handed sleptons.

157 ADRIANI 93M limit is for $m_{\widetilde{\tau}_L} \gg m_{\widetilde{\tau}_R}$.

158 DECAMP 92 limit is for $m_{\widetilde{\tau}_L} \gg m_{\widetilde{\tau}_R}$; for equal masses the limit would improve. They looked for acoplanar particles.

159 AKRAWY 90D look for acoplanar particles. For $m_{\widetilde{ au}_L} \gg m_{\widetilde{ au}_R}$, limit is 41.0 GeV, for

160 BUSKULIC 95E looked for $Z \to \tau_R^+ \tau_R^-$, where $\tau_R \to \tau \chi_1^0$ and χ_1^0 decays via R-parity violating interactions into two leptons and a neutrino.

161 BAER 90 limit from $\Delta\Gamma(Z)$ (nonhadronlc) < 53 MeV. Independent of decay modes. Mininal supersymmetry and $\tan\beta > 1$ assumed.

¹⁶²DECAMP 90C look for acoplanar charged particle pairs. Limit is for $m_{\widetilde{\tau}_l}=m_{\widetilde{\tau}_R}$. For $m_{\widetilde{\gamma}} \leq$ 24 GeV, the limit is 37 GeV. For $m_{\widetilde{\tau}_L} \gg m_{\widetilde{\tau}_R}$ and $m_{\widetilde{\gamma}} <$ 15 GeV, the limit

is 33 GeV. 163 ADACHI 89 assume only photon exchange, which gives a conservative limit. $m_{\widetilde{\tau}_L}$ $m_{\widetilde{ au}_R}$ assumed.

Stable & (Slepton) MASS LIMIT

Limits on scalar leptons which leave detector before decaying. Limits from Z decays are independent of lepton flavor. Limits from continuum e^+e^- annihilation are also independent of flavor for smuons and staus. However, selectron limits from continuum e^+e^- annihilation depend on flavor because there is an additional contribution from neutralino exchange that in general yields stronger limits. All limits assume $m_{\widetilde{\ell}_I}=$ $m_{\widetilde{\ell}_R}$ unless otherwise stated.

164 ABREU 97D bound applies only to masses above 45 GeV. The mass limit improves to 68 GeV for $\tilde{\mu}_L$, $\tilde{\tau}_L$. Data collected in e^+e^- collisions at \sqrt{s} =130–172 GeV.

165 BARATE 97K uses e^+e^- data collected at $\sqrt{s}=$ 130–172 GeV. The mass limit improves to 69 GeV for $\tilde{\mu}_L$ and $\tilde{\tau}_L$.

166 SAKAI 90 limit improves to 30.1 GeV for \tilde{e} if $m_{\tilde{\gamma}} \approx m_{\tilde{e}}$.

167 ADACHI 89 assume only photon (and photino for $\tilde{\epsilon}$) exchange. The limit for $\tilde{\epsilon}$ improves to 26 GeV for $m_{\widetilde{\gamma}} \approx m_{\widetilde{\delta}}$.

q̃ (Squark) MASS LIMIT

> 63

For $\dot{m_{\widetilde{q}}} >$ 60-70 GeV, it is expected that squarks would undergo a cascade decay via a number of neutralinos and/or charginos rather than undergo a direct decay to photinos as assumed by some papers. Limits obtained when direct decay is assumed are usually higher than limits when cascade decays are included. The limits from ${\cal Z}$ decay do not assume GUT relations and are more model independent.

168 ABE 96D searched for production of gluinos and five degenerate squarks in final states containing a pair of leptons, two jets, and missing E_T . The two leptons arise from the semileptonic decays of charginos produced in the cascade decays. The limit is derived for fixed $\tan\beta=4.0$, $\mu=-400$ GeV, and $m_{H^+}=500$ GeV, and with the cascade decays of the squarks and gluinos calculated within the framework of the Minimal Supergravity scenario.

scenario. 169 ABACHI 95c assume five degenerate squark flavors with $m_{\widetilde{Q}_L} = m_{\widetilde{Q}_R}$. Sleptons are assumed to be heavier than squarks. The limits are derived for fixed $\tan\beta = 2.0~\mu = -250~{\rm GeV}$, and $m_{H^+}{=}500~{\rm GeV}$, and with the cascade decays of the squarks and gluinos calculated within the framework of the Minimal Supergravity scenario. The bounds are weakly sensitive to the three fixed parameters for a large fraction of parameter space. No limit is given for $m_{\rm gluino} > 547~{\rm GeV}$.

170 DATTA 97 argues that the squark mass bound by ABACHI 95C can be weakened by 10–20 GeV if one relaxes the assumption of the universal scalar mass at the GUT-scale so that the $\widetilde{\chi}_1^{\pm}$, $\widetilde{\chi}_2^{0}$ in the squark cascade decays have dominant and invisible decays to

171 DERRICK 97 looked for lepton-number violating final states via R-parity violating couplings $\lambda'_{IJk}L_IQ_Jd_k$. When $\lambda'_{11k}\lambda'_{IJk}\neq 0$, the process $eu\to \overline{d}_k^*\to \ell_Iu_J$ is possible. When $\lambda'_{1J1}\lambda'_{IJk}\neq 0$, the process $e\overline{d}\to \widetilde{u}_J^*\to \ell_I\overline{d}_k$ is possible. 100% branching fraction $\widetilde{q}\to\ell_J$ is assumed. The limit quoted here corresponds to $\widetilde{t}\to \tau q$ decay, with $\lambda'=0.3$. For different channels, limits are slightly better. See Table 6 in their paper.

172 HEWETT 97 reanalyzed the limits on possible resonances in di-jet mode $(\tilde{q} \to q\tilde{g})$ from ALITTI 93 quoted in "Limits for Excited q (q^*) from Single Production," ABE 96 in "SCALE LIMITS for Contact Interactions: $\Lambda(q\,q\,q\,q)$," and unpublished CDF, DØ bounds. The bound applies to the gluino mass of 5 GeV, and improves for lighter gluino. The analysis has gluinos in parton distribution function.

173 TEREKHOV 97 improved the analysis of TEREKHOV 96 by including di-jet angular distributions in the analysis.

174 AID 96 looked for first-generation squarks as s-channel resonances singly produced in ep collision via the R-parity violating coupling in the superpotential $W = \lambda L_1 Q_1 d_1$. The degeneracy of squarks \widetilde{Q}_1 and \widetilde{d}_1 is assumed. Eight different channels of possible squark decays are considered.

175 AID 96c used electron-jet events with missing energy and momentum to look for $eq \rightarrow \tilde{e}\tilde{q}$ via neutralino exchange with decays into $(e\tilde{\chi}_1^Q)(q\tilde{\chi}_1^Q)$. See the paper for dependences on $m_{\tilde{e}}$, $m_{\tilde{\chi}0}$.

176 TEREKHOV 96 reanalyzed the limits on possible resonances in dI-jet mode $(\tilde{u} \rightarrow u\tilde{g})$ from ABE 95n quoted in "MASS LIMITS for g_A (axigluon)." The bound applies only to the case with a light gluino.

177 ABE 95T looked for a cascade decay of five degenerate squarks into $\widetilde{\chi}^0_2$ which further decays into $\widetilde{\chi}^0_1$ and a photon. No signal is observed. Limits vary widely depending on

the choice of parameters. For $\mu=-40$ GeV, $\tan\beta=1.5$, and heavy gluinos, the range $50{<}m_{\widetilde{o}}$ (GeV) ${<}110$ is excluded at 90% CL. See the paper for details.

178 BUSKULIC 95E looked for $Z \to \tilde{q}\tilde{q}$, where $\tilde{q} \to q \chi_1^0$ and χ_1^0 decays via *R*-parity violating interactions into two leptons and a neutrino.

violating interactions into two leptons and a neutrino. 179 AHMED 948 looked for squarks as s-channel resonance in ep collision via R-parity violating coupling in the superpotential $W=\lambda I_1 Q_1 d_1$. The degeneracy of all squarks Q_1 and d_1 is assumed. The squarks decay dominantly via the same R-violating coupling into eq or νq if $\lambda \gtrsim 0.2$. For smaller λ , decay into photino is assumed which subsequently decays into eq \overline{q} , and the bound depends on $m_{\overline{q}}$. See paper for excluded region on $(m_{\overline{q}}, \lambda)$ plane.

180 ADRIANI 93M limit from $\Delta\Gamma(Z)$ < 35.1 MeV and assumes $m_{\widetilde{q}_L}\gg m_{\widetilde{q}_R}$

181 ABE 92L assume five degenerate squark flavors and $m_{\widetilde{q}_L} = m_{\widetilde{q}_R}^2$. ABE 92L includes the effect of cascade decay, for a particular choice of parameters, $\mu = -250$ GeV, $\tan\beta = 2$. Results are weakly sensitive to these parameters over much of parameter space. No limit for $m_{\widetilde{q}} \leq 50$ GeV (but other experiments rule out that region). Limits are 10–20 GeV higher if $B(\widetilde{q} \to q\widetilde{\gamma}) = 1$. Limit assumes GUT relations between gaugino masses and the gauge coupling: in particular that for $|\mu|$ not small, $m_{\widetilde{\chi}_1^0} \approx m_{\widetilde{g}}/6$. This last

relation implies that as $m_{\widetilde{g}}$ increases, the mass of $\widetilde{\chi}^0_1$ will eventually exceed $m_{\widetilde{g}}$ so that no decay is possible. Even before that occurs, the signal will disappear; in particular no bounds can be obtained for $m_{\widetilde{g}} >$ 410 GeV. $m_{H^+} =$ 500 GeV.

 $^{182}\,\mathrm{ABE}$ 92L bounds are based on similar assumptions as ABACHI 95c. No limits for $m_{gluino} >$ 410 GeV.

183 ROY 92 reanalyzed CDF limits on di-lepton events to obtain limits on squark production in *R*-parity violating models. The 100% decay $\tilde{q} \to q \tilde{\chi}$ where $\tilde{\chi}$ is the LSP, and the LSP decays either into $\ell q \bar{d}$ or $\ell \ell \bar{e}$ is assumed.

184 NOJIRI 91 argues that a heavy squark should be nearly degenerate with the gluino in minimal supergravity not to overclose the universe.

185 ABREU 90F assume six degenerate squarks and $m_{\widetilde{q}_L}=m_{\widetilde{q}_R}$. $m_{\widetilde{q}}<$ 41 GeV is excluded at 95% CL for $m_{\rm LSP}< m_{\widetilde{q}}$ –2 GeV.

 $^{186}\,\mathrm{ABREU}$ 90F exclude $m_{\widetilde{d}}$ < 38 GeV at 95% for m_{LSP} < $m_{\widetilde{d}}$ $^{-}$ 2 GeV.

187 ABREU 90F exclude $m_{\widetilde{u}}$ < 36 GeV at 95% for $m_{\rm LSP}$ < $m_{\widetilde{u}}$ -2 GeV.

188 ALITTI 90 searched for events having ≥ 2 jets with $E_T^1 > 25$ GeV, $E_T^2 > 15$ GeV, $|\eta| < 0.85$, and $\Delta \phi < 160^\circ$, with a missing momentum > 40 GeV and no electrons. They assume $\tilde{q} \to q \tilde{\gamma}$ (if $m_{\tilde{q}} < m_{\tilde{g}}$) or $\tilde{q} \to q \tilde{g}$ (if $m_{\tilde{q}} > m_{\tilde{g}}$) decay and $m_{\tilde{q}} \lesssim 20$ GeV. Five degenerate squark flavors and $m_{\tilde{q}_L} = m_{\tilde{q}_R}$ are assumed. Masses below 50 GeV are not excluded by the analysis.

189 BAER 90 limit from $\Delta \Gamma(Z) < 120$ MeV, assuming $m_{\widetilde{d}_L} = m_{\widetilde{p}_L} = m_{\widetilde{e}_L} = m_{\widetilde{p}_L}$. Independent of decay modes. Minimal supergravity assumed.

¹⁹⁰BARKLOW 90 assume 100% $\tilde{q} \rightarrow q\tilde{\gamma}$.

 191 BARKLOW 90 assume five degenerate squarks (left- and right-handed). Valid up to $m_{\widetilde\chi_0^0} \lesssim [m_{\widetilde q} - 4~{\rm GeV}].$

 192 BARKLOW 90 result valid up to $m_{\widetilde{\chi}^0_1} \lesssim [m_{\widetilde{d}} - 5 \text{ GeV}].$

¹⁹³BARKLOW 90 result valid up to $m_{\widetilde{\chi}_1^0} \lesssim [m_{\widetilde{u}} - 6 \text{ GeV}].$

194 ADACHI 89 assume only photon exchange, which gives a a conservative limit. The limit is only for one flavor of charge 2/3 \tilde{q} . $m_{\widetilde{q}_L} = m_{\widetilde{q}_{\widetilde{R}}}$ and $m_{\widetilde{\gamma}} = 0$ assumed. The limit decreases to 26.1 GeV for $m_{\widetilde{\gamma}} = 15$ GeV. The limit for nondegenerate case is 24.4 GeV.

195 NATH 88 uses Kamioka limit of $\tau(p \to \overline{\nu}K^+) > 7 \times 10^{31}$ yrs to constrain squark mass $m_{\widetilde{q}} > 1000$ GeV by assuming that the proton decay proceeds via an exchange of a color-triplet Higgsino of mass $< 10^{16}$ GeV in the supersymmetric SU(5) GUT. The limit applies for $m_{\widetilde{\gamma}} \equiv (8/3) \sin^2 \theta_W \widetilde{m}_2 > 10$ GeV (\widetilde{m}_2) is the SU(2) gaugino mass) and for a very conservative value of the three-quark proton wave function, barring cancellation between second and third generations. Lower squark mass is allowed if $m_{\widetilde{\gamma}}$ as defined above is smaller.

above is smaller. 196 The limits of ALBAJAR 87D are from $p\overline{p} \to \widetilde{q}\overline{\overline{q}} X$ ($\overline{q} \to q\widetilde{\gamma}$) and assume 5 flavors of degenerate mass squarks each with $m_{\widetilde{q}_L} = m_{\widetilde{q}_R}$. They also assume $m_{\widetilde{g}} > m_{\widetilde{q}}$. These limits apply for $m_{\widetilde{\gamma}} \lesssim$ 20 GeV.

\tilde{b} (Sbottom) MASS LIMIT

Limits in e⁺ e⁻ depend on the mixing angle of the mass eigenstate $\tilde{b}_1 = \tilde{b}_L \cos\theta_b + \tilde{b}_R \sin\theta_b$. Coupling to the Z vanishes for $\theta_b \sim$ 1.17. In the Listings below, we use $\Delta m = m_{\widetilde{b}_1} - m_{\widetilde{\chi}_1^0}$.

				$\Delta(m) > 8 \text{ GeV}$

197 ACKERSTAFF 97Q data taken at $\sqrt{s}{\approx}130{-}172$ GeV. See paper for dependence on θ_b . No limit for $\theta_b\approx 1.17$.

 $198\, \rm BARATE$ 970 uses data at $\sqrt{s}{=}161,$ 170, and 172 GeV. The limit disappears when $\theta_b\approx 1.17.$

¹⁹⁹ Data taken at $\sqrt{s} \approx 130-136$ GeV.

²⁰⁰ACKERSTAFF 96 also studied θ_b dependence when there is a mixing $\tilde{b}_1 = \tilde{b}_L \cos\theta_b +$ $\tilde{b}_R \sin \theta_b$. Data taken at $\sqrt{s}=130$, 136, and 161 GeV. See the paper for dependence on θ_b . No limit for $\theta_b \approx 1.17$.

t (Stop) MASS LIMIT

Limit depends on decay mode. In e^+e^- collisions they also depend on the mixing angle of the mass eigenstate $\tilde{t}_1=\tilde{t}_L\cos\theta_t+\tilde{t}_R\sin\theta_t$. Coupling to Z vanishes when $\theta_t=0.98$. In the Listings below, we use $\Delta m\equiv m_{\tilde{t}_1}-m_{\tilde{\chi}_0}$ or $\Delta m\equiv m_{\tilde{t}_1}-m_{\tilde{\nu}}$. depending on relevant decay mode. See also bounds in "q (Squark) MASS LIMIT."

201				

- 201 ACKERSTAFF 97Q looked for \tilde{t} pair production. Data taken at \sqrt{s} =130, 136, 161, 170, and 172 GeV. Unless the ℓ = τ decay mode is explicitly indicated, the same branching fractions to ℓ =e, μ , and τ are assumed for $b\ell\tilde{\nu}_{\ell}$ modes. See Table 7 and Figs. 8–10 for other choices of θ_{ℓ} , $\Delta(m)$, and leptonic branching ratios.
- 202 BARATE 970 uses e^+e^- data at \sqrt{s} =161, 170, and 172 GeV. Unless the ℓ = τ decay mode is explicitly indicated, the same branching fractions to ℓ =e, μ , and τ are assumed for $b\ell\bar{\nu}_\ell$ modes. See their Figs. 4 and 5 for other choices of θ_{ℓ} , $\Delta(m)$, and leptonic branching ratios.
- 203 ABACHI 968 searches for final states with 2 jets and missing E_T . Limits on $m_{\widetilde{\tau}}$ are given as a function of $m_{\widetilde{\chi}_1^0}$. See Fig. 4 for details.
- ²⁰⁴ Data taken at $\sqrt{s}=130^{-1}36$ GeV.
 ²⁰⁵ ACKERSTAFF 96 looked for \tilde{t} pair production. See the paper for $\theta_{\tilde{t}}$ and $\Delta(m)$ dependece of the limits. Data taken at $\sqrt{s}=130$, 136, and 161 GeV.
- 206 AID 96 considers photoproduction of \widetilde{tt} pairs, with 100% R-parity violating decays of \widetilde{t} to eq, with q=d, s, or b quarks.
- 207 AID 96 considers production and decay of \tilde{t} via the *R*-parity violating coupling in the superpotential $W=\lambda L_1 \, Q_3 \, d_1$.
- 208 CHO 96 studied the consistency among the $B^0-\overline{B}^0$ mixing, ϵ in $K^0-\overline{K}^0$ mixing, and the measurements of V_{cb} , V_{ub}/V_{cb} . For the range 25.5 GeV $< m_{\widetilde{t}_1} < m_Z/2$ left by AKERS 94K for $\theta_{\ell}=0.98$, and within the allowed range in M_2 - μ parameter space from chargino, neutralino searches by ACCIARRI 95E, they found the scalar top contribution to $B^0 - \overline{B}{}^0$ mixing and ϵ to be too large if $\tan \beta <$ 2. For more on their assumptions, see the paper and their reference 10.
- ²⁰⁹ BUSKULIC 95E looked for $Z \to \tilde{t}\tilde{t}$, where $\tilde{t} \to c \chi_1^0$ and χ_1^0 decays via R-parity violating interactions into two leptons and a neutrino.
- 210 SHIRAI 94 bound assumes the cross section without the s-channel Z-exchange and the QCD correction, underestimating the cross section up to 20% and 30%, respectively. They assume $m_c=1.5$ GeV.

Heavy 👸 (Gluino) MASS LIMIT

For $m_{\widetilde{R}} > 60$ –70 GeV, it is expected that gluinos would undergo a cascade decay via a number of neutralinos and/or charginos rather than undergo a direct decay to photinos as assumed by some papers. Limits obtained when direct decay is assumed are usually higher than limits when cascade decays are included.

- ²¹¹ABE 97k searched for production of gluinos and five degenerate squarks in events with three or more jets but no electrons or muons and missing transverse energy $E_T > 60$ GeV. The limit for any $m_{\widetilde{q}}$ is for μ =-200 GeV and $\tan \beta$ =2, and that for $m_{\widetilde{q}}$ = $m_{\widetilde{g}}$ is for μ =-400 GeV and $\tan \beta$ =4. Different choices for $\tan \beta$ and μ lead to changes of the order of \pm 10 GeV in the limits. See Footnote [16] of the paper for more details on the assumptions.
- 212 ABE 96D searched for production of gluinos and five degenerate squarks in final states containing a pair of leptons, two jets, and missing $E_{\mathcal{T}}$. The two leptons arise from the semileptonic decays of charginos produced in the cascade decays. The limits are derived for fixed $\tan\beta=4.0$, $\mu=-400$ GeV, and $m_{H^+}=500$ GeV, and with the cascade decays of the squarks and gluinos calculated within the framework of the Minimal Supergravity scenario. The bounds are weakly sensitive to the values of the three fixed parameters for a large fraction of parameter space. See Fig. 2 for the limits corresponding to different parameter choices.
- parameter cnoices. 213 ABACHI 95c assume five degenerate squark flavors with with $m_{\widetilde{q}_L}=m_{\widetilde{q}_R}$. Sleptons are assumed to be heavier than squarks. The limits are derived for fixed $\tan\beta=2.0~\mu=-250~{\rm GeV}$, and $m_{H^\pm}=500~{\rm GeV}$, and with the cascade decays of the squarks and gluinos calculated within the framework of the Minimal Supergravity scenario. The bounds are
- weakly sensitive to the three fixed parameters for a large fraction of parameter space. ^214 ABE 95T looked for a cascade decay of gluino into \widetilde{x}_2^0 which further decays into \widetilde{x}_1^0 and a photon. No signal is observed. Limits vary widely depending on the choice of parameters. For $\mu=-40$ GeV, $\tan\beta=1.5$, and heavy squarks, the range $50 < m_{\widetilde{g}}$ (GeV)<140 is excluded at 90% CL. See the paper for details.
- 215 HEBBEKER 93 combined jet analyses at various e^+e^- colliders. The 4-jet analyses at TRISTAN/LEP and the measured α_S at PEP/PETRA/TRISTAN/LEP are used. A constraint on effective number of quarks N=6.3 \pm 1.1 is obtained, which is compared to that with a light gluino, N=8.
- 216 ABE 92L bounds are based on similar assumptions as ABACHI 95C. Not sensitive to $m_{\rm gluino}$ <40 GeV (but other experiments rule out that region).
- 217 ROY 92 reanalyzed CDF limits on di-lepton events to obtain limits on gluino production in R-parity violating models. The 100% decay $\widetilde{g} \to q \overline{q} \widetilde{\chi}$ where $\widetilde{\chi}$ is the LSP, and the LSP decays either into $\ell q \overline{d}$ or $\ell \ell \overline{e}$ is assumed.
- 218 HIDAKA 91 limit obtained from LEP and preliminary CDF results within minimal supersymmetry with gaugino-mass unification condition. HIDAKA 91 limit extracted from BAER 91 analysis.
- 219 NOJIRI 91 argues that a heavy gluino should be nearly degenerate with squarks in minimal supergravity not to overclose the universe.
- 220 ALITTI 90 searched for events having \geq 2 jets with E_T^1 > 25 GeV, E_T^2 > 15 GeV, $|\eta|~<~0.85$, and $\Delta\phi~<~160^{\circ}$, with a missing momentum >~40 GeV and no electrons. They assume $\widetilde{g} o q \overline{q} \widetilde{\gamma}$ decay and $m_{\widetilde{\gamma}} \lesssim$ 20 GeV. Masses below 50 GeV are not excluded by the analysis.
- 221 NAKAMURA 89 searched for a long-lived ($au \gtrsim 10^{-7}$ s) charge-(± 2) particle with mass 1.6 GeV in proton-Pt interactions at 12 GeV and found that the yield is less than 10^{-8} times that of the pion. This excludes R- Δ^{++} (a $\tilde{g}uuu$ state) lighter than 1.6
- GeV. 222 The limits of ALBAJAR 87D are from $\rho \overline{\rho} \to \widetilde{g} \widetilde{g} \times (\widetilde{g} \to q \overline{q} \widetilde{\gamma})$ and assume $m_{\widetilde{q}} >$ $m_{\widetilde{g}}$. These limits apply for $m_{\widetilde{\gamma}} \lesssim$ 20 GeV and $\tau(\widetilde{g}) < 10^{-10}$ s.
- 223 The limit of ANSARI 87D assumes $m_{\widetilde{q}} > m_{\widetilde{g}}$ and $m_{\widetilde{\gamma}} \approx 0$.

Supersymmetric Particle Searches

NOTE ON LIGHT GLUINO

Written March 1998 by H. Murayama (UC Berkeley).

It is controversial if a light gluino of mass below 5 GeV is phenomenologically allowed. Below we list some of the most important and least controversial constraints which need to be met for a light gluino to be viable. For reviews on the subject, see, e.g., Ref. 1.

- 1. Either $m_{\tilde{g}} \lesssim 1.5$ GeV or $m_{\tilde{g}} \gtrsim 3.5$ GeV to avoid the CAKIR 94 limit. See also Ref. 2 for similar quarkonium constraints on lighter masses.
- 2. The lifetime of the gluino or the ground state gluino-containing hadron (typically, $g\tilde{g}$) must be $\gtrsim 10^{-10}$ s in order to evade beam-dump and missing energy limits [1.2].
- Charged gluino-containing hadrons (e.g. ḡud̄) must decay into neutral ones (e.g. R⁰(ḡg)π⁺ or (ḡuū̄)e⁻v̄_e) with a lifetime shorter than about 10⁻⁷ s to avoid the AKERS 95R limit. Older limits for lower masses and shorter lifetimes are summarized in Ref. 1.
- 4. The lifetime of $R^0 \to \rho^0 \tilde{\gamma}$, if allowed, must be outside the ADAMS 97B range. The $R_p^+(\tilde{g}uud)$ state, which is believed to decay weakly into $S^0(\tilde{g}uds)\pi^\pm$ (FARRAR 96), must be heavier than 2 GeV or have lifetime $\tau_{R_p} \gtrsim 1$ ns or $\tau_{R_p} \lesssim 50$ ps (e.g. if the strong decay into S^0K^\pm is allowed), or its production cross sections must be at least a factor of 5 smaller than those of hyperons, to avoid ALBUQUERQUE 97
- 5. $m_{\tilde{g}} \geq 6.8$ GeV (95% CL) if the "experimental optimization" method of fixing the renormalization scale is valid and if the hadronization and resummation uncertainties are as estimated in BARATE 97L, from the D_2 event shape observable in Z^0 decay. The 4-jet angular distribution is less sensitive to renormalization scale ambiguities and yields a 90%CL exclusion of a light gluino (DEGOUVEA 97). A combined LEP analysis based on all the Z^0 data and using the recent NLO calculations [3] is warranted.
- 6. Constraints from the effect of light gluinos on the running of α_s apply independently of the gluino lifetime and are insensitive to renormalization scale. They disfavor a light gluino at 70% CL (CSIKOR 97), which improves to more than 99% with jet analysis.

224 ADAMS 978 looked for $\rho^0 \to \pi^+\pi^-$ as a signature of $R^0 = (\tilde{g}\,g)$ bound states. The experiment is sensitive to an R^0 mass range of 1.2–4.5 GeV and to a lifetime range of $10^{-10}-10^{-3}$ sec. Precise limits depend on the assumed value of $m_{R^0}/m_{\widetilde{\gamma}}$. See Fig. 7 for the excluded mass and lifetime region.

for the excluded mass and inetime region.

225 ALBUQUERQUE 97 looked for weakly decaying baryon-like states which contain a light giulno, following the suggestions in FARRAR 96. See their Table 1 for limits on the production fraction. These limits exclude gluino masses in the range 100–600 MeV for the predicted lifetimes (FARRAR 96) and production rates, which are assumed to be comparable to those of strange or charmed baryons.

226 BARATE 97L studied the QCD color factors from four-jet angular correlations and the differential two-jet rate in Z decay. Limit obtained from the determination of $n_f=4.24\pm0.29\pm1.15$, assuming $T_F/C_F=3/8$ and $C_A/C_F=9/4$.

227 CSIKOR 97 combined the α_s from $\sigma(e^+e^- \to \text{hadron})$, τ decay, and jet analysis in Z decay. They exclude a light gluino below 5 GeV at more than 99.7%CL.

228 DEGOUVEA 97 reaanalyzed AKERS 95A data on Z decay into four jets to place constraints on a light stable gluino. The mass limit corresponds to the pole mass of 2.8 GeV. The analysis, however, is limited to the leading-order QCD calculation.

- 229 FARRAR 96 studied the possible $R^0 = (\tilde{g}g)$ component in Fermilab E799 experiment and used its bound $B(K_L^0 \to \pi^0 \nu \bar{\nu}) \leq 5.8 \times 10^{-5}$ to place constraints on the combination of R^0 production cross section and its lifetime.
- 230 AKERS 95R looked for Z decay into $q \bar{q} \tilde{g} \tilde{g}$, by searching for charged particles with dE/dx consistent with \tilde{g} fragmentation into a state $(\tilde{g} q \bar{q})^{\pm}$ with lifetime $\tau > 10^{-7}$ sec. The fragmentation probability into a charged state is assumed to be 25%.
- fragmentation probability into a charged state is assumed to be 20%.

 231 CLAVELLI 95 updates the analysis of CLAVELLI 93, based on a comparison of the hadronic widths of charmonium and bottomonium 5-wave states. The analysis includes a parametrization of relativisitic corrections. Claims that the presence of a light gluino improves agreement with the data by slowing down the running of α₅.
- 232 CAKIR 94 reanalyzed TUTS 87 and later unpublished data from CUSB to exclude pseudo-scalar gluinonium $\eta_{\widetilde{g}}(\widetilde{g})$ of mass below 7 GeV. It was argued, however, that the perturbative QCD calculation of the branching fraction $\tau \to \eta_{\widetilde{g}} \gamma$ is unreliable for $m_{\eta_{\widetilde{g}}} < 3$ GeV. The gluino mass is defined by $m_{\widetilde{g}} = (m_{\eta_{\widetilde{q}}})/2$. The limit holds for any gluino lifetime.
- 233 LOPEZ 93C uses combined restraint from the radiative symmetry breaking scenario within the minimal supergravity model, and the LEP bounds on the (M_2,μ) plane. Claims that the light gluino window is strongly disfavored.
- 234 CLAVELLI 92 claims that a light gluino mass around 4 GeV should exist to explain the discrepancy between $\alpha_{\rm S}$ at LEP and at quarkonia (Υ), since a light gluino slows the running of the QCD coupling.
- 235 ANTONIADIS 91 argue that possible light gluinos (< 5 GeV) contradict the observed running of α_s between 5 GeV and m_Z . The significance is less than 2 s.d.
- 236 ANTONIADIS 91 intrepret the search for missing energy events in 450 GeV/c pN collisions, AKESSON 91, in terms of light gluinos.
- ²³⁷ The limits assume $m_{\widetilde{q}}=$ 100 GeV. See their figure 3 for limits vs. $m_{\widetilde{q}}.$
- 238 The gluino mass is defined by half the bound $\tilde{g}\tilde{g}$ mass. If zero gluino mass gives a $\tilde{g}\tilde{g}$ of mass about 1 GeV as suggested by various glueball mass estimates, then the low-mass bound can be replaced by zero. The high-mass bound is obtained by comparing the data with nonrelativistic potential-model estimates.
- 239 ALBRECHT 86c search for secondary decay vertices from $\chi_{b1}(1P) \rightarrow \tilde{g}\,\tilde{g}\,g$ where \tilde{g} 's make long-lived hadrons. See their figure 4 for excluded region in the $m_{\tilde{g}} m_{\tilde{g}}$ and $m_{\tilde{g}} m_{\tilde{g}}$ plane. The lower $m_{\tilde{g}}$ region below ~ 2 GeV may be sensitive to fragmentation effects. Remark that the \tilde{g} -hadron mass is expected to be ~ 1 GeV (glueball mass) in the zero \tilde{g} mass limit.
- 240 BADIER 86 looked for secondary decay vertices from long-lived \tilde{g} -hadrons produced at 300 GeV π^- beam dump. The quoted bound assumes \tilde{g} -hadron nucleon total cross section of 10 μ b. See their figure 7 for excluded region in the $m_{\widetilde{g}}-m_{\widetilde{q}}$ plane for several section of 10 μ b.
- assumed total cross-section values. 241 BARNETT 86 rule out light gluinos (m=3–5 GeV) by calculating the monojet rate from gluino gluino gluon events (and from gluino gluino events) and by using UA1 data from $p\bar{p}$ collisions at CERN.
- 242 VOLOSHIN 86 rules out stable gluino based on the cosmological argument that predicts too much hydrogen consisting of the charged stable hadron g̃ uud. Quasi-stable (τ > 1.×10⁻⁷s) light gluino of m_{g̃} <3 GeV is also ruled out by nonobservation of the stable charged particles, g̃ uud, in high energy hadron collisions.</p>
- charged particles, g uua, in right energy naturon compositions. 243 COOPER-SARKAR 85B is BEBC beam-dump. Glulnos decaying in dump would yield $\tilde{\gamma}$'s in the detector giving neutral-current-like interactions. For $m_{\widetilde{q}} > 330$ GeV, no limit is set.
- 244 DAWSON 85 first limit from neutral particle search. Second limit based on FNAL beam dump experiment.
- dump experiment. 245 FARRAR 85 points out that BALL 84 analysis applies only if the \tilde{g} 's decay before interacting, i.e. $m_{\tilde{q}} < 80 m_{\tilde{g}}^{-1.5}$. FARRAR 85 finds $m_{\tilde{g}} < 0.5$ not excluded for $m_{\tilde{q}} = 30$ –1000 GeV and $m_{\tilde{g}} < 1.0$ not excluded for $m_{\tilde{q}} = 100$ –500 GeV by BALL 84 experiment.
- ²⁴⁶ GOLDMAN 85 use nonobservation of a pseudoscalar \tilde{g} - \tilde{g} bound state in radiative ψ decay.
- 247 HABER 85 is based on survey of all previous searches sensitive to low mass \(\tilde{g}' \)'s. Limit makes assumptions regarding the lifetime and electric charge of the lightest supersymmetric particle.
- 248 BALL 84 is FNAL beam dump experiment. Observed no interactions of $\widetilde{\gamma}$ in the calorimeter, where $\widetilde{\gamma}$'s are expected to come from pair-produced \widetilde{g} 's. Search for long-lived $\widetilde{\gamma}$ interacting in calorimeter 56m from target. Limit is for $m_{\widetilde{q}}=$ 40 GeV and production cross section proportional to A $^{0.72}$. BALL 84 find no \widetilde{g} allowed below 4.1 GeV at CL = 90%. Their figure 1 shows dependence on $m_{\widetilde{q}}$ and A. See also KANE 82.
- ²⁴⁹ BRICK 84 reanalyzed FNAL 147 GeV HBC data for R- Δ (1232)⁺⁺ with $\tau > 10^{-9}$ s and $\rho_{\rm lab} > 2$ GeV. Set CL = 90% upper limits 6.1, 4.4, and 29 microbarns in ρp , $\pi^+ p$, $K^+ p$ collisions respectively. R- Δ^{++} is defined as being \tilde{g} and 3 up quarks. If mass =
- 1.2–1.5 GeV, then limits may be lower than theory predictions.
 250 FARRAR 84 argues that $m_{\widetilde{g}} < 100$ MeV is not ruled out if the lightest R-hadrons are long-lived. A long lifetime would occur if R-hadrons are lighter than $\widetilde{\gamma}$'s or if $m_{\widetilde{q}} > 100$
- GeV. 251 BERGSMA 83C is reanalysis of CERN-SPS beam-dump data. See their figure 1.
- ²⁵² CHANOWITZ 83 find in bag-model that charged s-hadron exists which is stable against strong decay if $m_{\widetilde{g}} < 1$ GeV. This is important since tracks from decay of neutral s-hadron cannot be reconstructed to primary vertex because of missed $\widetilde{\gamma}$. Charged s-hadron leaves track from vertex.
- leaves track from vertex.

 253 KANE 82 Inferred above \tilde{g} mass limit from retroactive analysis of hadronic collision and beam dump experiments. Limits valid if \tilde{g} decays inside detector.

Supersymmetry Miscellaneous Results

Results that do not appear under other headings or that make nonminimal assumptions.

VALUE	DOCUMENT ID		<u>TECN</u>	COMMENT
• • • We do not use the	following data for average	es, fits	i, limits,	, etc. • • •
	254 ABACHI	97	D0	77X
	²⁵⁵ BARBER	84B	RVUE	
	256 HOFFMAN	83	CNTR	$\pi p \rightarrow n(e^+e^-)$

- 254 ABACHI 97 searched for pp̄ → γγ ₽_T+X as supersymmetry signature. It can be caused by selectron, sneutrino, or neutralino production with a radiative decay of their decay products. They placed limits on cross sections.
- 255 BARBER 84B consider that $\tilde{\mu}$ and \tilde{e} may mix leading to $\mu \to e \tilde{\gamma} \tilde{\gamma}$. They discuss mass-mixing limits from decay dist asym in LBL-TRIUMF data and e^+ polarization in SIN data.
- 256 HOFFMAN 83 set CL = 90% limit $d\sigma/dt$ B(e⁺e⁻) < 3.5 × 10⁻³² cm²/GeV² for spin-1 partner of Goldstone fermions with 140 < m <160 MeV decaying $\rightarrow e^+e^-$ pair.

Quark and Lepton Compositeness, Searches for

SEARCHES FOR QUARK AND LEPTON COMPOSITENESS

Written 1994 by K. Hagiwara (KEK) and K. Hikasa (Tohoku Univ.).

If quarks and leptons are made of constituents, then at the scale of constituent binding energies, there should appear new interactions among quarks and leptons. At energies much below the compositeness scale (Λ) , these interactions are suppressed by inverse powers of Λ . The dominant effect should come from

the lowest dimensional interactions with four fermions (contact terms), whose most general chirally invariant form reads [1]

$$L = \frac{g^2}{2\Lambda^2} \left[\eta_{LL} \overline{\psi}_L \gamma_\mu \psi_L \overline{\psi}_L \gamma^\mu \psi_L + \eta_{RR} \overline{\psi}_R \gamma_\mu \psi_R \overline{\psi}_R \gamma^\mu \psi_R + 2\eta_{LR} \overline{\psi}_L \gamma_\mu \psi_L \overline{\psi}_R \gamma^\mu \psi_R \right] . \tag{1}$$

Chiral invariance provides a natural explanation why quark and lepton masses are much smaller than their inverse size Λ . We may determine the scale Λ unambiguously by using the above form of the effective interactions; the conventional method [1] is to fix its scale by setting $g^2/4\pi = g^2(\Lambda)/4\pi = 1$ for the new strong interaction coupling and by setting the largest magnitude of the coefficients $\eta_{\alpha\beta}$ to be unity. In the following, we denote

$$\begin{split} & \Lambda = \Lambda_{LL}^{\pm} \ \, \text{for} \ \, (\eta_{LL},\, \eta_{RR},\, \eta_{LR}) = (\pm 1,\, 0,\, 0) \;, \\ & \Lambda = \Lambda_{RR}^{\pm} \ \, \text{for} \ \, (\eta_{LL},\, \eta_{RR},\, \eta_{LR}) = (0,\, \pm 1,\, 0) \;, \\ & \Lambda = \Lambda_{VV}^{\pm} \ \, \text{for} \ \, (\eta_{LL},\, \eta_{RR},\, \eta_{LR}) = (\pm 1,\, \pm 1,\, \pm 1) \;, \\ & \Lambda = \Lambda_{AA}^{\pm} \ \, \text{for} \ \, (\eta_{LL},\, \eta_{RR},\, \eta_{LR}) = (\pm 1,\, \pm 1,\, \mp 1) \;, \end{split} \label{eq:lambda}$$

as typical examples. Such interactions can arise by constituent interchange (when the fermions have common constituents, e.g., for $ee \rightarrow ee$) and/or by exchange of the binding quanta (whenever binding quanta couple to constituents of both particles).

Another typical consequence of compositeness is the appearance of excited leptons and quarks (ℓ^* and q^*). Phenomenologically, an excited lepton is defined to be a heavy lepton which shares leptonic quantum number with one of the existing leptons (an excited quark is defined similarly). For example, an excited electron e^* is characterized by a nonzero transition-magnetic coupling with electrons. Smallness of the lepton mass and the success of QED prediction for g-2 suggest chirality conservation, *i.e.*, an excited lepton should not couple to both left- and right-handed components of the corresponding lepton.

Excited leptons may be classified by $SU(2)\times U(1)$ quantum numbers. Typical examples are:

1. Sequential type

$$\left(egin{array}{c}
u^* \\ \ell^* \end{array}
ight)_L \,, \qquad \left[
u^*_R
ight] \,, \qquad \ell^*_R \,.$$

 ν_R^* is necessary unless ν^* has a Majorana mass.

2. Mirror type

$$\left[
u_L^*
ight], \qquad \ell_L^*, \qquad \left(egin{array}{c}
u^* \ \ell^* \end{array}
ight)_R \,.$$

3. Homodoublet type

$$\begin{pmatrix} \nu^* \\ \ell^* \end{pmatrix}_L \,, \qquad \begin{pmatrix} \nu^* \\ \ell^* \end{pmatrix}_R \,.$$

Similar classification can be made for excited quarks.

Excited fermions can be pair produced via their gauge couplings. The couplings of excited leptons with Z are listed

	Sequential type	Mirror type	Homodoublet type
$V^{\ell^*} A^{\ell^*}$	$-\frac{1}{2}+2\sin^2\theta_W$	$-\frac{1}{2} + 2\sin^2\theta_W$	$-1+2\sin^2\!\theta_W$
A^{ℓ^*}	$-\frac{1}{2}$	$+\frac{1}{2}$	0
$V^{ u_D^*}$	$+\frac{\overline{1}}{2}$	$+\frac{1}{2}$	+1
$A^{ u_D^*}$	$+\frac{1}{2}$	$-\frac{1}{2}$	0
$V^{ u_M^*}$	0	0	
$A^{ u_M^*}$	+1	-1	

in the following table (for notation see Eq. (1) in "Standard Model of Electroweak Interactions"):

Here ν_D^* (ν_M^*) stands for Dirac (Majorana) excited neutrino. The corresponding couplings of excited quarks can be easily obtained. Although form factor effects can be present for the gauge couplings at $q^2 \neq 0$, they are usually neglected.

In addition, transition magnetic type couplings with a gauge boson are expected. These couplings can be generally parametrized as follows:

$$\mathcal{L} = \frac{\lambda_{\gamma}^{(f^{*})} e}{2m_{f^{*}}} \overline{f}^{*} \sigma^{\mu\nu} (\eta_{L} \frac{1-\gamma_{5}}{2} + \eta_{R} \frac{1+\gamma_{5}}{2}) f F_{\mu\nu}
+ \frac{\lambda_{Z}^{(f^{*})} e}{2m_{f^{*}}} \overline{f}^{*} \sigma^{\mu\nu} (\eta_{L} \frac{1-\gamma_{5}}{2} + \eta_{R} \frac{1+\gamma_{5}}{2}) f Z_{\mu\nu}
+ \frac{\lambda_{W}^{(\ell^{*})} g}{2m_{\ell^{*}}} \overline{\ell}^{*} \sigma^{\mu\nu} \frac{1-\gamma_{5}}{2} \nu W_{\mu\nu}
+ \frac{\lambda_{W}^{(\nu^{*})} g}{2m_{\nu^{*}}} \overline{\nu}^{*} \sigma^{\mu\nu} (\eta_{L} \frac{1-\gamma_{5}}{2} + \eta_{R} \frac{1+\gamma_{5}}{2}) \ell W_{\mu\nu}^{\dagger}
+ \text{h.c.},$$
(3)

where $g=e/\sin\theta_W$, $F_{\mu\nu}=\partial_\mu A_\nu-\partial_\nu A_\mu$ is the photon field strength, $Z_{\mu\nu}=\partial_\mu Z_\nu-\partial_\nu Z_\mu$, etc. The normalization of the coupling is chosen such that

$$\max(|\eta_L|, |\eta_R|) = 1.$$

Chirality conservation requires

$$\eta_L \eta_R = 0 \ . \tag{4}$$

These couplings can arise from $SU(2)\times U(1)$ -invariant higher-dimensional interactions. A well-studied model is the interaction of homodoublet type ℓ^* with the Lagrangian [2,3]

$$\mathcal{L} = \frac{1}{2\Lambda} \overline{L}^* (g f \frac{\tau^a}{2} W_{\mu\nu}^a + g' f' Y B_{\mu\nu}) \frac{1 - \gamma_5}{2} L + \text{h.c.} , \qquad (5)$$

where L denotes the lepton doublet (ν, ℓ) , Λ is the compositeness scale, g, g' are SU(2) and U(1) $_Y$ gauge couplings, and $W^a_{\mu\nu}$ and $B_{\mu\nu}$ are the field strengths for SU(2) and U(1) $_Y$ gauge fields. The same interaction occurs for mirror-type excited leptons. For sequential-type excited leptons, the ℓ^* and ν^* couplings become unrelated, and the couplings receive the extra

suppression of $(250\,{\rm GeV})/\Lambda$ or m_{L^*}/Λ . In any case, these couplings satisfy the relation

$$\lambda_W = -\sqrt{2}\sin^2\theta_W(\lambda_Z \cot\theta_W + \lambda_\gamma) \ . \tag{6}$$

Additional coupling with gluons is possible for excited quarks:

$$\mathcal{L} = \frac{1}{2\Lambda} \overline{Q}^* \sigma^{\mu\nu} \left(g_s f_s \frac{\lambda^a}{2} G^a_{\mu\nu} + g f \frac{\tau^a}{2} W^a_{\mu\nu} + g' f' Y B_{\mu\nu} \right)$$

$$\times \frac{1 - \gamma_5}{2} Q + \text{h.c.} , \qquad (7)$$

where Q denotes a quark doublet, g_s is the QCD gauge coupling, and $G^a_{\mu\nu}$ the gluon field strength.

Some experimental analyses assume the relation $\eta_L = \eta_R = 1$, which violates chiral symmetry. We encode the results of such analyses if the crucial part of the cross section is proportional to the factor $\eta_L^2 + \eta_R^2$ and the limits can be reinterpreted as those for chirality conserving cases $(\eta_L, \eta_R) = (1,0)$ or (0,1) after rescaling λ .

Several different conventions are used by LEP experiments to express the transition magnetic couplings. To facilitate comparison, we reexpress these in terms of λ_Z and λ_γ using the following relations and taking $\sin^2 \theta_W = 0.23$. We assume chiral couplings, i.e., |c| = |d| in the notation of Ref. 2.

1. ALEPH (charged lepton and neutrino)

$$\lambda_Z^{\text{ALEPH}} = \frac{1}{2} \lambda_Z$$
 (1990 papers) (8a)

$$\frac{2c}{\Lambda} = \frac{\lambda_Z}{m_{\ell^*}[\text{or } m_{\nu^*}]} \quad \text{(for } |c| = |d|)$$
 (8b)

2. ALEPH (quark)

$$\lambda_u^{\text{ALEPH}} = \frac{\sin \theta_W \cos \theta_W}{\sqrt{\frac{1}{4} - \frac{2}{3} \sin^2 \theta_W + \frac{8}{9} \sin^4 \theta_W}} \lambda_Z = 1.11 \lambda_Z \quad (9)$$

3. L3 and DELPHI (charged lepton)

$$\lambda^{\text{L3}} = \lambda_Z^{\text{DELPHI}} = -\frac{\sqrt{2}}{\cot \theta_W - \tan \theta_W} \lambda_Z = -1.10\lambda_Z \quad (10)$$

4. L3 (neutrino)

$$f_Z^{L3} = \sqrt{2}\lambda_Z \tag{11}$$

5. OPAL (charged lepton)

$$\frac{f^{\text{OPAL}}}{\Lambda} = -\frac{2}{\cot \theta_W - \tan \theta_W} \frac{\lambda_Z}{m_{\ell^*}} = -1.56 \frac{\lambda_Z}{m_{\ell^*}}$$
(12)

6. OPAL (quark)

$$\frac{f^{\text{OPAL}}c}{\Lambda} = \frac{\lambda_Z}{2m_{\sigma^*}} \quad (\text{for } |c| = |d|)$$
 (13)

7. DELPHI (charged lepton)

$$\lambda_{\gamma}^{\rm DELPHI} = -\frac{1}{\sqrt{2}} \, \lambda_{\gamma} \tag{14}$$

If leptons are made of color triplet and antitriplet constituents, we may expect their color-octet partners. Transitions

Quark and Lepton Compositeness

between the octet leptons (ℓ_8) and the ordinary lepton (ℓ) may take place via the dimension-five interactions

$$\mathcal{L} = \frac{1}{2\Lambda} \sum_{\ell} \left\{ \overline{\ell}_{8}^{\alpha} g_{S} F_{\mu\nu}^{\alpha} \sigma^{\mu\nu} \left(\eta_{L} \ell_{L} + \eta_{R} \ell_{R} \right) + h.c. \right\}$$
 (15)

where the summation is over charged leptons and neutrinos. The leptonic chiral invariance implies $\eta_L \ \eta_R = 0$ as before.

>0.275	95	⁵¹ BAGNAIA	84C UA2	Repl. by APPEL 85	

⁴¹ ABE 96 finds that the inclusive jet cross section for E_T >200 GeV is significantly higher than the $\mathcal{O}(\alpha_s^3)$ perturbative QCD prediction. This could be interpreted as the effect of a contact interaction with $\Lambda_{LL} \sim$ 1.6 TeV. However, ABE 96 state that uncertainty in the parton distribution functions, higher-order QCD corrections, and the detector calibration may possibly account for the effect.
42 ABE 96s limit is from dijet angular distribution in $p\bar{p}$ collisions at $E_{\rm Cm}=1.8$ TeV. The

limit for Λ_{II}^- is $> 1.4\,\text{TeV}$. ABE 965 also obtain limits for flavor symmetric contact

interactions among all quark flavors: $\Lambda_{LL}^+~>1.8$ TeV and $\Lambda_{LL}^-~>1.6$ TeV.

 43 ABE 93G limit is from dijet mass distribution in $p\overline{p}$ collisions at $E_{\rm Cm}=1.8$ TeV. The limit is the weakest from several choices of structure functions and renormalization scale. 44 Limit is from inclusive jet cross-section data in $p\overline{p}$ collisions at $E_{\rm Cm}=1.8$ TeV. The limit takes into account uncertainties in choice of structure functions and in choice of

45 ABE 92M limit is from dijet angular distribution for $m_{\text{dijet}} > 550 \text{ GeV}$ in $p\overline{p}$ collisions at E_{cm}=1.8 TeV.

46 ALITTI 91B limit is from inclusive jet cross section in $p\overline{p}$ collisions at $E_{\rm CM}=630$ GeV. The limit takes into account uncertainties in choice of structure functions and in choice

of process scale.

47 ABE 89H limit is from dijet angular distribution for $m_{\rm dijet} > 200$ GeV at the Fermilab Tevatron Collider with $E_{\rm CM} = 1.8$ TeV. The QCD prediction is quite insensitive to choice of structure functions and choice of process scale.

48 ARNISON 86C limit is from the study of inclusive high- p_T jet distributions at the CERN \bar{p} p collider ($E_{\rm CM} = 546$ and 630 GeV). The QCD prediction-renormalized to the low- p_T region gives a good fit to the data.

49 ARNISON 860 limit is from the study of dijet angular distribution in the range 240 < m(dijet) < 300 GeV at the CERN \bar{p} p collider ($E_{\rm CM} = 630$ GeV). QCD prediction using

EHLQ structure function (EICHTEN.84) with $\Lambda_{QCD}=0.2$ GeV for the choice of $Q^2=$ p_T^2 gives the best fit to the data.

⁵⁰ APPEL 85 limit is from the study of inclusive high- p_T let distributions at the CERN p_T collider ($E_{Cm} = 630$ GeV). The QCD prediction renormalized to the low- p_T region gives a good description of the data.

gives a good description of the data. 5 BAGNAIA 84C limit is from the study of jet p_T and dijet mass distributions at the CERN $\bar{p}p$ collider ($E_{\rm CM}=540$ GeV). The limit suffers from the uncertainties in comparing the data with the QCD prediction.

MASS LIMITS for Excited e (e*)

Most e^+e^- experiments assume one-photon or Z exchange. The limits from some e^+e^- experiments which depend on λ have assumed transition couplings which are chirality violating $(\eta_L=\eta_R)$. However they can be interpreted as limits for chirality-conserving interactions after multiplying the coupling value λ by $\sqrt{2}$; see Note.

Excited leptons have the same quantum numbers as other ortholeptons. See also the searches for ortholeptons in the "Searches for Heavy Leptons"

Limits for Excited e (e*) from Pair Production

These limits are obtained from $e^+e^- \rightarrow e^{*+}e^{*-}$ and thus rely only on the (electroweak) charge of e*. Form factor effects are ignored unless noted. For the case of limits from Z decay, the e^* coupling is assumed to be of sequential type. Possible t channel contribution from transition magnetic coupling is neglected. All limits assume $e^* \rightarrow e\gamma$ decay except the limits from $\Gamma(Z)$.

For limits prior to 1987, see our 1992 edition (Physical Review D45, 1 June, Part II

52 From e^+e^- collisions at \sqrt{s} =170–172 GeV. ACKERSTAFF 98c also obtain limit from $e^* \rightarrow \nu W$ decay mode: $m_{e^*} >$ 81.3 GeV.

⁵³ From e^+e^- collisions at $\sqrt{s}=$ 161 GeV.

⁵⁴ ABREU 97B also obtain limit from charged current decay mode $e^* \rightarrow \nu W$, $m_{e^*} > 70.9$

GeV. SS ABREU 978 also obtain limit from charged current decay mode $e^* \to \nu W$, $m_{e^*} >$ 44.6

56 GeV. SACKERSTAFF 97 also obtain limit from charged current decay mode $e^{\bf k} \to \nu W, \, m_{\nu_e^{\bf k}}$ >

77.1 GeV. 57 From e^+e^- collisions at $\sqrt{s}=$ 130–136 GeV.

⁵⁸ From e^+e^- collisions at \sqrt{s} = 130–140 GeV.

⁵⁹BARDADIN-OTWINOWSKA 92 limit is independent of decay modes. Based on $\Delta\Gamma(Z)$ <36 MeV.

 60 Limit is independent of e^* decay mode.

61 ADEVA 90F is superseded by ADRIANI 93M.

62 Superseded by DECAMP 92.

63 ABE 888 limits assume $e^+e^- \rightarrow e^{*+}e^{*-}$ with one photon exchange only and $e^* \rightarrow$ eγ giving eeγγ.

Limits for Excited $e(e^*)$ from Single Production

These limits are from $e^+e^- \to e^*e$, $W \to e^*\nu$, or $ep \to e^*X$ and depend on transition magnetic coupling between e and e^* . All limits assume $e^* \to e\gamma$ decay except as noted. Limits from LEP, UA2, and H1 are for chiral coupling, whereas all other limits are for nonchiral coupling, $\eta_L=\eta_R=1$. In most papers, the limit is expressed in the form of an excluded region in the $\lambda-m_{e^*}$ plane. See the original

- ⁶⁴ BREITWEG 97C search for single e^* production in ep collisions with the decays $e^* o$ $e\gamma$, eZ, νW . $f=-f'=2\Lambda/m_{e^*}$ is assumed for the e^* coupling. See their Fig. 9 for the exclusion plot in the mass-coupling plane.
- 65 ACKERSTAFF 98C from e^+e^- collisions at \sqrt{s} =170–172 GeV. See their Fig. 11 for the exclusion limit in the mass-coupling plane.
- 66 From e^+e^- collisions at $\sqrt{s}=$ 161 GeV.
- 67 See Fig. 4a and Fig. 5a of ABREU 97B for the exclusion limit in the mass-coupling plane. 68 See Fig. 2 and Fig. 3 of ACCIARRI 97G for the exclusion limit in the mass-coupling plane.
- ⁶⁹ ACKERSTAFF 97 result is from e^+e^- collisions at \sqrt{s} = 161 GeV. See their Fig. 3 for the exclusion limit in the mass-coupling plane.
- To ADLOFF 97 search for single e^* production in ep collisions with the decays $e^* \rightarrow e\gamma$, eZ, νW . See their Fig. 4 for the rejection limits on the product of the production cross section and the branching ratio into a specific decay channel.
- 71 ABREU 96K result is from e $^+$ e $^-$ collisions at \sqrt{s} = 130–136 GeV. See their Fig. 4 for the exclusion limit in the mass-coupling plane.
- 72 ACCIARRI 96D result is from e^+e^- collisions at \sqrt{s} = 130–140 GeV. See their Fig. 2 for
- the exclusion limit in the mass-coupling plane. 73 ALEXANDER 96Q result is from e^+e^- collisions at $\sqrt{s}=$ 130–140 GeV. See their Fig. 3a
- for the exclusion limit in the mass-coupling plane. 74 BUSKULIC 96w result is from e^+e^- collisions at $\sqrt{s}=$ 130–140 GeV. See their Fig. 3 for the exclusion limit in the mass-coupling plane.
- 75 DERRICK 958 search for single e* production via e* e γ coupling in e ρ collisions with the decays $e^* \rightarrow e\gamma$, eZ, νW . See their Fig. 13 for the exclusion plot in the $m_{e^*} - \lambda \gamma$
- plane. 76 ABT 93 search for single e^* production via $e^*e\gamma$ coupling in ep collisions with the m - λ , plane. decays $e^* \to e \gamma$, e Z, νW . See their Fig. 4 for exclusion plot in the $m_{e^*} - \lambda_{\gamma}$ plane.
- 77 DERRICK 93B search for single e^* production via e^*e_γ coupling in e_P collisions with the decays $e^* \to e\gamma$, eZ, νW . See their Fig. 3 for exclusion plot in the $m_{\rho *} - \lambda_{\gamma}$ plane.
- ⁷⁸ Superseded by ADRIANI 93M.
- ⁷⁹ Superseded by DECAMP 92.
- 80 ABE 888 limits use $e^+e^-\to ee^*$ where t-channel photon exchange dominates giving $e\gamma(e)$ (quasi-real compton scattering).
- 81 ANSARI 87D is at $E_{\rm cm}=546-630$ GeV.

Limits for Excited e (e^*) from $e^+e^- \rightarrow \gamma\gamma$

These limits are derived from indirect effects due to e^* exchange in the t channel and depend on transition magnetic coupling between e and e^* . All limits are for $\lambda_{\gamma}=1$. All limits except ABE 89J are for nonchiral coupling with $\eta_L=\eta_R=1$.

For limits prior to 1987, see our 1992 edition (Physical Review D45, 1 June, Part II (1992)).

- 82 BUSKULIC 93Q obtain Λ^+ >121 GeV (95%CL) from ALEPH experiment and Λ^+ >135 GeV from combined TRISTAN and ALEPH data. These limits roughly correspond to limits on m_{e^*} .
- 83 ADRIANI 92B superseded by ACCIARRI 95G.
- 84 BARDADIN-OTWINOWSKA 92 limit from fit to the combined data of DECAMP 92, ABREU 91E, ADEVA 90K, AKRAWY 91F.
- ASKEU 91E, ADEVA 90E, ANKAWY 91F. 85 SHIMOZAWA 92 fit the data to the limiting form of the cross section with $m_{e^*}\gg E_{CM}$ and obtain $m_{e^*}>168$ GeV at 95%CL. Use of the full form would reduce this limit by a few GeV. The statistically unexpected large value is due to fluctuation in the data.
- ⁸⁶ The ABE 891 limit assumes chiral coupling. This corresponds to $\lambda_{\gamma}=$ 0.7 for nonchiral counting.

Indirect Limits for Excited e (e*)

These limits make use of loop effects involving e^* and are therefore subject to theoretical uncertainty.

VALUE (GeV)	DOCUMENT ID		TECN	COMMENT
• • • We do not use the	e following data for average	s, fit	s, Ilmits,	etc. • • •
	87 DORENBOS	89	CHRM	$egin{array}{l} \overline{ u}_{\mu} e ightarrow \overline{ u}_{\mu} e ightarrow u_{\mu} e \end{array}$
	⁸⁸ GRIFOLS			$\nu_{\mu}e \rightarrow \nu_{\mu}e$
	⁸⁹ RENARD	82	THEO	g-2 of electron

- 87 DORENBOSCH 89 obtain the limit $\lambda_{\gamma}^2 \Lambda_{\text{Cut}}^2 / m_{e^*}^2 < 2.6$ (95% CL), where Λ_{Cut} is the cutoff scale, based on the one-loop calculation by GRIFOLS 86. If one assumes that $\Lambda_{\text{cut}} = 1$ TeV and $\lambda_{\gamma} = 1$, one obtains $m_{e^*} > 620$ GeV. However, one generally expects $\lambda_{\gamma} \approx m_{e^*} / \Lambda_{\text{cut}}$ in composite models.
- 88 GRIFOLS 86 uses $\nu_{\mu}e \rightarrow \nu_{\mu}e$ and $\overline{\nu}_{\mu}e \rightarrow \overline{\nu}_{\mu}e$ data from CHARM Collaboration to derive mass limits which depend on the scale of compositeness.
- 89 RENARD 82 derived from g-2 data limits on mass and couplings of e^* and μ^* . See figures 2 and 3 of the paper.

MASS LIMITS for Excited μ (μ *)

Limits for Excited μ (μ *) from Pair Production

These limits are obtained from $e^+\,e^-\,
ightarrow\,\mu^{*+}\,\mu^{*-}$ and thus rely only on the (electroweak) charge of μ^* . Form factor effects are ignored unless noted. For the case of limits from Z decay, the μ^* coupling is assumed to be of sequential type. All limits assume $\mu^* \to \mu \gamma$ decay except for the limits from $\Gamma(Z)$.

For limits prior to 1987, see our 1992 edition (Physical Review D45, 1 June, Part II (1992)). (GeV) CL%

- 136 BEHREND 86 limit is at $E_{\rm cm}=$ 33–46.8 GeV.

MASS LIMITS for Excited Neutrino (ν^*)

Limits for Excited ν (ν^{+}) from Pair Production

These limits are obtained from $e^+e^- \rightarrow \nu^*\nu^*$ and thus rely only on the (electroweak) charge of ν^* . Form factor effects are ignored unless noted. The ν^* coupling is assumed to be of sequential type unless otherwise noted. Limits assume $\nu^* \to \nu \gamma$ decay except for the $\Gamma(Z)$ measurement which makes no assumption about decay mode.

none 5-23.2	95	197 BARTEL	87B	JADE	$\mu_8: e^+e^- \rightarrow \mu\mu +$ lets
		198 BARTEL	85K	JADE	e ₈ : e ⁺ e ⁻ → gg; R

- 193 ABE 89D look for pair production of unit-charged particles which leave the detector before decaying. In the above limit the color octet lepton is assumed to fragment into a unit-charged or neutral hadron with equal probability and to have long enough lifetime not to decay within the detector. The limit improves to 99 GeV if it always fragments into a unit-charged hadron.
- 194 ABT 93 search for e_8 production via e-gluon fusion in e_p collisions with $e_8 \rightarrow e_g$. See their Fig. 3 for exclusion plot in the m_{e_8} - Λ plane for $m_{e_8} = 35$ -220 GeV.
- 195 KIM 90 is at $E_{\rm cm} =$ 50–60.8 GeV. The same assumptions as in BARTEL 878 are used.
- 196 KIM 90 result (m_{eg} Λ_M)^{1/2} > 178.4 GeV (95%CL, α_S = 0.16 used) is subject to the same restriction as for BARTEL 85K.
 197 BARTEL 878 is at E_{CM} = 46.3-46.78 GeV. The limits assume ℓ₈ pair production cross sections to be eight times larger than those of the corresponding heavy lepton pair
- production. 198 in BARTEL 85K, R can be affected by $e^+e^- o gg$ via e_q exchange. Their limit $m_{\rm e_8}$ >173 GeV (CL=95%) at $\lambda=m_{\rm e_8}/\Lambda_{\rm M}=1$ ($\eta_L=\eta_R=1$) is not listed above because the cross section is sensitive to the product $\eta_L\eta_R$, which should be absent in

ordinary theory with electronic chiral invariance.

MASS LIMITS for Color Octet Neutrinos (va)

$\lambda \equiv m_{\ell_0}/\Lambda$		•				
VALUE (GeV)	CL%	DOCUMENT ID		TECN	COMMENT	
>110	90	199 BARGER	89	RVUE	$\nu_8: \rho \overline{\rho} \rightarrow$	ν ₈ ν 8
• • • We do not use t	he follo	wing data for average				
none 3.8-29.8	95	200 KIM	90	AMY	ν ₈ : e ⁺ e ⁻	→ acoplanar
none 9–21.9	95	²⁰¹ BARTEL	878	JADE	ν ₈ : e ⁺ e ⁻	→ acoplanar

- 199 BARGER 89 used ABE 898 limit for events with large missing transverse momentum. Two-body decay $\nu_8 \rightarrow \nu_g$ is assumed.
- $200\,\rm KIM$ 90 is at $E_{\rm cm}=50\text{--}60.8$ GeV. The same assumptions as in BARTEL 878 are used. 201 BARTEL 87B is at $E_{\rm cm}=$ 46.3–46.78 GeV. The limit assumes the $\nu_{\rm 8}$ pair production cross section to be eight times larger than that of the corresponding heavy neutrino pair production. This assumption is not valid in general for the weak couplings, and the limit can be sensitive to its ${\rm SU}(2)_L \times {\rm U}(1)_Y$ quantum numbers.

MASS LIMITS for Wa (Color Octet W Boson)

VALUE (GeV)	DOCUMENT ID		COMMENT
• • • We do not use the	following data for averages,	fits, limits	, etc. • • •
	²⁰² ALBAJAR 8	9 UA1	$p\overline{p} \rightarrow W_8 X, W_8 \rightarrow W_g$
202 ALBAJAR 89 give σ($W_0 \rightarrow W + \text{jet})/\sigma(W) < 0$.019 (90%	CL) for $m_{M/L} > 220$ GeV.

Limits on $ZZ\gamma$ Coupling

Limits are for the electric dipole transition form factor for $Z\to \gamma Z^*$ parametrized as $f(s')=\beta(s'/m_Z^2-1)$, where s' is the virtual Z mass. In the Standard Model

WIMPs and Other Particle Searches

OMITTED FROM SUMMARY TABLE WIMPS AND OTHER PARTICLE SEARCHES

Revised October 1997 by K. Hikasa (Tohoku University).

We collect here those searches which do not appear in any of the above search categories. These are listed in the following order:

- 1. Galactic WIMP (weakly-interacting massive particle) searches
- 2. Concentration of stable particles in matter
- 3. Limits on neutral particle production at accelerators
- 4. Limits on jet-jet resonance in hadron collisions
- 5. Limits on charged particles in e^+e^- collisions
- 6. Limits on charged particles in hadron reactions
- 7. Limits on charged particles in cosmic rays

Note that searches appear in separate sections elsewhere for Higgs bosons (and technipions), other heavy bosons (including W_R, W', Z' , leptoquarks, axigluons), axions (including pseudo-Goldstone bosons, Majorons, familons), heavy leptons, heavy neutrinos, free quarks, monopoles, supersymmetric particles, and compositeness. We include specific WIMP searches in the appropriate sections when they yield limits on hypothetical particles such as supersymmetric particles, axions, massive neutrinos, monopoles, etc.

We omit papers on CHAMP's, millicharged particles, and other exotic particles. We no longer list for limits on tachyons and centauros. See our 1994 edition for these limits.

GALACTIC WIMP SEARCHES Cross-Section Limits for Dark Matter Particles (X^0) on Nuclei

These limits are for weakly-interacting stable particles that may constitute the invisible mass in the galaxy. Unless otherwise noted, a local mass density of 0.3 GeV/cm³ is assumed; see each paper for velocity distribution assumptions. In the papers the limit is given as a function of the X^0 mass. Here we list limits only for typical mass values of 20 GeV, 100 GeV, and 1 TeV. Specific limits on supersymmetric dark matter particles may be found in the Supersymmetry section.

For $m_{\chi 0} = 20 \text{ GeV}$

 1 BERNABEI 97 give $\sigma < 12$ pb (90%CL) for the spin-dependent X^0 -proton cross section. 2 BELLI 96 limit for inelastic scattering X^0 $^{129}{\rm Xe} \rightarrow~X^0$ $^{129}{\rm Xe}^*(39.58$ keV).

 3 BELLI 96C use background subtraction and obtain $\sigma <$ 150 pb (< 1.5 fb) (?%CL) for spin-dependent (Independent) X⁰-proton cross section.

⁴ BERNABEI 96 use pulse shape discrimination to enhance the possible signal. The limit here is from R. Bernabel, private communication, September 19, 1997.

5 SARSA 96 search for annual modulation of WIMP signal. See SARSA 97 for details of the analysis. The limit here is from M.L. Sarsa, private communication, May 26, 1997. 6 SMITH 96 use pulse shape discrimination to enhance the possible signal. A dark matter density of 0.4 GeV cm $^{-3}$ is assumed.

7 GARCIA 95 limit is from the event rate. A weaker limit is obtained from searches for

diurnal and annual modulation.

8 SNOWDEN-IFFT 95 look for recoil tracks in an ancient mica crystal. Similar limits are also given for ²⁷Al and ²⁸Si. See COLLAR 96 and SNOWDEN-IFFT 96 for discussion on potential backgrounds.

⁹ REUSSER 91 limit here is changed from published (0.04) after reanalysis by authors. L. Vullieumier, private communication, March 29, 1996.

For $m_{\chi^0} = 100 \text{ GeV}$

LIMITS ON NEUTRAL PARTICLE PRODUCTION

Production Cross Section of Radiatively-Decaying Neutral Particle

VALUE (pb)	CL%	DOCUMENT ID TECN COMMENT
• • • We do not	use the followir	ng data for averages, fits, limits, etc. • • •
<(2.5-0.5)	95	³⁶ ACKERSTAFF 97B OPAL $e^+e^- \rightarrow X^0 Y^0$, $X^0 \rightarrow Y^0 \gamma$
<(1.6-0.9)	95	³⁷ ACKERSTAFF 97B OPAL $e^+e^- \rightarrow X^0X^0$, $X^0 \rightarrow Y^0\gamma$

³⁶ ACKERSTAFF 97B associated production limit is for $m_{\chi 0} =$ 80–160 GeV, $m_{\gamma 0} =$ 0 from 10.0 pb⁻¹ at $\sqrt{s} = 161$ GeV. See their Fig. 3(a).

 37 ACKERSTAFF 97B pair production limit is for $m_{\chi^0}=40$ –80 GeV, $m_{\gamma^0}=0$ from 10.0 pb⁻¹ at $\sqrt{s} = 161$ GeV. See their Fig. 3(b).

Heavy Particle Production Cross Section

VALUE (cm ² /N)	CL%	EVTS	DOCUMENT ID		TECN	COMMENT
• • • We do not u	se th	e followin	g data for averages	, fits	, limits,	etc. • • •
$< 10^{-36} - 10^{-33}$			38 GALLAS	95	TOF	m= 0.5-20 GeV
$<(4-0.3)\times10^{-31}$ $<2\times10^{-36}$	95		³⁹ AKESSON	91	CNTR	m = 0-5 GeV
	90	0	⁴⁰ BADIER	86	BDMP	$\tau = (0.05-1.) \times 10^{-8}$ s
<2.5 × 10 ⁻³⁵		0	⁴¹ GUSTAFSON	76	CNTR	$\tau > 10^{-7} \text{ s}$

 38 GALLAS 95 limit is for a weakly interacting neutral particle produced in 800 GeV/c pN interactions decaying with a lifetime of 10^{-4} – 10^{-8} s. See their Figs. 8 and 9. Similar limits are obtained for a stable particle with interaction cross section 10^{-29} – 10^{-33} cm².

 39 AKESSON 91 limit is from weakly interacting neutral long-lived particles produced in pN reaction at 450 GeV/c performed at CERN SPS. Bourquin-Gaillard formula is used as the production model. The above limit is for $\tau > 10^{-7}\,\mathrm{s}$. For $\tau > 10^{-9}\,\mathrm{s}$, $\sigma < 10^{-30} \, \text{cm}^{-2} / \text{nucleon is obtained.}$

 40 BADIER 86 looked for long-lived particles at 300 GeV π^- beam dump. The limit applies for nonstrongly interacting neutral or charged particles with mass >2 GeV. The limit applies for particle modes, $\mu^+\pi^-$, $\mu^+\mu^-$, $\pi^+\pi^-$ X, $\pi^+\pi^-\pi^\pm$ etc. See their figure 5 for the contours of limits in the mass- τ plane for each mode.

 41 GUSTAFSON 76 is a 300 GeV FNAL experiment looking for heavy (m>2 GeV) long-lived neutral hadrons in the M4 neutral beam. The above typical value is for m=3GeV and assumes an interaction cross section of 1 mb. Values as a function of mass and interaction cross section are given in figure 2.

Production of New Penetrating Non-v Like States in Beam Dump

WIMPs and Other Particle Searches

- 46 BARATE 97K search for pair production of long-lived charged particles at $\sqrt{s}=130,\,136,\,161,\,$ and 172 GeV and give limits $\sigma<(0.2\text{-}0.4)$ pb (95%CL) for spin-0 and spin-1/2 particles with m=45-65 GeV. The limit is translated to the cross section at $\sqrt{s}=172$ GeV with the \sqrt{s} dependence described in the paper. See their Figs. 2 and 3 for limits on J=1/2 and J=0 cases.
- 47 AKERS 95R is a CERN-LEP experiment with W $_{
 m cm}~\sim~m_Z$. The limit is for the production of a stable particle in multihadron events normalized to $\sigma(e^+e^- \to \text{hadrons})$. Constant phase space distribution is assumed. See their Fig. 3 for bounds for $Q=\pm 2/3$,
- 48 BUSKULIC 93C is a CERN-LEP experiment with W_{CM} = m_Z. The limit is for a pair or single production of heavy particles with unusual ionization loss in TPC. See their Fig. 5
- 49 ADACHI 90C is a KEK-TRISTAN experiment with W_{cm} = 52–60 GeV. The limit is for pair production of a scalar or spin-1/2 particle. See Figs. 3 and 4.
- 50 ADACHI 90E is KEK-TRISTAN experiment with $W_{cm} = 52-61.4$ GeV. The above limit is for inclusive production cross section normalized to $\sigma(e^+e^-\to \mu^+\mu^-)\cdot\beta(3-\beta^2)/2$, where $\beta=(1-4m^2/W_{\rm cm}^2)^{1/2}$. See the paper for the assumption about the production prochairs
- 51 KINOSHITA 82 is SLAC PEP experiment at $W_{cm} = 29$ GeV using lexan and 39 Cr plastic
- Sheets sensitive to highly lonizing particles.
 BARTEL 80 is DESY-PETRA experiment with W_{cm} = 27-35 GeV. Above limit is for inclusive pair production and ranges between 1. x 10⁻¹ and 1. x 10⁻² depending on mass and production momentum distributions. (See their figures 9, 10, 11).

78 SAITO 90 candidates carry about 450 MeV/nucleon. Cannot be accounted for by conventional backgrounds. Consistent with strange quark matter hypothesis.

ventional backgrounds. Consistent with strange quark matter hypothesia.

79 MINCER 85 is high statistics study of calorimeter signals delayed by 20–200 ns. Callbration with AGS beam shows they can be accounted for by rare fluctuations in signals from low-energy hadrons in the shower. Claim that previous delayed signals including BJORNBOE 68, DARDO 72, BHAT 82, SAKUYAMA 838 below may be due to this fake effect.

enerct.

80 SAKUYAMA 83B analyzed 6000 extended air shower events. Increase of delayed particles and change of lateral distribution above 10¹⁷ eV may indicate production of very heavy parent at top of atmosphere.

B1 BHAT 82 observed 12 events with delay $> 2. \times 10^{-8}$ s and with more than 40 particles. 1 eV has good hadron shower. However all events are delayed in only one of two detectors in cloud chamber, and could not be due to strongly interacting massive particle.

82 MARINI 82 applied PEP-counter for TOF. Above limit is for velocity = 0.54 of light. Limit is inconsistent with YOCK 80 YOCK 81 events if isotropic dependence on zenith angle is assumed.

83 YOCK 81 saw another 3 events with $Q=\pm 1$ and m about 4.5 m_p as well as 2 events with $m>5.3m_p$, $Q=\pm 0.75\pm 0.05$ and $m>2.8m_p$, $Q=\pm 0.70\pm 0.05$ and 1 event with $m=(9.3\pm 3.)m_p$, $Q=\pm 0.89\pm 0.06$ as possible heavy candidates.

84 YOCK 80 events are with charge exactly or approximately equal to unity.

 85 BHAT 78 is at Kolar gold fields. Limit is for $au > 10^{-6}$ s.

86 YOCK 74 events could be tritons.

Superheavy Particle (Quark Matter) Flux in Cosmic Rays

87 ASTONE 93 searched for quark matter ("nuclearites") in the velocity/c range = 10^{-3} -1. Their Table 1 gives a compilation of searches for nuclearites.

88 AHLEN 92 searched for quark matter ("nuclearites"). The bound applies to velocity/c $< 2.5 \times 10^{-3}$. See their Fig. 3 for other velocity/c and heavier mass range.

 89 NAKAMURA 85 at KEK searched for quark-matter. These might be lumps of strange quark matter with roughly equal numbers of u, d, s quarks. These lumps or nuclearites were assumed to have velocity/c of 10^{-4} – 10^{-3} .

90 ULLMAN 81 is sensitive for heavy slow singly charge particle reaching earth with vertical velocity 100–350 km/s.
