For in every adult there dwells the child that was, and in every child there lies the adult that will be. — John Connolly, The Book of Lost Things

The 11th World Kidney Day will be celebrated on 10 March 2016, around the globe. This annual event, sponsored jointly by the International Society of Nephrology (ISN) and the International Federation of Kidney Foundations (IFKF), has become a highly successful effort to inform the general public and policymakers about the importance and ramifications of kidney disease. In 2016, World Kidney Day will be dedicated to kidney disease in childhood and the antecedents of adult kidney disease, which can begin in earliest childhood.

Children who endure acute kidney injury (AKI) from a wide variety of conditions may have long-term sequelae that can lead to chronic kidney disease (CKD) many years later [1–4]. Furthermore, CKD in childhood, much of it congenital, and complications from the many non-renal diseases that can affect the kidneys secondarily, not only lead to substantial morbidity and mortality during childhood but also result in medical issues beyond childhood (Figure 1). Indeed, childhood deaths from a long list of communicable diseases are inextricably linked to kidney involvement. For example, children who succumb to cholera and other diarrheal infections often die, not from the infection, but because of AKI induced by volume depletion and shock. In addition, a substantial body of data indicates that hypertension, proteinuria and CKD in adulthood have childhood antecedents—from as early as \textit{in utero} and perinatal life (see Table 1 for definitions of childhood). World Kidney Day 2016 aims to heighten general awareness that much adult renal disease is actually initiated in childhood. Understanding high-risk diagnoses and events that occur in childhood provides the potential to identify and intervene pre-emptively in those people at higher risk for CKD during their lifetime.

Worldwide epidemiological data on the spectrum of both CKD and AKI in children are currently limited, though increasing in scope. The prevalence of CKD in childhood is rare and has been variously reported at 15–74.7 per million children [3]. Such variation probably arises because data on CKD are influenced by regional and cultural factors, as well as by the methodology used to generate them. The World Health Organization (WHO) has recently added kidney and urological disease to mortality information tracked worldwide, which should be a valuable source of such data over time—yet WHO does not post the information by age group [5]. Databases such as the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) [6], the US Renal Data System (USRDS) [7] and the European Dialysis and Transplant Association (EDTA) registry [8] include data on paediatric end-stage renal disease (ESRD), and some on CKD. Projects such as the ItalKid [9] and Chronic Kidney Disease in Children (CKiD) [10] studies, the Global Burden of Disease Study 2013, as well as registries that now exist in many countries provide important information, and more is required [11].

AKI may lead to CKD, according to selected adult population studies [12]. The incidence of AKI among children admitted to an intensive care unit (ICU) varies widely—from 8 to 89% [1]. The outcome depends on the available resources. The results from projects such as the Assessment of Worldwide Acute
Kidney Injury, Renal Angina and Epidemiology (Aware) study, a five-nation study of AKI in children, are awaited [13]. Single-centre studies as well as meta-analyses indicate that both AKI and CKD in children account for a minority of CKD worldwide [2, 3]. However, it is increasingly evident that kidney disease in adulthood often springs from a childhood legacy.

The conditions that account for CKD in childhood, with a predominance of congenital and hereditary disorders, differ substantially from those in adults. To date, mutations in >150 genes have been found to alter kidney development or specific glomerular or tubular functions [14]. Most of these genetic disorders present during childhood, and many lead to progressive CKD. Congenital anomalies of the kidney and urinary tract (CAKUT) account for the largest category of CKD in children (see Table 2) and include renal hypoplasia/dysplasia and obstructive uropathy. Important subgroups among renal dysplasia are the cystic kidney diseases, which originate from genetic defects of the primary cilia of tubulointerstitial cells. Many paediatric glomerulopathies are caused by genetic or acquired defects of the podocytes, the unique cell type lining the glomerular capillaries. Less common but important causes of childhood CKD are inherited metabolic disorders such as hyperoxaluria and cystinosis, and atypical haemolytic uraemic syndrome (HUS), a thrombotic microangiopathy related to genetic abnormalities of complement, coagulation or metabolic pathways.

In various classifications, it is not clear how to categorise children who have suffered AKI and apparently recovered, or how and whether to include those children who have had perinatal challenges that are likely to have resulted in a relatively low nephron number.

Among children with childhood-onset ESRD, glomerulopathies are slightly more and congenital anomalies less common (Table 2), due to the typically more rapid nephron loss in glomerular disease. However, recent evidence suggests that many patients with milder forms of CAKUT may progress to ESRD during adulthood, peaking in the fourth decade of life [15].

There are national and regional differences in the types and course of both AKI and CKD during childhood and beyond. Death from kidney disease is higher in developing nations, and national and regional disparities in care and outcome must be addressed. Furthermore, access to care is variable, depending on the region, the country and its infrastructure. By focussing on kidney disease in childhood, cost-effective solutions may be reached, as treating disease early and pre-emptively may prevent later, more advanced CKD. Expectations depend on the availability of care and management. Treating children, even from infancy, who have AKI and CKD that requires renal replacement therapy (RRT) can be effective in mitigating the burden of kidney disease in adulthood. Doing so requires resources that focus on the most expeditious and cost-effective ways to deliver acute RRT in childhood.

In regions where antenatal foetal ultrasounds are routine, many children with urological abnormalities are identified antenatally, which permits early intervention. However, in many parts of the world, children with structural abnormalities are not identified.
until much later, when symptoms develop. While generalized screening for proteinuria, haematuria and urinary tract infections is carried out in some countries and regions, there is a lack of consensus as to its effectiveness. However, there is general agreement that children with antenatal ultrasound studies that indicate possible genitourinary anomalies, children with a family history of kidney disease and children with signs such as failure to thrive or a history of urinary tract infection, voiding dysfunction or an abnormal appearing urine should be examined. Initial screening would include a focussed physical examination and a urine dipstick, formal urinalysis and a basic chemistry panel, followed by a more focussed evaluation if indicated.

Depending on the diagnosis, definitive therapy may be indicated. However, the evidence that therapy will slow progression of CKD in childhood remains limited. Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, antioxidants and, possibly, dietary changes may be indicated, depending on the diagnosis. However, dietary changes need to permit adequate growth and development. The ESCAPE Trial provided evidence that strict blood pressure control retards progression of CKD in children irrespective of the type of underlying kidney disease [16].

Some very young children may require RRT in early infancy. Recent data pooled from registries worldwide indicate good survival, even when dialysis is required from neonatal age [2, 17]. Kidney transplantation, the preferred RRT in children, is generally suitable after 12 months of age, with excellent patient and allograft survival, growth and development.

Evidence is accumulating that childhood-onset CKD leads to accelerated cardiovascular morbidity and shortened life expectancy. Ongoing large prospective studies such as the Cardiovascular Comorbidity in Children with CKD (4C) study are expected to inform about the causes and consequences of early cardiovascular disease in children with CKD [18].

In addition to those children with congenital kidney disease, it is now known that perinatal events may affect future health in the absence of evident kidney disease in early life [19]. Premature infants appear to be particularly at risk for kidney disease long after they are born, based both on observational cohort studies, as well as on case reports. Increasingly premature infants survive, including many born well before nephrogenesis is complete [20]. The limited available data indicate that in the process of neonatal ICU care, such babies receive many nephrotoxins, and that those dying prior to discharge from the nursery have fewer and larger glomeruli [21]. Additionally, those surviving have evidence of renal impairment that may be subtle [22]. Even more concerning, abundant epidemiological data indicate that persons born at term but with relatively low birth weights may be at high risk for hypertension, albuminuria and CKD later in life [23]. When direct measurements are pursued, such persons, as adults, may have fewer nephrons, and thus a low cardiorenal endowment.

In focussing on children for World Kidney Day, we would note that it is key to follow kidney function and blood pressure throughout life in those persons born early or small-for-dates. By doing so, and avoiding nephrotoxic medications throughout life, it may be possible to avert CKD in many people.

Disparities exist in the availability of resources to treat AKI in children and young people; consequently, too many children and young adults in developing nations succumb if AKI occurs. To address the problem, the ISN has initiated the Saving Young Lives Project, which aims both to prevent AKI with prompt treatment of infection and/or delivery of appropriate fluid and electrolyte therapy, and to treat AKI when it occurs. This ongoing project in Sub-Saharan Africa and South East Asia, in which four kidney foundations participate equally [IPNA (International Pediatric Nephrology Association), ISN, ISPD (International Society for Peritoneal Dialysis) and SCKCF (Sustainable Kidney Care Foundation)], focuses on establishing and maintaining centres for the care of AKI, including the provision of acute peritoneal dialysis. It links with the ISN’s 0 by 25 project, which calls on members to ensure by 2025 that nobody dies from preventable injury and AKI.

In view of the preponderance of congenital and hereditary disorders, therapeutic resources for children with CKD have historically been limited to a few immunological conditions. Very recently, progress in drug development in concert with advances in genetic knowledge and diagnostic capabilities has begun to overcome the long-standing ‘therapeutic nihilism’ in paediatric kidney disease. Atypical HUS, long considered ominous, with a high likelihood of progression to ESRD and post-transplantation recurrence, has turned into a treatable condition with the advent of a monoclonal antibody that specifically blocks C5 activation [24]. Another example is the use of vasopressin receptor antagonists to retard cyst growth and preserve kidney function in polycystic kidney disease [25]. First proven efficacious in adults with autosomal dominant polycystic kidney disease, therapy with vaptans holds promise also for the recessive form of the disease, which presents and often progresses to ESRD during childhood.

However, patient benefit from pharmacological research breakthroughs is jeopardized on a global scale by the enormous cost of some of the new therapeutic agents. The quest for affordable innovative therapies for rare diseases will be a key issue in paediatric nephrology in the years to come.

The identification of children likely to benefit from novel therapeutic approaches will be greatly facilitated by the development of clinical registries that inform about the natural disease course, including genotype–phenotype correlations. Apart from disease-specific databases, there is also a need for treatment-specific registries. These are particularly relevant in areas where clinical trials are difficult to perform due to small patient numbers and lacking industry interest, as well as for therapies in need of global development or improvement. For instance, there is currently a large international gradient in the penetration and performance of paediatric dialysis and transplantation. Whereas paediatric patient and technique survival rates are excellent and even superior to those of adults in many industrialized countries, it is estimated that almost half of the world’s childhood population is not offered chronic RRT at all. Providing access to RRT for all children will be a tremendous future challenge. To obtain reliable information on the demographics and outcomes of paediatric RRT, the IPNA is about to launch a global population-based registry. If successful, the IPNA RRT registry might become a role model for global data collection.

Transition of care for adolescents with kidney disease into an adult setting is critical for both patients and their caregivers. Non-adherence is a too-frequent hallmark of transition from paediatric
to adult care for young patients with chronic disease states [26–28]. Hence, considered steps combined with systematically defined procedures supported by validated pathways and credible guidelines must be in place to ensure successful outcomes.

In the process of change from paediatric to adult care, ‘transition’, which should occur gradually, must be distinguished from ‘transfer’, which is often an abrupt and mechanistic change in provider setting. Introducing the concept of transition should be pre-emptive, starting months to years prior to the targeted time, as children move into adolescence and adulthood. The ultimate goal is to foster a strong relationship and individualized plan in the new setting that allows the patient to feel comfortable enough to report non-adherence and other lapses in care.

A transition plan must recognize that the emotional maturity of children with kidney disease may differ widely. Assessment of the caregiver and the family structure as well as cultural, social and financial factors at the time of transition are key, including a realistic assessment of caregiver burden [4]. The appropriate timing and format of transition may vary widely among different patients and in different settings; therefore, a flexible process without a set date and even without a delineated format may be preferred.

Importantly, transition may need to be slowed, paused or even reversed temporarily during crises such as disease flares or progression, or if family or societal instability occurs. A recent joint consensus statement by the ISN and the IPNA proposed steps consistent with the points just outlined, aiming to enhance the transition of care in kidney disease in clinical practice [29, 30].

Given the vulnerabilities of children with kidney disease, including impact on growth and development and future life as an adult, and given the much greater proportion of children in developing nations facing resource constraints, educating everyone involved is imperative in order to realign communications and actions [31, 32]. These efforts should foster regional and international collaborations and exchange of ideas between local kidney foundations, professional societies, other not-for-profit organizations, and states and governments, so as to help empower all stakeholders to improve the health, well-being and quality of life of children with kidney diseases and to ensure their longevity into adulthood.

Until recently, however, the WHO consensus statement on non-communicable diseases (NCDs) included cardiovascular disease, cancer, diabetes and chronic respiratory disease, but not kidney disease [33, 34]. Fortunately, due, in part, to a global campaign led by the ISN, the Political Declaration on NCDs from the United Nations Summit in 2011 mentioned kidney disease under Item 19 [35].

Increasing education and awareness about renal diseases in general and kidney disease in childhood in particular is consistent with the objectives of the WHO to reduce mortality from NCD, with 10-year target population level initiatives focussing on changes in life style (including tobacco use reduction, salt intake control, dietary energy control and alcohol intake reduction) and effective interventions (including blood pressure, cholesterol and glycaemic control). Heightened efforts are needed to realign and expand these multidisciplinary collaborations with more effective focus on early detection and management of kidney disease in children. Whereas the issues related to kidney disease may be overshadowed by other NCDs with apparently larger public health implications such as diabetes, cancer and cardiovascular diseases, our efforts should also increase education and awareness on such overlapping conditions as cardiorenal connections, the global nature of the CKD and ESRD as major NCDs, and the role of kidney disease as the multiplier disease and confounder for other NCDs. White papers including consensus articles and blueprint reviews by world class experts can serve to enhance these goals [36].
