Abstract

This work presents the results of a study where synchrotron based x-ray computed microtomography (CMT) was used to investigate changes in pore morphology during calcium carbonate biomineralization. We simultaneously examine changes in pore microstructure and bulk permeability within glass bead columns during biogenic CaCO_3 precipitation induced by *Sporosarcina pasteurii*. We observe a three order of magnitude reduction in permeability over relatively short time-scales (~60 hrs) during the carbonate precipitation process. The resulting precipitates were a micro-porous composite of spherical and cubic CaCO_3 precipitates. CMT images taken during precipitation were analyzed for effective pore radii, effective throat radii, and other pore-scale characteristics using 3DMA-ROCK. The Kozeny-Carman relation provided a poor fit to the raw permeability data, however, once this function was augmented with geometric information extracted from CMT imagery a better fit was provided suggesting that pore geometry should be considered temporally variable when modeling permeability change during biomineralization.

1. Introduction

Biom mineralization is a natural subsurface process that can dramatically alter the physical properties of porous media. In particular, porosity and permeability changes, attributed to biologically assisted CaCO_3 precipitation, can have a direct effect on fluid flow and transport properties [Whiffin *et al.*, 2007]. A key factor relevant to permeability alteration is the characteristic pattern of precipitation with respect to the granular matrix i.e. are precipitates localized in pore throats, pore bodies, or on grain surfaces? Since effective medium models describing permeability [e.g. Carrier, 2003] and elastic properties [Dvorkin *et al.*, 1999] are dependent on such patterns, the appropriate choice of a scenario or trajectory between scenarios (i.e. where is precipitation localized and how does localization change temporally) is a key step in building a quantitative understanding of the effects of biom mineralization.

We selected *Sporosarcina pasteurii* as our model organism for studying the mineralization process, a prevalent aerobic, rod-shaped, motile, soil microbe with a very active urease enzyme [Whiffin *et al.*, 2007]. Hydrolysis of urea by the urease enzyme generates carbon dioxide and ammonia $\{\text{CO}(\text{NH}_2)_2 + \text{H}_2\text{O} \rightarrow 2\text{NH}_3 + \text{CO}_2\}$, causing an increase in pH $\{2\text{NH}_3 + 2\text{H}_2\text{O} \leftrightarrow 2\text{NH}_4^+ + 2\text{OH}^-\}$. Within this alkaline environment carbonate ions form $\{\text{CO}_2 + 2\text{OH}^- \leftrightarrow \text{CO}_3^{2-} + \text{H}_2\text{O}\}$ and precipitation of calcium carbonate is favored $\{\text{CO}_3^{2-} + \text{Ca}^{2+} \leftrightarrow \text{CaCO}_3(\text{s})\}$, [Stocks-Fischer *et al.*, 1999].

One of the simplest permeability models is the Kozeny-Carman (KC) model which attempts to describe permeability in terms of porosity starting from first principles [Carrier, 2003]. The KC function often fails to represent empirical data, however, this type of relationship is vital for the design and modeling of many engineered processes (e.g. geological carbon storage and hydrocarbon recovery).

A complete derivation of the KC functions (**Equation 1** and **2**) used herein is presented by [Costa, 2006]. Permeability can be calculated using:

$$\kappa = c (R^2/8)(\theta/\tau) \text{ (1)}$$

where, R is effective radius, τ is tortuosity, and θ is porosity. However, R and τ are hard to measure/define, thus the concept of hydraulic radius is usually defined and incorporated into

Equation 1 which gives the following formula:

$$\kappa = C_{kc}(\theta^3)/(1-\theta)^2 \text{ (2)}$$

where, C_{kc} is an empirical constant. **Equation 2** is essentially the classical KC function and is the starting point of our analysis. Average effective throat radius measured from CMT imagery is incorporated into **Equation 1** and fitted to the empirical data.

2. Methods

2.1 Experimental Setup

A schematic of the flow-through bioreactor ($L = 12$ mm, $ID = 8$ mm) is provided in the **Auxiliary Material 1**. The reactor was equipped with internal pressure ports and separate flow lines for urea media and calcium chloride to prevent precipitation outside the column. The column was packed with 600 μ m diameter soda lime glass beads.

2.2 Cementation Treatment

S. pasteurii (ATCC 6453) was grown to late exponential stage (~18 hours) in batch culture.

Prior to inoculation, microbes were rinsed with urea media (20.0 g $\text{CO}(\text{NH}_2)_2$, 10.0 g NH_4Cl , 2.1 g NaHCO_3 , 3.0 g Difco Nutrient Broth, total volume 1.0 L DI H_2O) by three rounds of centrifugation and resuspension in fresh urea media followed by pH adjustment to 6.5 with 1 N HCl. Columns were inoculated with approximately 10^{10} cells/ml and flow was discontinued for 4 hours allowing the microbes to revive and increase pore water pH. After the stagnant period

urea media was pumped at 1.00 ml/hr and CaCl_2 (100 g/L) at 0.067 ml/hr (using a Harvard '33' syringe pump) giving a total Darcy velocity of $5.9\text{E-}6$ m/hr and a 20mM calcium concentration.

2.3 Computed Microtomography

Imaging was performed at Beamline 8.3.2 at the Advanced Light Source (ALS), Lawrence Berkeley National Laboratory. Projections were acquired at $4.5\text{ }\mu\text{m/pixel}$ resolution with a monochromatic energy of 30 KeV and flow was discontinued during each scan which took ~40 minutes.

2.4 Porosity and Permeability Measurements

Permeability was measured under fixed flux conditions using a differential pressure transducer (Validyne, Model P55D, 1 PSI differential). CMT volumes were segmented into solid and fluid phases for porosity calculations. After applying a median filter (3x3x3 kernel) it was determined that a simple threshold was sufficient to segment the solid (glass and calcium carbonate) and liquid phases (image histograms are provided in **Auxiliary Material 2**).

2.5 Image Analysis Using 3DMA-ROCK

Segmented volumes were imported into 3DMA-ROCK (3DMA) for medial axis and pore body/throat construction. When referring to the 3DMA data, effective pore radi is the radius of a sphere of equivalent volume and effective throat radi is the radius of a circle of equivalent area. For more detailed information on the algorithms used within 3DMA refer to the manuscript by [Prodanović *et al.*, 2006] and references therein. A example medial axis and the corresponding pore throats is provided in **Auxiliary Material 3**.

Since medial axis and pore body/throat construction can be time intensive the analyzed image volume was restricted to a volume that could be processed within a reasonable amount of time. A

volume of 25 mm³ was found reasonable and took ~40 hours on a 64GB RAM, dual quad core Xeon X5355 2.66GHz processor platform to process.

3. Results

In total, 5 columns were analyzed, 1 column was a clean bead pack used to characterize the system prior to precipitation and the other 4 columns contained bioprecipitates. Once a column was imaged with CMT the experiment was ceased. This type of terminal sampling was required since preliminary experiments showed that x-ray exposure during a scan (2.2×10^{11} photons/(s mm²), ~40 minutes) killed 99 out of 100 microbes.

Porosity and permeability data for the 5 columns which range in porosity from 0.35 to 0.26 and had measured permeabilities ranging from 4 D to 20mD are shown in Figure 1. The clean glass bead pack is labeled as 5 in Figure 1. For the column with the smallest porosity change labeled as 4 in Figure 1 the cementation treatment took ~1day, the two columns labeled 3 and 2 in Figure 1 with intermediate porosity changes were treated for ~2 days, while the column with the greatest porosity change labeled 1 in Figure 1 was treated for ~3 days. The porosity profile over the vertical axis for each column is shown in **Figure 1A**. The average porosity versus measured permeability is shown in **Figure 1B** and shows a dramatic decrease in permeability from the starting point at $\theta = 0.35$ (5) for a clean glass bead pack to $\theta = 0.26$ (1) for a completely cemented packing. Initially the KC function ($\kappa = C_{kc}(\theta^b)$) was fitted to the raw data in log space with $C_{ck} = 7.0E-7$ and $b = 16.54$ providing the best fit possible, however, the variable b deviates far from realistic b values derived from KC theory (**Figure 1B**). More information on curve fitting and quality-of-fit statistics are provided in **Auxiliary Material 6** and **7**.

The average effective pore body radius, average effective pore throat radius, and permeability for each column are shown in the **Auxiliary Material 4**. The average effective pore

body and average effective throat radii decrease during precipitation. Because a fixed water flux was imposed by pumping, mean pore velocity and pore pressure significantly increase within the highly precipitated channel. Washout of precipitates was observed in the lower permeability columns and was likely due to this increased pore velocity; however, no data is available to quantify the amount of precipitate that was washed out.

As shown in the CMT images provided in **Figure 2A, B & C** calcium carbonate appears to precipitate on the glass bead surface and extend outward into the pore space. This type of arrangement is indicative of the coupling of mass transfer and growth kinetics where calcium must diffuse from the bulk pore-space to the reactive surface (**Figure 2C**) where precipitation occurs and extends the surface outward into the pore space. However, this arrangement could also be attributed to inconsistent local cell densities causing a variation in precipitation rate. Either way, this effectively causes some regions to develop “peaks” where precipitation is favored (i.e. accelerated). These “peak” regions extend into the pore space dividing up what was a single pore into multiple pores (as identified by 3DMA, **Auxiliary Material 4**) and in some locations enough precipitation occurs that adjacent beads become cemented together.

To better represent the permeability data with the KC function, average effective throat radius ($R_{\text{effective}}$) data were used to supplement **Equation 1**. For porosity values where $R_{\text{effective}}$ values were not available, a linear interpolation between measured $R_{\text{effective}}$ values was used. Tortuosity was held constant at 1.5 (average theoretical tortuosity for a clean glass bead pack) and the KC function with $R_{\text{effective}}$ was fit to the raw data, results (**Figure 1B**) show a better fit, however, this function still failed to represent the empirical data (fitting parameter, $C = 5.3$). In a third attempt tortuosity was used as a fitting parameter and allowed to change for each porosity value. The KC function with $R_{\text{effective}}$ and tortuosity included provided the best fit (**Figure 1B**,

fitting parameters, $C = 5.3$ & $\tau = 1.5$ to 7.2). However, this approach still did not completely represent the empirical data and a tortuosity value of 7.2 seems unrealistic. Most likely, in the case of biomineralization, the KC function is too simple to properly represent the complex porosity-permeability relationship. However, two reasonable propositions that could explain our inability to predict the empirical data with the KC function must be addressed, which are either (1) sub-CMT resolution precipitate morphology is significantly reducing permeability or (2) biofilm formation which is not visible with CMT is reducing permeability.

To address the first proposition, backscattered electron SEM images (Hitachi TM-1000, **Figure 2D, E, & F**) of the precipitates were acquired; the excavated samples were drained and air dried at 30°C for 48 hours before being mounted with carbon tape and imaged in low vacuum conditions to mitigate charging artifacts. SEM images show that calcium carbonate precipitates are an assemblage of spherical and cubic precipitates that are micro-porous. **Figure 2** suggests that when modeling biomineralization the precipitate should not be considered a solid phase, and thus, its internal micro-porosity should be considered. However, it is reasonable to suggest that micro-porosity would not dramatically effect permeability since the pores appear too small for bulk advective transport. **Supplementary Material** sections **8** and **9** provide additional details concerning the mixed precipitate morphology and precipitate composition. As found by Fredrich et al., 2006, the relationship between porosity and permeability depends on effective porosity and not the disconnected microporosity that exists at near sub-CMT resolution. Overall, micro-porosity is more likely an important parameter when considering reactivity, structural soil mechanics, and the geophysical signature of biomineralization.

A second possibility is clogging due to accumulated non-mineral biological products. Microbes and exopolymeric substances have very similar x-ray attenuation coefficient as water

and are not readily seen with CMT, thus any additional clogging due to bioaccumulation would not have been accounted for. However, recent confocal laser scanning microscopy images of *S. pasteurii* reported by [Shultz *et al.*, 2011] show that this particular organism forms a very sparse biofilm. Nevertheless, permeability reduction due to biofilm formation cannot be ruled out, at this point.

4. Conclusion

Our results demonstrate that traditional KC models are not sufficient for predicting the porosity-permeability relationship observed during biomineralization and geometric information from CMT images were needed to supplement the KC function. A similar conclusion was reached by Chen *et al.*, 2008, where inorganic colloid deposition within an initially simple porous media produced sufficient internal complexity, such that, the KC function could not provided a good fit. Pore morphology dramatically changed as a result of precipitation, increasing the number of pore bodies (and throats) and decreasing the effective radii of pore throats and pore bodies. The discrepancy with the simple KC function suggests that field scale reactive transport models will require more sophisticated porosity/permeability models to effectively capture changes in transport properties generated during bioremediation or biologically-enhanced CO₂ sequestration. Overall, biomineralized CaCO₃ substantially reduced permeability. When modeling this reduction, porosity, effective throat radius, tortuosity, and the biofilm phase should be considered to vary both spatially and temporally.

8. 2011GL046916-fs08.jpg Results of SEM/EDS characterization of precipitates covering bead surface : verification of precipitate composition. A sample from one of the reacted micro-columns was drained, air-dried for 48 hours at 50 C, and mounted on an SEM stub using carbon tape followed by Au/Pd coating. The sample was then imaged using a Zeiss Ultra 55 in high vacuum mode with a 5 kEv beam current. Both SE and EDS data (EDAX detector, 10mm²) were acquired for a select region of the sample. EDS data was acquired in a qualitative capacity due to the significant surface topography which makes quantitative elemental mapping procedures problematic. Panel (a) shows a secondary electron image of one glass bead with precipitates extracted from a reacted micro column. Panels (b,c,d,e) show elemental maps for Si, Ca, O, and P as characterized by EDS for the inset area. As can be seen, the glass bead is Si rich (SiO₂) while the precipitates are Ca rich (presumably CaCO₃) with O present in both phases. Phosphorus, a component of the media with crystallization potential, is not present in significant amount. Maps of Cl (not shown) demonstrate that negligible CaCl remained on the grain surface.

Small amounts of Ca are present within the glass (aprox. 9% by weight); this results in a measurable Ca fraction outside of the precipitate region (frame c). Fe, Mg, and Al were not present in large amounts. Considering the available cation supply present in the reactor influent, these results verify that the precipitates are CaCO_3 as anticipated.

9. 2011GL046916-fs09.jpg Results of environmental SEM characterization of precipitates showing mixed morphology (cubic vs. spheroidal). A sample from one of the reacted micro-columns was drained, air dried for 24 hours at 30 C, and mounted on an SEM stub with carbon tape. The uncoated sample was imaged under low vacuum to avoid charging effects in a low pressure SEM (Hitachi TM-1000) with a small water film intact. Panels (a) and (b) show BSE images of two areas with examples of precipitates composed of a mixture of morphologies; spheroidal features (presumably vaterite) in close proximity with more crystalline cubic features (presumably calcite).
