Abstract. We have analysed time-slice simulations from 17 global models, participating in the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP), to explore changes in present-day (2000) hydroxyl radical (OH) concentration and methane (CH\textsubscript{4}) lifetime relative to preindustrial times (1850) and to 1980. A comparison of modeled and observation-derived methane and methyl chloroform lifetimes suggests that the present-day global multimodel mean OH concentration is overestimated by 5 to 10% but is within the range of uncertainties. The models consistently simulate higher OH concentrations in the Northern Hemisphere (NH) compared with the Southern Hemisphere (SH) for the present-day (2000; inter-hemispheric ratios of 1.13 to 1.42), in contrast to observation-based approaches which generally indicate higher OH in the SH although uncertainties are large. Evaluation of simulated carbon monoxide (CO) concentrations, the primary sink for OH, against ground-based and satellite observations suggests low biases in the NH that may contribute to the high north–south OH asymmetry in the models. The models vary widely in their regional distribution of present-day OH concentrations (up to 34%). Despite large regional changes, the multi-model global mean (mass-weighted) OH concentration changes little over the past 150 yr, due to concurrent increases in factors that enhance OH (humidity, tropospheric ozone, nitrogen oxide (NO\textsubscript{x}) emissions, and UV radiation due to decreases in stratospheric ozone), compensated by increases in OH sinks (methane abundance, carbon monoxide and non-methane volatile organic carbon (NMVOC) emissions). The large inter-model diversity in the sign and magnitude of preindustrial to present-day OH changes (ranging from a decrease of 12.7% to an increase of 14.6%) indicate that uncertainty remains in our understanding of the long-term trends in OH and methane lifetime. We show that this diversity is largely explained by the different ratio of the change in global mean tropospheric CO and NO\textsubscript{x} burdens (ACO/ΔNO\textsubscript{x}, approximately represents changes in OH sinks versus changes in OH sources) in the models, pointing to a need for better constraints on natural precursor emissions and on the chemical mechanisms in the current generation of chemistry-climate models. For the 1980 to 2000 period, we find that climate warming and a slight increase in mean OH (3.5 ± 2.2%) leads to a 4.3 ± 1.9% decrease in the methane lifetime. Analysing sensitivity simulations performed by 10 models, we find that preindustrial to present-day climate change decreased the methane lifetime by about four months, representing a negative feedback on the climate system. Further, we analysed attribution experiments performed by a subset of models relative to 2000 conditions with only one precursor at a time set to 1860 levels. We find that global mean OH increased by 46.4 ± 12.2% in response to preindustrial to present-day anthropogenic NO\textsubscript{x} emission increases, and decreased by 17.3 ± 2.3%, 7.6 ± 1.5%, and 3.1 ± 3.0% due to methane burden, and anthropogenic CO, and NMVOC emissions increases, respectively.

1 Introduction

The hydroxyl radical (OH) is the dominant oxidizing agent in the global troposphere as it reacts with most pollutants (Levy, 1971; Logan et al., 1981; Thompson, 1992), thereby controlling their atmospheric abundance and lifetime. Any changes in OH affect the tropospheric chemical lifetime of methane (CH\textsubscript{4}), the most abundant organic species in the atmosphere and a potent greenhouse gas, since reaction with OH is the primary mechanism by which it is removed from the atmosphere. Complex series of chemical reactions involving tropospheric ozone (O\textsubscript{3}), methane, carbon monoxide (CO), non-methane volatile organic compounds (NMVOCs), and nitrogen oxides (NO\textsubscript{x} = NO + NO\textsubscript{2}), as well as the levels of solar radiation and humidity, determine the tropospheric abundance of OH (Logan et al., 1981; Thompson, 1992). The more-than-doubling of global methane abundance since preindustrial times (Petit et al., 1999; Loulergue et al., 2008; Sapart et al., 2012), combined with the rise in emissions of NO\textsubscript{x}, CO and NMVOCs (Lamarque et al., 2010), is likely to have had some influence on OH and consequently on the chemical methane lifetime in the past 150 yr. We analyse results from global chemistry-climate models participating in the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP; see www.giss.nasa.gov/projects/accmip) to investigate the changes in tropospheric OH abundance and its drivers, and methane lifetime over the historical period between 1850 and 2000.

Primary production of tropospheric OH occurs when electronically excited O(\textsuperscript{1}D) atoms, produced by ozone photolysis at wavelengths less than 340 nm, react with water vapor:

$$O_3 + h\nu(\lambda < 340\text{ nm}) \rightarrow O(\textsuperscript{1}D) + O_2$$  \hspace{1cm} (R1)

$$O(\textsuperscript{1}D) + H_2O \rightarrow 2OH$$  \hspace{1cm} (R2)

Therefore, production of OH is highest in the tropical lower to middle troposphere, reflecting the combined impact of high levels of water vapour, and low stratospheric ozone column, meaning higher incident ultraviolet (UV) radiation (Logan et al., 1981; Spivakovsky et al., 2000; Lelieveld et al., 2002). OH has a tropospheric lifetime on the order of seconds, reacting rapidly with CO, methane and NMVOCs to produce HO\textsubscript{2} or an organic peroxy radical (RO\textsubscript{2}), key species for the secondary production of OH:

$$OH + CO(+O_2) \rightarrow HO_2 + CO_2$$  \hspace{1cm} (R3)

$$OH + RH(+O_2) \rightarrow RO_2 + H_2O$$  \hspace{1cm} (R4)

Secondary formation of OH can occur in the presence of NO\textsubscript{x} since NO reacts with HO\textsubscript{2} or RO\textsubscript{2} to recycle OH (Crutzen, 1973; Zimmerman et al., 1978):

$$HO_2 + NO \rightarrow NO_2 + OH$$  \hspace{1cm} (R5)

$$RO_2 + NO(+O_2) \rightarrow R’CHO + NO_2 + OH$$  \hspace{1cm} (R6)

Additional OH is produced because NO\textsubscript{2} can photolyse resulting in the formation of ozone, the primary precursor to
There is significant yield (Dillon and Crowley, 2008 and references therein):...
in OH and methane lifetime based on the current generation of chemistry-climate models (CCMs). Here our goals are to (1) evaluate the present-day (2000) OH in the models, (2) explore changes in OH and methane lifetimes since preindustrial times, and (3) investigate the impact of individual factors (climate and ozone precursor emissions) driving these changes. A parallel study compares future projections of OH and methane lifetime in the ACCMIP models (Voulgarakis et al., 2013). We provide a summary of models used, the experiments they performed, and our analysis approach in Sect. 2. Historical OH and methane lifetime are presented in Sect. 3. Changes in OH, methane lifetime, and their driving factors in the present-day (2000) relative to preindustrial (1850) and to 1980 are discussed in Sects. 4 and 5, respectively. The sensitivity of OH and methane lifetime to historical change in climate, and changes in methane burden and emissions are presented in Sects. 6 and 7, respectively, with conclusions drawn in Sect. 8.

2 Methodology

2.1 ACCMIP models

We analyse results from 17 different global models to investigate how OH and methane lifetime in the present-day has changed relative to 1850 and to 1980. In other studies, ACCMIP results have been analysed to compare changes in atmospheric composition from 1850 to 2100 with a focus on physical climate variables (Lamarque et al., 2013), tropospheric ozone (Young et al., 2013) and its radiative forcing (Stevenson et al., 2013; Bowman et al., 2013), black carbon (Lee et al., 2013), and on aerosol radiative forcing (Shindell et al., 2013). Detailed descriptions of ACCMIP models are provided by Lamarque et al. (2013).

Nearly all the models are run as coupled chemistry-climate models (CCMs), driven by climatologically monthly mean sea surface temperatures (SSTs) and sea ice coverage (SIC) either from observations or from the corresponding coupled ocean–atmosphere model integrations submitted to the Coupled Model Intercomparison Project Phase 5 (CMIP5). Three models, namely CICERO-OsloCTM2, MOCAGE, and TM5 are chemistry transport models (CTMs) driven by meteorological fields from an offline reanalysis or output from a general circulation model. Meteorological fields used to run CICERO-OsloCTM2 and TM5 did not vary across time-slice simulations. GISS-E2-R and GISS-E2-R-TOMAS are two different configurations of the same model – GISS-E2-R is a fully interactive coupled ocean–atmosphere-chemistry model with a simple mass-based representation of aerosols, while GISS-E2-R-TOMAS uses SSTs and SIC from GISS-E2-R with a more detailed aerosol microphysics scheme. Similarly, HadGEM2 and HadGEM2-ExtTC are the same, except HadGEM2 includes a simple tropospheric chemistry scheme, while HadGEM2-ExtTC incorporates a more detailed chemistry scheme with many more hydrocarbons.

Key characteristics of the models relevant for simulating atmospheric OH and methane lifetime are presented in Table A1 of Voulgarakis et al. (2013). Briefly, anthropogenic and biomass burning emissions are taken from Lamarque et al. (2010) and vary over the historical period (Young et al., 2013). Natural emissions for NOx, CO, and NMVOCs were specified from different sources and are one of the major sources of diversity in model results (Table A1; source-wise emissions for 2000 implemented in the models are summarized in Table S1 in the Supplement). Other sources of differences across the models are expected to result from diversity in the complexity of NMVOC chemistry (mechanisms include a range from 16 to 100 species), stratospheric ozone representations, and resulting impacts on ozone photolysis rates (see Table 3 of Lamarque et al. (2013) for further details). Most models prescribe methane values at the surface (but allow it to undergo chemical processing elsewhere in the atmosphere) from the historical reconstruction of Meinshausen et al. (2011) though a few models use alternative approaches. Two models (STOC-HadAM3 and UM-CAM) apply a uniform global concentration and another (LMDzORINCA) applies emission fluxes. The temperature-dependent rate coefficient \((k_{\text{CH}_4+\text{OH}})\) for methane oxidation (R4) applied in most models is from Sander et al. (2011). Global and annual average \(k_{\text{CH}_4+\text{OH}}\) implemented in the models are shown in Table S2 in the Supplement. The coefficient of variation (CV; standard deviation as a percentage of the multi-model mean) for \(k_{\text{CH}_4+\text{OH}}\) across models is less than 2 %, suggesting that the impact of differences in temperature across models on \(k_{\text{CH}_4+\text{OH}}\) is minimal and is, therefore, unlikely to contribute to the diversity in methane lifetime shown later.

2.2 Simulations

We analysed three time-slice simulations over the historical period – 1850, 1980 and 2000, performed by 16 models (HadGEM2-ExtTC performed only attribution simulations described below). The models were typically run for 4 to 10 yr for each time-slice, though GEOSCCM performed 14 yr integrations, CICERO-OsloCTM2 and TM5 performed single year simulations (the reference year for TM5 present-day simulation being 2006), and GISS-E2-R and LMDzORINCA were run transiently for the entire historical period. For the analysis performed here, we averaged results over all the available years of each of the three historical time-slices. In the case of the GISS-E2-R and LMDzORINCA models, we averaged years centered on the time-slice (except average over 1850–1859 was used for 1850 and average over 1996–2000 was used for 2000 for LMDzORINCA). Interannual variability in OH is not explicitly addressed here because ACCMIP simulations were designed to address only long-term changes.

Atmos. Chem. Phys., 13, 5277–5298, 2013 www.atmos-chem-phys.net/13/5277/2013/
Of the 17 models, 10 models performed an additional simulation (Em2000C11850) with emissions fixed at 2000 levels, but with climate (SSTs and SIC) set to 1850 conditions (well-mixed greenhouse gases, including methane and ozone depleting substances (ODSs) were also set to 1850 levels for radiation calculations). The difference of Em2000C11850 from the 2000 simulation allows us to investigate the influence of historical climate change on global OH and the methane lifetime. Furthermore, a few of these models performed a series of attribution experiments, specifically designed to ascribe ozone and OH changes to the increases in anthropogenic emissions of individual species (NOx, CO, NMVOCs) and to the rise in methane concentrations (Stevenson et al., 2013).

### 2.3 Analysis approach

We calculate the tropospheric methane lifetime against loss by OH ($\tau_{CH_4}$) as the ratio of the global atmospheric methane burden ($B_{CH_4}$) and the global annual mean tropospheric methane–OH oxidation flux ($L_{CH_4}$) provided by each model for each year and then averaged over the number of years for each time-slice. Hereafter, “methane lifetime” refers to the lifetime against loss by tropospheric OH ($\tau_{CH_4}$). The total methane lifetime additionally includes the small stratospheric and soil sinks (Prather et al., 2001; Stevenson et al., 2006; Voulgarakis et al., 2013). For tropospheric global budgets, we define the troposphere to extend from the surface to a fixed pressure level of 200 hPa on each model’s native vertical grid. We calculated methane lifetime with the tropopause defined as air with ozone concentrations less than or equal to 150 ppbv in the 1850 time-slice simulation (Stevenson et al., 2006; Young et al., 2013) (Table S3 in Supplement) and found it to be within 1% of the values obtained with the tropopause at 200 hPa (Table 1). Thus we conclude that the definition of the tropopause has minimal effect on the calculated methane lifetime. With the exception of global budget terms, we weight global mean quantities reported here by the mass of air in each model grid cell.

We also calculate the tropospheric lifetime of CH3CCl3 against OH loss ($\tau_{CH_3CCl_3}$) as a means of testing model simulated global mean tropospheric OH concentrations for present-day. Since models did not simulate the chemistry and distribution of CH3CCl3, we calculate its tropospheric lifetime by scaling the methane lifetime with the ratio of the rate coefficient of the reactions of methane and CH3CCl3 with OH (Prather and Spivakovsky, 1990) integrated from the surface to the tropopause as $\tau_{CH_3CCl_3} = \frac{\tau_{CH_4} f_{sfc}}{f_{sfc} \frac{k_{CH_3CCl_3+OH}(T)}{k_{CH_4+OH}(T)}}$, where $k_{CH_3CCl_3+OH}(T)$, the temperature-dependent rate coefficient for the oxidation of CH3CCl3 by tropospheric OH is $1.64 \times 10^{-12} \exp(-1520/T) \text{ mole}^{-1} \text{ cm}^3 \text{ s}^{-1}$ (Sander et al., 2011). We apply monthly mean 3-dimensional temperature as diagnosed by each model to calculate this rate coefficient. The derived tropospheric chemical lifetime of CH3CCl3 is referred to as “CH3CCl3 lifetime” here and does not include
the small stratospheric and oceanic losses (Prinn et al., 2005; Prather et al., 2012).

### 3 Historical OH and methane lifetime

Table 1 shows annual mean global total methane burden, tropospheric mean OH and methane lifetime from the 16 global models for the 1850, 1980 and 2000 time-slices. The global methane burden increases by more than a factor of two from 1850 to 2000 in all models. Simulated methane abundances are not sensitive to how methane was prescribed in the models (Lamarque et al., 2013). Despite similar imposed changes in emissions, specifically increases in the emissions of NOx (contributing to secondary OH production), CO and NMVOCs (OH sinks) (Young et al., 2013), and in the methane burden over the 1850 to 2000 period, the models simulate different change in OH ranging from an increase to a decrease. All models simulate larger increases or smaller decreases in tropospheric OH abundance in the Northern Hemisphere (NH) compared to the Southern Hemisphere (SH) consistently from 1850 to 2000 (Table 2). We explore the changes in OH, methane lifetime and their driving factors for present-day relative to preindustrial and to 1980 in Sects. 4 and 5, respectively, in an attempt to identify the key processes responsible for the different simulated OH trends.

#### 3.1 Evaluation of present-day OH

Comparison between modeled and observed OH concentrations provides insight into the budget of OH and an understanding of the underlying chemistry (e.g. Stone et al., 2012 and references therein). A thorough evaluation of models against direct OH measurements (ground-based, aircraft) is not particularly useful for constraining global mean OH because of the enormous temporal and spatial variability in OH concentrations. Since our simulations represent average climatological conditions, we focus our evaluation on some of the factors controlling OH distributions at regional and global scales.

Lifetimes of methane and CH$_3$CCl$_3$ against reaction with tropospheric OH provide the best constraints on the global mean tropospheric OH concentration. We compare present-day (2000) methane and CH$_3$CCl$_3$ lifetimes obtained from models against observationally derived estimates to evaluate the global mean OH concentrations simulated by the models. The multi-model mean methane lifetime against OH loss of 9.7 ± 1.5$^1$ years (Table 1) is about 5% lower than the mean 1978–2004 tropospheric methane lifetime of 10.2$^{±0.7}$ yr estimated by Prinn et al. (2005), and is about 13% lower than the most up-to-date observationally derived estimate of 11.2$^{±1.2}$ yr for 2010 (Prather et al., 2012). It is identical to the methane lifetime of 9.7 ± 1.7 yr obtained from a previous multi-model analysis (Shindell et al., 2006b), and is about 5% lower than the 10.2 ± 1.7 yr reported in the recent Hemispheric Transport of Air Pollution (HTAP) multi-model study (Fiore et al., 2009). The variation in methane lifetime across participating models is about the same as that across the previous multi-model estimates (Shindell et al., 2006b; Fiore et al., 2009). Similarly, the multi-model mean CH$_3$CCl$_3$ lifetime of 5.7 ± 0.9 yr (Table 1), is about 5% lower than the observationally derived tropospheric lifetime of 6.0$^{±0.5}$ years over the period 1978–2004 (Prinn et al., 2005), and is about 10% lower than the recent estimate of 6.3 ± 0.4 years (Prather et al., 2012) obtained using CH$_3$CCl$_3$ observations over the period 1998–2007 (Montzka et al., 2011). This comparison suggests that the multi-model mean present-day global tropospheric OH abundance of 11.1 ± 1.6 × 10$^3$ molec cm$^{-3}$ is overestimated by 5 to 10% but is within the uncertainty range of observations.

Since the atmospheric oxidizing capacity is sensitive to both the OH amount and its spatial distribution (Lawrence et al., 2000), we examine the regional OH distribution in the models as depicted in Fig. 1a showing the multi-model mean OH concentrations in the different atmospheric sub-domains for the 2000 time-slice (individual models are shown in Fig. S1 in the Supplement). Consistent with previous studies,

---

$^1$Slightly different from that reported by Voulgarakis et al. (2013) as we have included results from GISS-E2-R-TOMAS and TM5.
The greatest OH concentrations are found in the tropical troposphere reflecting the abundant sunlight and water vapor (Fig 1a). The individual model biases in tropical specific humidity compared with reanalysis and satellite measurements (Lamarque et al., 2013) are generally consistent with OH concentrations in the tropical troposphere, i.e., models with high water vapor biases simulate high OH (compare Figs. S1 with S4 of Lamarque et al., 2013). The NH extratropical troposphere is characterized by higher OH concentrations than that in the SH extra-tropics reflecting the influence of higher ozone and NOx emissions. A comparison of present-day model tropospheric ozone concentrations against ozonesonde and satellite data indicates that models may have a systematic high bias in the extratropical NH (Young et al., 2013) perhaps contributing to the high NH extratropical OH. The larger model overestimate of the total column ozone (mainly reflecting stratospheric ozone column) relative to satellite measurements from the merged Total Ozone Mapping Spectrometer/solar backscatter ultraviolet (TOMS/SBUV) data averaged over the 1996–2005 time period (Fig. S2) in the SH than in the NH may also contribute to lower simulated OH concentrations in the extratropical SH.

Overall, there is large model-to-model variability in the regional distribution of OH. There is, however, less inter-model diversity in the mid-troposphere OH concentrations compared with those in the lower and upper troposphere (Fig. 1b), except in the SH troposphere where the large inter-model variation possibly reflects diversity in the simulated stratospheric ozone columns and differences in how these influence photolysis in the models. Clouds have also been shown to influence the regional distribution of OH via photolysis (Liu et al., 2006; Voulgarakis et al., 2009). Evaluation of parent climate models of many of the ACCMIP models against “A-Train” satellite observations indicates that water vapor and clouds are simulated better in the lower and middle troposphere than in the upper troposphere (Jiang et al., 2012) – a factor possibly contributing to the large uncertainty in upper tropospheric OH concentrations. An exhaustive evaluation of the regional distributions of OH requires more process-level information from the models (e.g. OH production and loss fluxes, and cloud properties) and should be a priority for future model inter-comparisons.

The present-day multi-model mean OH inter-hemispheric (N/S) ratio is 1.28 ± 0.1 (Table 2), in contrast to the range of N/S values derived from measurements of CH3CCl3 encompassing the 1980 to 2000 period (Montzka et al., 2000; Prinn et al., 2001; Krol and Lelieveld, 2003; Bousquet et al., 2005). For example, with CH3CCl3 measurements for 1998–1999, Montzka et al. (2000) estimate that annual mean OH concentrations are 15 ± 10 % higher south of the inter-tropical convergence zone (ITCZ) than north of it, while Prinn et al. (2001) derive annual mean OH concentrations that are 14 ± 35 % higher in the SH than the NH over the 1978–2000 time period. These observational estimates of N/S OH ratio are highly uncertain as they rely on the assumption of accurate CH3CCl3 emission estimates and its atmospheric observations. Nevertheless, model derived N/S inter-hemispheric asymmetry is consistent with present-day tropospheric ozone distributions in the ACCMIP models that are biased high and low in the NH and SH, respectively, against satellite and ozonesonde observations (Young et al., 2013). The models thus overestimate OH production from ozone in the NH relative to SH.

Several factors including model-to-model differences in emissions, particularly natural emissions (since models used similar anthropogenic emissions), underlying chemical mechanisms (that dictate the VOC speciation and emissions), stratospheric ozone column, cloud amounts, photolysis schemes, and interactions with aerosols likely all contribute to the large inter-model variation in the simulated present-day tropospheric OH concentrations (and methane and CH3CCl3 lifetimes). For example, lowest tropospheric mean OH in UM-CAM most likely stems from its offline photolysis scheme that does not account for changes in clouds, overhead ozone column, or aerosols, resulting in very low photolysis rates and OH (Voulgarakis et al., 2013). The highest tropospheric mean OH abundances are simulated by the CESM-CAM-superfast and MOCAGE models. The representation of NMVOCs is minimal in CESM-CAM-superfast model as it includes isoprene only, thus simulating a smaller sink for OH. Even though MOCAGE has the highest NMVOC emissions, thus a bigger OH sink, (Table S1), other factors contribute to its high OH, including the lack of inclusion of aerosol photochemical effects in the model (Bousserez et al., 2007). In addition, low stratospheric ozone columns in MOCAGE may enhance UV radiation resulting in greater OH production, although we cannot directly diagnose this as photolysis rates are not available from MOCAGE. High NMVOC emissions have also been suggested as a possible reason for high OH in MOCAGE (Voulgarakis et al., 2013). Availability of key OH diagnostics from all models participating in future multi-model
intercomparison projects will facilitate a better understanding of inter-model diversity in OH distributions and contribute to a process-based understanding of the drivers of OH.

3.2 Comparison of present-day CO with observations

CO is the major sink of tropospheric OH (Jacob 1999; Duncan and Logan, 2008), hence, any biases in CO will likely influence the distribution of OH. Here, we evaluate the simulated CO distributions against surface and satellite measurements to test if OH sinks may also be too low in the NH compared with the SH resulting in higher NH-OH concentrations. We compare annual mean CO from the models with surface CO measurements averaged over the 1996–2005 period from the NOAA Global Monitoring Division (GMD) Carbon Cycle Cooperative Global Air Sampling Network (Novelli and Masarie, 2010) for 50 sites (Fig. 2a) and with the observed mean 2000–2006 CO distribution at 500 hPa from the Measurements of Pollution In The Troposphere (MOPITT) instrument (Fig. 2b). For comparison with surface observations, we sampled model results at pressure levels closest to the pressure altitude, latitude and longitude of the observation sites. For comparison with MOPITT CO, we used monthly mean daytime values derived from version 4 (V4) level 3 retrievals from March 2000 to December 2006 provided at a horizontal resolution of $1^\circ \times 1^\circ$ and at 10 retrieval levels (Deeter et al., 2010). For proper comparison, we transformed each model’s CO by first interpolating it to the MOPITT grid and then applying the averaging kernel and a priori profile associated with each MOPITT retrieval (Shindell et al., 2006b; Emmons et al., 2009). A priori profiles associated with V4 are based on a monthly climatology from the global chemical transport model MOZART-4. Detailed evaluation of MOPITT V4 CO retrievals between 2002 and 2007 with in situ measurements show biases of less than 1% at the surface, 700 hPa and 100 hPa, and a bias of about $-6\%$ at 400 hPa (Deeter et al., 2010).

The multi-model mean underestimates the observed surface CO concentrations at most sites in the NH (Fig. 2a), with strong negative biases (up to 60 ppbv) at many high latitude sites. Negative biases persist at the northern mid-latitude sites albeit with smaller magnitudes than at the northern high-latitude sites. In the SH, the multi-model mean is within $\pm 2$ ppbv at most sites. Consistent with the surface CO comparison, the multi-model mean underestimates the MOPITT CO at 500 hPa throughout the NH, except over northern India and south-central China (Fig. 2b). The overestimate over these South Asian regions is present in all models (Fig. S3) and is particularly dominant in the comparison for September (not shown), indicating excessive transport and/or emissions. The multi-model mean CO reproduces the MOPITT values over much of the SH, except over central Africa, western South America, Indonesia and surrounding Indian and Pacific oceans possibly related to discrepancies in biomass burning emissions (Fig 2b). Despite these regional biases, the models capture the overall spatial distribution of MOPITT CO fairly well as indicated by the high values of spatial correlation coefficients (Table 3).

The multi-model mean CO concentrations generally agree better with observations in the SH, and are biased low in the NH, similar to the earlier multi-model results of Shindell et al. (2006b). The simulated low CO levels in the NH are consistent with a weaker-than-observed OH sink that contributes to the larger OH north-to-south asymmetry compared to that derived from CH$_3$CCl$_3$ observations.

4 Preindustrial to present-day changes in OH and methane lifetime, and their driving factors

We now explore the changes in OH from preindustrial to present-day and their driving factors. The multi-model tropospheric mean OH oxidative capacity has remained nearly constant over the past 150 yr (Table 4). Globally, increases in factors that enhance OH – humidity (4.7 ± 2.6%), tropospheric ozone (38 ± 10.8%; Young et al., 2013) and NO$_x$
Table 3. Model versus MOPITT CO annual mean bias for the Northern Hemisphere (NH), Southern Hemisphere (SH), and Global at 500 hPa. Annual mean spatial pattern correlation coefficients ($r$) between model and MOPITT CO global retrievals are in the right-most column.

Table 4. Preindustrial (1850) to present-day (2000) changes in global mean tropospheric OH, tropospheric methane lifetime ($\tau_{CH_4}$), CO and NOx burdens, stratospheric ozone column (Strat O3), humidity (Q), and temperature (T). Absolute changes in airmass-weighted temperature are given, while the rest of the quantities are expressed as percentage changes relative to 1850. Models that simulate reductions in present-day OH relative to preindustrial are shown in bold. A cell with * means that the model did not report that quantity.

</table>

(as NO + NO2) burdens (108.0 ± 75.4 %), and decreases in stratospheric ozone (−4.5 ± 4.8 %), which modulate tropospheric ozone photolysis rates – are compensated by increases in OH sinks – doubling of methane (Table 1) and CO burdens (Table 4). Tropospheric temperature that controls water vapour abundance and reaction rates also increases (0.8 ± 0.4 K) during this period. The near-constant global mean OH over the historical period is consistent with the findings of Lelieveld et al. (2002, 2004). There is, however, large intermodel spread in the simulated changes in OH, ranging from a decrease of 12.7 % (GEOSCCM) to an increase of 14.6 % (MOCAGE) (Table 4). It is notable that with the consistent ACCMIP modeling specifications, the preindustrial to present-day percent changes in OH for all ACCMIP models are within ± 15 %, a range significantly reduced from the previously published model estimates of
preindustrial to present-day OH changes (Table 1 of John et al., 2012).

We now discuss regional changes in annual mean OH by relating them to regional changes in chemistry (CO, NO\(_x\) burdens, stratospheric ozone) and climate drivers (humidity and temperature) of OH. Preindustrial to present-day changes in multi-model mean OH, CO and NO\(_x\) burdens, humidity and temperature for 12 tropospheric subdomains, as defined by Lawrence et al. (2001), are shown in Fig. 3 (left column). Strong intermodel diversity exists in the magnitude of NO\(_x\) burden changes, particularly in the upper troposphere (Fig. 3e), possibly reflecting the model-to-model differences in processes that dominate the response in this region and the uncertainty associated with lightning NO\(_x\) emissions.

The intermodel diversity in CO, humidity and temperature changes is much lower compared to that for NO\(_x\) changes. Strong intermodel variation exists in both the sign and magnitude of regional preindustrial to present-day changes in OH (see Fig. S4 for regional OH changes in individual models). For many atmospheric regions, the standard deviation in OH change across models is greater than the multi-model mean change (Fig. 3a) suggesting that the changes are not statistically significant. The NH lower tropospheric (surface to 750 hPa) extra-tropics (30\(^\circ\)–90\(^\circ\) N) is the only region of the atmosphere where the models agree on the sign of OH change (increase), and its magnitude appears to be statistically significant (multi-model mean greater than standard deviation). This is also the region with the largest increases in CO and NO\(_x\) burdens (Fig. 3c, e), driven by the changes in anthropogenic emissions which are similar in all the models. Humidity levels increase everywhere (Fig. 3g) in response to temperature increases (Fig. 3i). Strong increases in tropospheric ozone, the primary source of OH, are also simulated in the NH lower troposphere in response to emission increases (Young et al., 2013). Thus, combined increases in water vapor, ozone and NO\(_x\) outweigh CO increases resulting in enhanced OH levels in the NH extratropical lower troposphere in the present-day relative to preindustrial.

Reflecting the changes in OH, there is a large intermodel variability in the preindustrial to present-day change in methane lifetime (Table 4) with increase of 12 % (GEOSCCM) to decrease of 14.1 % (NCAR-CAM3.5). Changes in methane lifetime for each model are inversely proportional to the OH change in the model, except for HadGEM2 which shows no change in global mean OH.

### 4.1 Diversity in preindustrial to present-day changes

Here, we explore the diversity in preindustrial to present-day changes in global OH using the ratio of the change in global mean tropospheric CO and NO\(_x\) burdens (\(\Delta CO/\Delta NO_x\) - approximately represents changes in OH sinks versus changes in OH sources) simulated by the models. Previous studies have found a linear dependence of changes in global mean OH to the ratio of CO and hydrocarbon sources and NO\(_x\) sources (Wang and Jacob, 1998) or to the ratio of CO and NO\(_x\) emissions when changes in VOC emissions are small (Dalsøren and Isaksen, 2006). We find that intermodel variation in the sign and magnitude of the preindustrial to present-day change in global mean OH, whether positive or negative, correlates strongly with \(\Delta CO/\Delta NO_x\) (Fig. 4; coefficient of determination \((r^2) = 0.7\)). Models that simulate decreases in present-day global mean OH relative to

---

**Fig. 3.** Multi-model mean percentage change in tropospheric OH, CO and NO\(_x\) burdens, humidity (Q), and absolute change in temperature for 12 subdomains of the atmosphere as defined by Lawrence et al. (2001) for 2000–1850 (left) and 2000–1980 (right). Decreases are shown in red and increases are in black. Changes in the mean global (Glob), Southern Hemisphere (SH), and Northern Hemisphere (NH) troposphere (surface to 200 hPa) are shown in the topmost row of each plot.
Fig. 4. Scatterplot of absolute change in annual average tropospheric mean OH concentration from preindustrial (1850) to present-day (2000) versus the ratio of absolute changes in annual average total tropospheric CO and NO\textsubscript{x} burdens for each of the 16 models. Each model data point is denoted by the first two letters of the model name shown in Table 1. Solid line corresponds to a linear regression of changes in OH with the ratio of changes in CO and NO\textsubscript{x} burdens. The regression equation is shown on the upper right corner of the plot.

Preindustrial have stronger increases in OH sinks compared with sources (except HadGEM2), while models that simulate increase in OH show larger relative increases in sources versus sinks (except GISS-E2-R and GISS-E2-R-TOMAS) (Table 4). Removing the three outlier models increases the $r^2$ to 0.8. The correlation is particularly tight for models that simulate preindustrial to present-day OH decreases.

This analysis leads to the question of why the preindustrial to present-day changes in global CO and NO\textsubscript{x} burdens are different across models despite imposing seemingly similar trends in total CO and NO\textsubscript{x} emissions and methane burdens (Fig. 1 and Table S1 of Young et al., 2013). We attribute the diversity in $\Delta$CO/$\Delta$NO\textsubscript{x} to differences in emissions and chemical schemes implemented in the models. The variation in the simulated preindustrial to present-day methane burden trends is small (Table 1), however there are large differences in the CO, NO\textsubscript{x} and NMVOC emission trends (Table S4) as implemented in the models that drive differences in $\Delta$CO/$\Delta$NO\textsubscript{x}, and therefore, OH. Variation in CO and NO\textsubscript{x} emissions is due to differences in natural emissions (CO from oceans and vegetation; NO\textsubscript{x} from soils and lightning) (Young et al., 2013). Additional spread in CO source strength is due to the complexity of NMVOC chemical mechanism included in the models (Young et al., 2013), since NMVOC oxidation is a major CO source (Holloway et al., 2000; Duncan et al., 2007; Grant et al., 2010). For example, some models with simpler NMVOC chemistry include extra CO emissions to account for missing NMVOCs (see Table A1). Different NMVOC oxidation mechanisms lead to a wide range in both anthropogenic (prescribed mostly from the inventory of Lamarque et al., 2010) and biogenic NMVOC emissions. Additional diversity in biogenic NMVOC emission trends comes from the different ways these (particularly isoprene as it is the dominant biogenic NMVOC) are specified (constant versus climate-sensitive) in the models (Table A1). Furthermore, even if the total emissions were identical across models, differences in the way the physical processes (for example, deposition loss, photolysis) that influence the atmospheric lifetimes of CO and NO\textsubscript{x} in the models will likely produce differences in their atmospheric distributions and trends. Thus, uncertainties in natural emissions and differences in chemical and physical processes implemented in the models drive the spread in the interplay between OH sources and sinks (approximated as $\Delta$CO/$\Delta$NO\textsubscript{x}) resulting in the diversity in preindustrial to present-day OH changes.

Better constraints on natural emissions and the key physical processes controlling the distribution of OH sources and sinks will help advance our understanding of the evolution of atmospheric OH. Furthermore, concerted efforts to evaluate tropospheric chemistry mechanisms implemented in the models (Luecken et al., 2008; Emmerson and Evans, 2009; Archibald et al., 2010; Shen et al., 2010; Barkley et al., 2011) will also help to make progress in understanding the diversity in OH distributions and long-term trends across the current generation of chemistry-climate models.

5 1980 to 2000 changes in OH and methane lifetime

We now explore the change in OH and methane lifetime over the 1980 to 2000 period. Consistent with prior modeling studies (Karlsdóttir and Isaksen, 2000; Dentener et al., 2003; Dalsøren and Isaksen, 2006; Hess and Mahowald, 2009; John et al., 2012; Holmes et al., 2013), the multi-model mean OH increases slightly from 1980 to 2000 by 3.5 ± 2.2% (Table 5). Over this period, increases in OH sinks, specifically the methane (12 ± 1.9%) and CO (5.2 ± 2.0%) burdens are slightly outweighed by increases in humidity (2.8 ± 1.3%), NO\textsubscript{x} burdens (4.3 ± 12.3%), and stratospheric ozone loss (3.1 ± 2.3%). In contrast to the disagreement in the sign of OH change for the 1850–2000 period, all models agree on a small OH increase from 1980 to 2000. The multi-model mean methane lifetime decreases by 4.3 ± 1.9% from 1980 to 2000 reflecting the small increase in tropospheric OH and warming of 0.4 ± 0.2 K. While the models are consistent with each other, the observational estimates of trends in OH derived from CH\textsubscript{3}CCl\textsubscript{3} measurements indicate a ~10% decrease over a similar period (Prinn et al., 2001; Bousquet et al., 2005). More recent analysis of CH\textsubscript{3}CCl\textsubscript{3} observations over the 1998–2007 period indicates that global OH is well buffered against perturbations (Montzka et al., 2011) and suggests that the uncertainties in CH\textsubscript{3}CCl\textsubscript{3} data before 1998 may have led to artificially large OH trends reported in previous studies. Better constraints on OH trends are important for
6 Sensitivity of OH and methane lifetime to climate

We investigate the influence of climate change on OH and methane lifetime by analysing the simulations performed by 10 models with 2000 emissions but driven by 1850s climate (Em2000C11850). We compare the base 2000 time-slice and Em2000C11850 simulations to diagnose the impact of climate change from 1850 to 2000.

Preindustrial to present-day climate change causes a multimodel mean global OH increase of 2.1 \pm 2.0 \% (Fig. 5) and a methane lifetime decrease of 0.30 \pm 0.24 yr (Table 6). All models, except GFDL-AM3, simulate OH increases (Fig. 5) and methane lifetime decreases (Table 6) in response to historical climate change. GISS-E2-R produces the strongest methane lifetime decrease, while STOC-HadAM3 produces the strongest methane lifetime decrease per unit temperature increase. Increases in water vapour cause tropospheric OH increases, particularly in the upper troposphere where the relative increases in humidity (Fig. 6a) are greatest. Warmer temperatures and increased OH enhance oxidative loss of methane (Fig. 6c), decreasing the methane lifetime by 0.30 \pm 0.24 yr (Table 6) and representing a small negative climate feedback, in agreement with prior studies (Stevenson et al., 2000, 2006; Johnson et al., 2001; Voulgarakis et al., 2013).

7 Attribution of OH changes to methane burden and NOx, CO, and NMVOC emissions

A subset of the models performed a series of attribution experiments with 2000 climate conditions but with anthropogenic CO, NOx, and NMVOC emissions, and methane concentrations individually set to preindustrial levels. For the methane attribution experiment performed by eight models (Em2000CH41850), the methane concentration was fixed at an 1850s level (791 ppbv), while for the emissions attribution experiments (Em2000CO1850, Em2000NOx1850, and Em2000NMVOC1850) conducted by six models, methane was fixed at a 2000s level (1751 ppbv) and anthropogenic emissions were reduced to their 1850 values separately for each simulation. We subtract results of each perturbation simulation from the base 2000 time-slice simulation to diagnose the impact of preindustrial (1850) to present-day (2000) changes in each of the specific drivers on OH, as shown in Fig. 5. Because methane concentrations were prescribed (rather than using emissions), these attribution simulations are not at steady state with respect to methane concentration and, therefore, OH (Prather, 1994, 1996; Fuglestvedt et al., 1999; Derwent et al., 2001; Wild et al., 2001; Stevenson et al., 2004; Naik et al., 2005; Shindell et al., 2005, 2009; West et al., 2007; Fiore et al., 2008). Here, we only diagnose instantaneous changes in methane lifetime; steady-state changes are addressed by Stevenson et al. (2013).

The largest change in global mean OH is simulated for preindustrial to present-day increases in anthropogenic NOx emissions, followed by increases in methane concentrations, while smaller changes result from increases in CO and NMVOCs emissions across the subset of models (Fig. 5). Global mean OH increases by 46.4 \pm 12.2 \% due to NOx.
Table 5. Same as in Table 4 but for changes in present-day (2000) relative to 1980.

* Temperature change is slightly different from that reported in Table 4 as a different base simulation was used to compare the Em2000Cl1850 simulation.

emission increases as a result of increases in both primary and secondary OH production. The more than a factor of two increases in methane concentrations at present-day NOₓ levels leads to increases in tropospheric ozone, the primary source of OH. However, OH is consumed during the oxidation of methane and its oxidation products, so that the net result is a global OH decrease of 17.3 ± 2.3 %. Smaller decreases in mean OH occur in response to anthropogenic CO (7.6 ± 1.5 %) and NMVOC emission (3.1 ± 3.0 %) increases (Fig. 7). Despite being the major OH sink, the decrease in OH from CO increase is smaller than that from methane increase because of the lack of additional oxidation products that can further consume OH.

Methane lifetime also responds most strongly to increases in NOₓ, followed by methane, CO and NMVOC, respectively. However, the response in the perturbation lifetime is different when the nonlinear feedback of methane on its own lifetime is considered (Stevenson et al., 2013). Furthermore, the sum of OH or methane lifetime changes diagnosed from the individual attribution experiments performed by a model is not equal to the total preindustrial to present-day diagnosed from the historical time-slice simulations (Table 4). This is partly because of the inherent nonlinear chemical system and partly because all the offsetting processes influencing OH in the coupled chemistry-climate system are not included in these attribution experiments.

Regionally, OH reductions are slightly stronger in the SH compared with the NH in response to methane changes (Fig. 7a) since methane is a more important OH sink in the SH than in NH (Spivakovsky et al., 2000). On the other
Fig. 6. Percent change in multi-model mean (10 models) regional a) specific humidity, b) tropospheric OH and c) methane loss flux due to climate change only (2000–Em2000Cl1850). Decreases are shown in red and increases are in black.

Fig. 7. Percent change in multi-model mean OH in 12 subdomains of the atmosphere for 2000 relative to attribution experiments: a) Em2000CH41850 (8 models), b) Em2000CO1850 (6 models), c) Em2000NOx1850 (6 models), d) Em2000NMVOC1850 (6 models). OH increases are shown in black and decreases are in red.

hand, OH decreases are stronger in the NH compared with SH for CO and NMVOC emission increases (Fig. 7b, d), reflecting higher anthropogenic sources in the NH and shorter lifetimes. Increases in anthropogenic NOx emissions produce the largest inter-hemispheric asymmetry in the OH response (Fig. 7c).

Intermodel diversity in the response of OH to methane and CO perturbations is small, compared with that for NMVOC and NOx perturbations (Fig. 7). Significant diversity in the sign and magnitude of OH change for different tropospheric regions due to NMVOC emissions (Fig. 7d) reflect the differences in chemistry mechanisms implemented in the models and uncertainties in natural emissions. The chemical mechanisms to represent NMVOC degradation included in models are highly uncertain and better constraints are needed (Archibald et al., 2010; Barkley et al., 2011). The response of OH to NMVOCs, particularly biogenic NMVOCs, is an area of active research as several proposed oxidation mechanisms implemented in global chemistry-climate models have yet to satisfactorily explain the model underestimate of OH concentrations observed over dense tropical forests in low-NOx conditions (e.g., Butler et al., 2008; Lelieveld et al., 2008; Hofzumahaus et al., 2009; Peeters et al., 2009; Paulot et al., 2009; Stavrakou et al., 2010; Whalley et al., 2011; Barkley et al., 2011). Efforts that combine observations and modeling activities can help reduce uncertainties in our understanding of the response of OH to individual driving factors.

8 Conclusions

We have investigated the changes in global hydroxyl (OH) radical and methane lifetime in the present-day (2000) relative to preindustrial (1850) and to 1980 by analysing results from 17 global chemistry-climate models. We determined a multi-model mean present-day tropospheric methane lifetime of 9.7 ± 1.5 yr, which is 5 to 13 % lower than recently published observational estimates (Prinn et al., 2005; Prather et al., 2012). Our estimated mean present-day tropospheric methyl chloroform (CH3CCl3) lifetime of 5.7 ± 0.9 yr is also about 5 to 10 % lower than recent observationally derived estimates (Prinn et al., 2005; Prather et al., 2012). Both the lower methane and methyl chloroform lifetimes suggest that the multi-model tropospheric mean OH is slightly overestimated but is within the uncertainty range of observations. There is large intermodel variability in the regional distribution of OH although the models consistently simulate higher OH concentrations in the Northern Hemisphere (NH) than in the Southern Hemisphere (SH). The models likely overestimate OH abundances in the NH versus SH, as suggested by lower simulated CO concentrations and higher ozone concentrations (Young et al., 2013) in the NH compared with observations.

We calculated the change in OH and methane lifetime for present-day relative to preindustrial and to 1980 to gain...
a better understanding of their long-term changes. Globally, we find that concurrent increases in factors that enhance OH (humidity, tropospheric ozone, and NOx emissions), together with decreases in stratospheric ozone and increase in tropospheric temperature, have been compensated by increases in OH sinks (methane concentration, CO and NMVOC emissions). The net result is a nearly constant global mean OH concentration over the past 150 yr, despite large regional changes, consistent with previous studies (Lelieveld et al., 2002, 2004). Over the same time period, the tropospheric methane lifetime against loss by OH has decreased slightly ($-2.0 \pm 8.8\% $), possibly resulting from a warming-induced increase in its chemical loss. For the 1980 to 2000 period, we find that global mean OH has increased only slightly ($3.5 \pm 2.2\% $) and methane lifetime has decreased by about $4.3 \pm 1.9\%$ in response to this small OH increase and climate warming ($0.4 \pm 0.2\%$). The multi-model mean OH change for 1980–2000 disagrees with previous work based on CH$_3$CCl$_3$ observations, which suggest a reduction in OH in 2000 relative to 1980 (Prinn et al., 2001; Bousquet et al., 2005), but agrees well with other modeling studies (Karlsson and Isaksen, 2000; Dentener et al., 2003; Dalsøren and Isaksen, 2006; Hess and Mahowald, 2009; John et al., 2012; Holmes et al., 2013) as well as a recent study of OH variability inferred from CH$_3$CCl$_3$ observations (Montzka et al., 2011).

Substantial intermodel diversity exists in the calculated trends (sign and magnitude) in OH and methane lifetimes for the preindustrial to present-day change, stemming from the differences in the representation of chemical and physical processes that influence OH within each model. Particularly, we find that the preindustrial to present-day OH trend simulated by a model depends linearly on the ratio of the change in global mean tropospheric CO and NOx burdens ($\Delta$CO/$\Delta$NOx – approximately represents changes in OH sinks versus changes in OH sources). With a few exceptions, models with high $\Delta$CO/$\Delta$NOx predict OH decreases while those with lower values simulate OH increases from preindustrial to present day (Fig. 4). The intermodel diversity in $\Delta$CO/$\Delta$NOx reflects the diversity in the chemical mechanisms as well as uncertainties in natural CO, NOx and NMVOC emissions implemented in the models. There is, thus, a need for better constraints on natural precursor emissions and on the chemical mechanisms in the current generation of chemistry-climate models. Further, model-to-model differences in stratospheric ozone columns, photolysis schemes, clouds, and interactions with aerosols likely all contribute to the inter-model variability in simulated OH trends. The extent to which each of these factors drives change in global OH in the different models can be ascertained with well-coordinated process-oriented evaluation of chemistry-climate models.

Using a subset of the models, we further explored the sensitivity of OH and methane lifetime to historical climate change. We find that preindustrial to present-day climate change has increased global mean OH by $2.1 \pm 2.0\%$ and has decreased the methane lifetime by $0.30 \pm 0.24$ years, representing a small negative feedback on the climate system. We further attribute preindustrial to present-day OH changes to individual increases in methane burden, and anthropogenic emissions of CO, NOx, and NMVOCs employing additional perturbations simulations from a few models. With fixed methane burden, we find that NOx emissions increase OH by $46.4 \pm 12.2\%$, while methane, CO and NMVOCs decrease OH by $17.3 \pm 2.3\%$, $7.6 \pm 1.5\%$, and $3.1 \pm 3.0\%$, respectively. The response of OH and methane lifetime to emission perturbations would be somewhat different if we had allowed methane abundances to respond to these perturbations, lessening the response to NOx increases but amplifying to methane, CO and NMVOCs increases (Shindell et al., 2005, 2009; Stevenson et al., 2013).

To fully attribute preindustrial to present-day changes in OH, it is necessary to consider changes in other processes that influence OH. Previous studies have shown OH to be sensitive to biogenic NMVOCs (Wu et al., 2007 and references therein), natural (soil + lightning) NOx emissions (Labrador et al., 2004; Steinkamp et al., 2009), and aerosols (Lamarque et al., 2005b; John et al., 2012, Mao et al., 2013). For example, future studies with chemistry-climate models should explore how potential climate and land-use driven changes in biogenic NMVOCs (Lathière et al., 2010) and natural NOx emissions since preindustrial times have impacted the present-day OH abundance and methane lifetime. Furthermore, similar attribution simulations would be helpful in interpreting the influence of each driving factor on OH and methane lifetime since 1980. The role of stratospheric ozone loss in driving OH changes over this period is particularly important (e.g., Dentener et al., 2003).

Overall, we show that the multi-model mean OH abundance has remained nearly constant over the past 150 years. There is, however, large model-to-model variability in the simulated OH trend, suggesting that a better understanding of the processes influencing atmospheric OH is needed to reduce uncertainties in its long-term trends and interannual variability (Holmes et al., 2013). We cannot overemphasize the value of accurate observational constraints on OH (Stone et al., 2012; and references therein), either through direct measurements or by indirect methods using proxies, to improve our understanding of OH distributions as represented in global models.
