Using carboranes as counterions, fluorinated benzyl-type carbocations such as \((p\text{-FC}_6\text{H}_4)\text{H}_2\text{C}\text{F}^+, (p\text{-FC}_6\text{H}_4)(\text{CH}_3)\text{CF}^+\) and fluorinated trityl ions are readily isolated for X-ray and IR structural characterization.

The intermediacy of carbocations in electrophilic reactions of polyfluorinated compounds,¹ and the challenge of selective activation of fluorocarbons,²³ make the characterization of fluorinated carbocations important. The potential value of X-ray structural data as a complement to NMR characterization has been anticipated for some time⁴ but only one report of X-ray studies has appeared. The cations \((m\text{-CF}_3\text{-C}_6\text{H}_4)(\text{CH}_3)\text{CF}^+\) and \((\text{CH}_3)\text{CF}^+\) were isolated at low temperature from superacid media and characterized as fluoroarsenate salts.⁵ Given the ability of carborane counterions to stabilize carbocations such \(t\)-butyl cation for X-ray characterization at room temperature,⁶ it is of interest to investigate whether carborane anions would confer comparable stability on fluorinated carbocations.

Fluoride ion abstraction from a fluorocarbon using a trialkylsilyl carborane agent is a logical extension of successful chloride and triflate ion abstraction reactions with \(\text{RSi(carborane)}\) in the formation of \(\text{H(carborane)}\) superacids from \(\text{HCl}\) and highly electrophilic alkylating reagents, \(\text{R(carborane)}\), from alkyl triflates, respectively.⁷,⁸ Treatment of \(p\text{-FC}_6\text{H}_4\text{H}_2\text{C}\text{F}_3\) or \(\text{CH}_3\text{CF}_3\) with \(\text{Et}_3\text{Si(\text{CHB}_{11}\text{H}_{11})}\) using fluorobenzene as a solvent effects immediate abstraction of fluoride at temperatures as low as \(-25\) °C, as evidenced by the formation of \(\text{Et}_3\text{SiF} (\text{\(^{19}\text{F} NMR 173.9\) ppm})\). The highly reactive difluoro cations \(p\text{-FC}_6\text{H}_4\text{H}_2\text{CF}_2^+\) and \(\text{CH}_3\text{CF}_2^+\) are presumably formed but they apparently participate immediately in an electrophilic aromatic substitution reaction with the fluorobenzene solvent to form \((p\text{-FC}_6\text{H}_4\text{H}_2)\text{CF}^+ (\text{I}^+)\) and \((p\text{-FC}_6\text{H}_4)\text{(CH}_3)\text{CF}^+ (\text{II}^+)\). These cations have been prepared previously for low temperature NMR characterization by fluoride abstraction from appropriate difluoromethyl precursors using \(\text{SbF}_5\)⁹,¹⁰ and the arylation chemistry of fluoro carbocations has been studied extensively by Shteingarts.¹¹

Single crystals of \([(p\text{-FC}_6\text{H}_4)\text{CF]}\text{CHB}_{11}\text{H}_{11}]\text{C}_6\text{H}_3\text{F}, \text{I}, and \([(p\text{-FC}_6\text{H}_4)(\text{CH}_3)\text{CF}]\text{CHB}_{11}\text{H}_{11}], \text{II}, were grown from fluorobenzene solution at room temperature and \(-20\) °C respectively. Their X-ray structures¹¹ are shown in Figs. 1 and 2.† The cations are planar at their carbocationic centers having the sum of bond angles within experimental error of 360°. In contrast to the previously determined fluoroarsenate structures⁵ where distances between the carbocationic \(C^+\) atom and the anion \(\text{F}\) atom (2.66–3.04 Å) are shorter than the sum of the van der Waals radii (3.17 Å),¹²,¹³ there is no close approach of the carborane anion to the \(C^+\) atom in I and II. The shortest \(C^+\)–\(I\) distance is 4.22 Å in I and 3.90 Å in II whereas the sum of the van der Waals radii is 3.68 Å.

The closest approach of the anion to the cation in I is indicated by three \(I\) atom contacts at 3.48, 3.55 and 3.72 Å with the \(F\) atom attached to the \(C^+\) center. The triangular disposition of three

halide atoms of a carborane anion towards a cation reflects the purely electrostatic nature of the interaction.\textsuperscript{14}

The closest approach of the anion to the cation in 2 is indicated by two I atom contacts at 3.07 and 3.13 Å with H atoms of the CH$_3$ group. This is structural evidence for high acidity of the methyl group in this carbocation and is corroborated by IR spectroscopy. The νCH band is unusually broad and centered at very low energy (2750 cm$^{-1}$).

The sp$^2$ C–F bond lengths are 1.300(4) and 1.302(4) Å for 1 and 2 respectively, shorter than the average 1.342 Å for the sp$^2$ C–F bonds of the fluorobenzyl rings. This ca. 0.04 Å shortening must reflect the p$_x$ ability of F to backbond into the formally empty 2p$_z$ orbital on the C$^+$ atom. The C–F bond lengths are within three standard deviations of those in the fluoroarsenate structures, 1.316(5) Å in [(m-CF$_3$C$_6$H$_4$)(C$_6$H$_5$)$_2$CF][AsF$_6$] and 1.28(1) Å in the less precisely determined [(CH$_3$)$_2$CF][AsF$_6$].\textsuperscript{5} indicating less dependence on ancillary substituents than might have been expected. Even though the present structures have better R factors than the fluoroarsenate structures, more structural data will be necessary to understand the effect of charge distribution of C–F bond lengths. The competing effects of (a) different types of cation–anion electrostatic interactions, (b) conjugative effects of aryl substituents, and (c) hyperconjugative effects of alkyl substituents in delocalizing the positive charge cannot be presently delineated.

The C$^+$–C$_6$H$_4$F bond length of 1.430(4) Å in 2, as well as the average of 1.436(5) Å for the same bonds in 1, is shorter than the C$^+$–CH$_3$ bond in 2 (1.460(5) Å), reflecting the better conjugative ability of the aromatic group to stabilize the carbocationic center.

The IR band associated with the vCF for the C$^+$–F group in 1 and 2 appears as a sharp, strong absorption at 1155 and 1174 cm$^{-1}$ respectively. To the best of our knowledge, this is the first report of vCF at a carbocationic center. The frequencies are higher than vCF in neutral aliphatic fluorocarbons (ca. 1100 cm$^{-1}$),\textsuperscript{15} reflecting the double bond character arising from p$_x$(F) back donation to C$^+$.

The vCF bands associated with the p-F-phenyl groups in 1 and 2 deserve mention because they reflect charge density on the aryl ring. Frequencies increase in the order fluorobenzene < (p-F-C$_6$H$_4$)$_2$CF < (p-F-C$_6$H$_4$)$_2$(CH$_3$)CF < protonated p-fluorobenzene\textsuperscript{16} with values of 1239, 1265, 1290 and 1308 cm$^{-1}$ respectively, as expected from size-to-charge considerations.

While 2 slowly decomposes at room temperature, the (p-F-C$_6$H$_4$)$_2$CF$^+$ cation in 1 simply converts over several days in fluorobenzene to the (p-F-C$_6$H$_4$)$_2$C(=O)$^+$ trityl ion, detected by UV–vis spectroscopy some years ago.\textsuperscript{17} Thus, all of the C–F bonds of the original trifluoromethyl group have been broken, two of them being converted to C–C bonds. In an analogous reaction using the more highly fluorinated substrate C$_6$H$_4$F$_2$–CH$_3$, Trifluoromethyl-1,2,3-carborane (CHB$_1$Cl$_1$)$_2$ in fluorobenzene as solvent, the new trityl ion (p-F-C$_6$H$_4$)$_2$[CHB$_1$Cl$_1$]$_2$1.5CF$_3$H$_2$F, 3, and [(p-F-C$_6$H$_4$)$_2$(p-CH$_3$–C$_6$F$_4$)][CHB$_1$Cl$_1$]$_2$.1.5CF$_3$H$_2$F, 4, were formed readily and the X-ray structures determined.\textsuperscript{5,11}

The structures of the cations in 3 and 4 are generally similar to those of unfluorinated trityl ions and that in 4 is shown in Fig. 3.

They adopt propeller configurations with dihedral angles between the aryl groups and carbocation plane in the range 28–46°. However, unlike structures with fluoroanions,\textsuperscript{8,19} there are no close approaches of anion atoms to the carbocationic C atom. With their large size and low charge density, carborane anions tend to yield cation structures in their most “free” or intrinsic state. One feature of 4 that appears to be significant is the long C$^+$–Cipso bond to the tetrafluorophenyl group (1.460(4) Å). This compares to the average of 1.436(5) Å for the fluorophenyl rings in the same cation, the average of 1.439(6) for the three fluorophenyl rings in 3, and the average of 1.443(3) Å in the unfluorinated trityl salt with the BF[CF$_3$F$_4$(C$_6$H$_5$)$_3$] anion.\textsuperscript{19} Short distances are observed between the ortho F atoms and the C$^+$ center (2.831 and 2.858 Å compared to 3.17 sum of the van der Waals radii for C and F), suggesting intramolecular stabilization of positive charge. This would diminish the necessity of p$_x$ conjugative stabilization of charge by the aryl group and lengthen the C$^+$–Cipso bond.

In summary, this work shows that the use of carborane counterions instead of those from traditional superacids (fluoroarsenates and fluorantimonates) allows the intrinsic stability of fluorinated carbocations to be demonstrated. Corrosive media such as AsF$_5$ or SbF$_5$ can be avoided and long lived fluorinated carbocations can be produced in common organic solvents. The good crystallizing properties of carborane salts allow single crystals to be readily grown for X-ray characterization and IR analysis. The limitation to stabilizing more highly reactive fluorinated carbocations is now the solvent, not the anion. Future work with carboranes in less nucleophilic solvents (e.g. SO$_2$, SO$_2$CF$_2$) is anticipated to lead to the isolation of more highly fluorinated cations such as difluoro carbocations (RCF$_2^+$).

We thank Dr Bruno Donnadieu for assistance with X-ray structure determination and the National Science Foundation for support.
