#### Abstract

Hormesis has been widely observed and debated in a variety of context in biomedicine and toxicological sciences. Detecting its presence can be an important problem with wide ranging implications. However, there is little work on constructing an efficient experiment to detect its existence or estimate the threshold dose. We use optimal design theory to develop a variety of locally optimal designs to detect hormesis, estimate the threshold dose and the zero-equivalent point (ZEP) for commonly used models in toxicology and risk assessment. To facilitate use of more efficient designs to detect hormesis, estimate threshold dose and estimate the ZEP in practice, we implement computer algorithms and create a user-friendly web site to help the biomedical researcher generate different types of optimal designs. The online tool facilitates the user to evaluate robustness properties of a selected design to various model assumptions and compare designs before implementation.

a monograph on hormesis (Luckey 1991). Other examples can be found in disciplines, such as biomedical or toxicological sciences; see for example, Rodricks (2003), Calabrese (2005), Cook and Calabrese (2006a), Thayer et al. (2006), Cook and Calabrese (2006b), Calabrese (2009), Foran (1988), Sielken and Stevenson (1998), Teeguarden et al. (2000). Hormesis is characterized by having beneficial effect when the mean response is stimulated at low doses and becomes inhibitory at high doses (Calabrese 2005; Thayer et al. 2006). For hormesis to exist, there is conceptually an assumed threshold and the question becomes whether such a threshold exists in the assumed model that matches reality (Cox 1987; Slob 1999). Such an issue was discussed as early as 1971 in Hatch (1971) and continues to today in disciplines such as aging, biology, crop growth, environmental science, food chemistry, material science, medicine, pharmaceutical sciences, radiation physics, technology; some recent examples include Vaiserman (2011), Radak et al. (2017), Zou et al. (2017), Sthijns et al. (2017), Abbas et al. (2017), Roullier-Gall et al. (2016), Ji et al. (2016).

Detecting the presence of hormesis can be an important problem with wide ranging implications (Cook and Calabrese 2006a; Foran 1988; Sielken and Stevenson 1998; Teeguarden et al. 2000). As the dose increases, the shapes of the mean toxicological response can vary from J-shaped to inverted U-shaped with different threshold models (Goetghebeur and Pocock 1995; Hunt and Rai 2005; Ulm 1991). There is also recent research that suggests exercise, oxidants and antioxidants may change the shape of a belled shape hormetic response curve (Radak et al. 2017).

An example that shows possible existence of hormesis in an aquatic toxicological experiment conducted by the US Environmental Protection Agency to identify effluents and receiving waters containing toxic materials. The whole effluent toxicity (WET) test is used to estimate the toxicity of waste water caused by many different species (Denton and Norberg-King 1996; Lewis et al. 1994). There are several endpoints to measure the aggregate toxic effect of an effluent. For many of these biological endpoints, toxicity is manifested as a reduction in the response relative to the control group. The WET testing involves multi-concentrations and includes several concentrations of effluent and a control group with a zero dose. More information about the WET testing can be found at https://www3.epa.gov/. Figure 1 shows a somewhat inverted U-shaped dose-response curve constructed using data set collected in Lewis et al. (1994) for a real study. The species in this experiment is Ceriodaphnia dubia, which is frequently used in toxicity testing of waste water treatment plant effluent water in the United States. The endpoint is a measure of reproduction given by the total number of young Ceriodaphnia dubia.

Experimental designs for studying the existence of hormesis are not well investigated at all. We could only locate a couple of references that discussed design issues for such studies and they include Hunt (2002a), Hunt (2002b) and Hunt and Bowman (2004). One of their findings was that increasing the number of low-level doses improves the power for detecting hormetic effect and that current designs do not seem adequate to detect existence of hormesis. The work by Dette et al. (2011) appears to be the first technical piece of work to set up formal hypotheses to detect hormesis and estimate threshold level and construct different types of optimal designs for various purposes in such studies. In particular, a hypothesis to formally test whether hormesis exists using a model based approach is formulated in Dette et al. (2011).

A main goal of this paper is to study design issues for detecting hormesis for the two models proposed in Deng et al. (2001) where both models have an inverted U-shaped mean response curve. A second goal is to create a set of user-friendly codes that is freely accessible to all and allows researchers to find tailor-made optimal designs for their problems, compare competing designs and evaluate robustness properties of a selected design. In particular, the online tool allows us to readily compare efficiencies of different designs across models, including the different models proposed for study-ing hormesis in Dette et al. (2011). We expect that having an online tool is likely going to be more effective than providing computer programs to researchers in biomedicine in terms of encouraging them to explore important design issues. Our hope is that the web-based tool will facilitate researchers in using a more informed design for their studies to investigate the existence of hormesis and estimate the threshold dose.

Section 2 provides the statistical background for our model-based approach to find an optimal experiment design using theory. In Sect. 3, we discuss two models in Deng et al. (2001) and determine different types of locally optimal designs for the two models. In Sect. 4 we evaluate robustness properties of an optimal design to various violations in the model assumptions. This is an important task to undertake before implementing the optimal design because an optimal design can be sensitive to model assumptions and optimality criteria, see for example, Wong (1994); Moerbeek (2005). Section 5 describes our newly created website that enables users to compute and select more effective designs for detecting hormesis and the threshold value.

#### 2 Statistical background

In this section we recall background and review theory for finding an optimal design. We present statistical models and optimality criteria based on information matrices.

#### 2.1 Statistical models

The mean response of the extended Gompertz model is given by

$$\mu(d,\theta) = \theta_1 - \theta_2 d + \frac{\theta_3}{\theta_4} (1 - e^{-\theta_4 d}), \tag{1}$$

🖄 Springer

where  $\theta_1$  is the intercept,  $\theta_2$  is a rate constant,  $\theta_3$  is a hybridized parameter and  $\theta_4$  is a first-order rate constant. The covariate *d* may be the age for describing the agespecific mortality rate (Boxenbaum et al. 1988; Neafsey et al. 1988) or represent a dose concentration used to arrest the growth of a cancerous tumor.

An alternative model—with also four nonlinear parameters—is the linear-logistic model whose mean response is given by

$$\mu(d,\theta) = \frac{\theta_1 + \theta_2 d}{1 + e^{-\theta_3} d^{\theta_4}}.$$
(2)

This model was proposed in Vanewijk and Hoekstra (1993) where d may represent the dose concentration for testing hormesis in ecotoxology and toxicological studies. A similar model with an additional linear parameter was used in Brain and Cousens (1989) in herbicide dose–response studies.

The errors in both models are assumed to be normally and independently distributed each with mean 0 and constant variance. These assumptions are the same as those used in Dette et al. (2011) for designing studies to detect existence of hormesis. In both models,  $\theta = (\theta_1, \theta_2, \theta_3, \theta_4)$  denotes the vector of parameters in the model.

#### 2.2 Approximate design and information matrix

Suppose we have resources to take a predetermined number N of observations from the study. Researchers choose several doses  $d_1, d_2, \ldots, d_k$  from a given dose interval  $[0, \bar{d}]$  to observe the N responses. Given a design criterion, a statistical model and a known value of  $\bar{d}$ , the design questions are the optimal number k and locations of these design points, along with the optimal proportion of observations  $w_i$ to take at  $d_i, i = 1, \ldots, k$ . We denote this generic k-point approximate design by  $\xi = \{d_1, d_2, \ldots, d_k; w_1, w_2, \ldots, w_k\}$ . In practice, a simple way to implement the experiment is by rounding each  $Nw_i$  to an integer  $N_i$  so that  $N_1 + \ldots + N_k = N$ . For more sophisticated rounding procedures, see Pukelsheim and Rieder (1992).

Approximate designs can be studied under a broad framework when the design criterion is convex or concave on the set of approximate designs. In particular, it is straightforward to use the so-called Equivalence Theorem (Kiefer and Wolfowitz 1960), which is based on the directional derivative of the convex functional, to verify whether an approximate design is optimal among all designs on  $[0, \bar{d}]$ . If it is not, the theory also provides us an assessment of its proximity to the optimum, without knowing the optimum; see Sect. 3. Monographs on optimal design theory, such as Fedorov (1972) and Atkinson et al. (2007) , provide details and applications of the theory to find different types of optimal designs. Wong and Lachenbruch (1996) gives a tutorial on finding optimal approximate designs for dose response studies.

Given a design  $\xi$ , the covariance matrix of the least squares estimator of  $\theta$  is asymptotically proportional to the inverse of the normalized information matrix

$$M(\xi,\theta) = \sum_{i=1}^{k} w_i f(d_i,\theta) f^T(d_i,\theta),$$

where

$$f(d, \theta) = \frac{\partial \mu(d, \theta)}{\partial \theta}$$

is the vector of partial derivatives of  $\mu(d, \theta)$  with respect to the model parameters. For instance, for models (1) and (2) we have, respectively

$$\begin{split} f(d,\theta) &= \left(1, -d, \frac{1}{\theta_4}(1 - e^{-\theta_4 d}), -\frac{\theta_3}{\theta_4^2}(1 - (\theta_4 d + 1)e^{-\theta_4 d})\right)^T, \\ f(d,\theta) &= \left(\frac{1}{1 + e^{-\theta_3}d^{\theta_4}}, \frac{d}{1 + e^{-\theta_3}d^{\theta_4}}, \frac{(\theta_1 + \theta_2 d)e^{-\theta_3}d^{\theta_4}}{(1 + e^{-\theta_3}d^{\theta_4})^2}, \right. \\ &\left. -\frac{(\theta_1 + \theta_2 d)e^{-\theta_3}d^{\theta_4}\ln(d)}{(1 + e^{-\theta_3}d^{\theta_4})^2}\right)^T. \end{split}$$

#### 2.3 Optimality criteria

There are different purposes in a study and the design optimality criterion should be suitably chosen. If there is interest in estimating all parameters in the mean response, an appropriate choice is the popular *D*-optimality criterion. In toxicology there is often interest to estimate a meaningful function of the model parameters. For instance, we may be interested to find an efficient design to estimate the zero equivalent point (ZEP) dose  $\tau$  (Deng et al. 2001) or a design that is most efficient for detecting existence of hormesis.

The *D*-optimal criterion seeks to maximize the determinant of the information matrix  $M(\xi, \theta)$  over all possible designs on the dose interval of interest. Mathematically, this is the same as maximizing the log determinant of the information matrix, which is a concave function of the information matrix. For a nonlinear model, any criteria depends on some of the unknown parameters and consequently any *D*-optimal design that optimizes the determinant depends on the unknown parameters  $\theta$ .

This means that we require nominal values of the model parameters before we can compute a locally optimal design that optimizes a user-selected criterion. The nominal values typically come from expert opinions or related studies. Therefore, we denote the *D*-optimal design by  $\xi_D^*(\theta)$ . More generally, optimal designs that depend on the unknown parameter  $\theta$  are called locally optimal designs. When errors are normally and independently distributed, *D*-optimal designs minimize the generalized variance of the estimates for all parameters and so these designs are appropriate for estimating model parameters. From Kiefer and Wolfowitz (1960), if errors have constant variances, *D*optimal designs are also optimal designs for estimating the response surface across the design interval.

To define the  $\tau$ -optimality design criterion for estimating the ZEP dose  $\tau$  we recall the definition of the ZEP dose

$$\tau = \tau(\theta) = \max\{d \in [0, d] : \mu(d, \theta) = \mu(0, \theta)\}.$$

1311

Using Delta's method, the asymptotic variance of its estimate is proportional to

$$\operatorname{Var}_{\tau}(\xi) = b^{T}(\theta)M^{-1}(\xi,\theta)b(\theta),$$

where  $b(\theta) = \partial \tau(\theta) / \partial \theta$  and assuming  $\tau$  is differentiable with respect to  $\theta$ . The locally  $\tau$ -optimal design  $\xi_{\tau}^*(\theta)$  is the approximate design that minimizes  $\operatorname{Var}_{\tau}(\xi)$  over all other approximate designs on the given dose interval.

To detect existence of J-shaped hormesis, Dette et al. (2011) showed that an appropriate hypothesis to test is

$$H_0: \mu'(0,\theta) \ge 0$$
 vs.  $H_1: \mu'(0,\theta) < 0$ ,

but for the inverted U-shaped hormesis considered here, the null hypothesis is  $H_0$ :  $\mu' \leq 0$ , where  $\mu'(d, \theta) = \partial \mu(d, \theta) / \partial d$  and assuming  $\mu$  is differentiable with respect to *d*.

To maximize the power of this test, we first need an estimate of the model parameters  $\theta$ ; subsequently we minimize the asymptotic variance of  $\mu'(d, \hat{\theta})$ , which is proportional to

$$\operatorname{Var}_{h}(\xi) = h^{T}(\theta) M^{-1}(\xi, \theta) h(\theta),$$

where  $h(\theta) = \partial \mu'(0, \theta) / \partial \theta$ . A design  $\xi_h^*(\theta)$  is a locally *h*-optimal design if it minimizes  $\operatorname{Var}_h(\xi)$  over the set of all approximate designs on the dose interval.

The two asymptotic variances defined just above have the same functional form,  $c^{T}(\theta)M^{-1}(\xi,\theta)c(\theta)$  for a known vector  $c(\theta)$ . That is, they are particular cases of the well known c-optimality criterion commonly discussed in design monographs, such as Fedorov (1972) and Silvey (1980).

#### 3 Efficiencies and locally optimal designs

In practice, nominal values from experts or previous studies may not be accurate and it is important to evaluate how robust the optimal design is to mis-specification of the nominal values. This assessment is commonly made using the concept of the efficiency of a design. For example, suppose we have a nonlinear model with *m* parameters in the mean response and the vector of nominal values for the parameters is  $\theta$ . If  $\xi_D^*(\theta), \xi_\tau^*(\theta), \xi_h^*(\theta)$  is, respectively, the *D*,  $\tau$  and *h*-optimal designs for the problem, the *D*-efficiency of an approximate design  $\xi$  is

$$\operatorname{Eff}_{D}(\xi,\theta) = \left(\frac{\det M(\xi,\theta)}{\det M(\xi_{D}^{*}(\theta),\theta)}\right)^{1/m}$$

Similarly, the  $\tau$ -efficiency of  $\xi$  is

$$\operatorname{Eff}_{\tau}(\xi,\theta) = \frac{\operatorname{Var}_{\tau}(\xi_{\tau}^{*}(\theta),\theta)}{\operatorname{Var}_{\tau}(\xi,\theta)}$$

and the *h*-efficiency of  $\xi$  is

$$\operatorname{Eff}_{h}(\xi,\theta) = \frac{\operatorname{Var}_{h}(\xi_{h}^{*}(\theta),\theta)}{\operatorname{Var}_{h}(\xi,\theta)}$$

If the efficiency is 0.5, the design  $\xi$  has to be replicated twice to have the same criterion value as that of the optimal design. In the ideal world, we want designs with high efficiencies across different criteria, different models and reasonable changes in the nominal values.

The concept of efficiency is useful also when we do not know the optimum design. In fact when we wish to compare two designs  $\xi_1$  and  $\xi_2$ , we compute their relative efficiency using an appropriate ratio of the values of the optimality criterion evaluated at the two designs. If the relative efficiency is close to unity, the two designs are about equally efficient. Furthermore, when the criterion is convex or concave, the equivalence theorem can also be used to confirm the optimality of any approximate design. The mathematical derivation of the equivalence theorem provides, as a side product, an efficiency lower bound for the design under investigation (Pukelsheim 1993). This is helpful because we can check how close a design is to the optimum without knowing the optimum; if this efficiency lower bound is sufficiently high, say 99%, the practitioner may terminate the search for the optimal design, declare it as a nearly optimal design and use it in practice.

We next present locally optimal designs for the two models that we have found numerically. We also report efficiencies of the design

$$\xi_p = \{0, 1.56, 3.12, 6.25, 12.5; 1/5, \dots, 1/5\},\tag{3}$$

used in the WET test (Deng et al. 2001) under the 3 criteria considered in the paper for different choices of nominal values of the parameter models. Practitioners can reproduce our results using the web-based tool; even more, with the available app they can evaluate the efficiency of any other design, any other values of the model parameters or a combination of both.

#### 3.1 Locally D-optimal designs

The locally *D*-optimal designs are found by straightforward maximization of the determinant of the information matrix of a 4-point design using nominal values for the parameters. For approximate designs, we first search among all 4-point designs because the number of design points for a *D*-optimal approximate design is frequently equal to the number of the parameters in the mean response and when this is true, the weights at the design points can be shown to be equal (see Lemma on p. 42 in Silvey (1980)). We may use an equivalence theorem (see White (1973) for the nonlinear models case) to verify the optimality of an approximate design under a concave functional, like *D*-optimality. These equivalence theorems are widely discussed in design monographs (Fedorov 1972; Silvey 1980). If conditions in the equivalence theorem are violated, the computed 4-point design is not optimal and we consider optimizing the information matrix over the space of all 5-point designs, and so on. Table 1 Locally D-optimal and h-optimal designs for model (1) for selected values of  $\theta_4$ 

The last two columns show *D*-efficiencies (first 3 rows) and *h*-efficiencies (last 3 rows) of  $\xi_p$  and of the locally *D*-optimal and *h*-optimal designs with a vector of mis-specified nominal values where  $\theta_4^0 = 0.09$ 

the number of support points and the number of parameters in the nonlinear case is not so straightforward: this observation dates back to Ford et al. (1992)

For model (1), we can theoretically verify that the locally *D*-optimal design  $\xi^*(\theta)$  does not depend on  $\theta_1$ ,  $\theta_2$  and  $\theta_3$  and depends only on  $\theta_4$ . This is because the information matrix for the model does not depend on parameters  $\theta_1$ ,  $\theta_2$  and  $\theta_3$  nonlinearly. In contrast, the locally *D*-optimal design  $\xi^*(\theta)$  for model (2) depends on all parameters  $\theta_1$ ,  $\theta_2$ ,  $\theta_3$  and  $\theta_4$ .

Table 1 displays optimal design points or doses  $d_1, d_2, d_3$  and  $d_4$  of the equally weighted locally D-optimal design for model (1) for several nominal values of  $\theta_4$ . Table 2 displays the corresponding results for model (2) for various nominal values of the parameters vector  $\theta$ . The choice of the first nominal values for each model displayed in each Table comes from fitting the data in the WET test (see Fig. 1). It is important to choose meaningful values of the parameters to investigate. This may not be obvious and the range of alternative values of the parameter to study can be highly model dependent. Plotting the mean response for different sets of nominal values can be helpful to arrive at a meaningful range of values in the parameters to investigate. For example, for Gompertz curve the choice of  $\theta_4 = 0.15$  (maintaining the values of the other model parameters) is unacceptable because the mean response curve becomes negative when the dose levels exceed 10 units. This is problematic because the mean response is the total number of young Ceriodaphnia dubia and so it cannot take on negative values. Therefore, we chose closest values to  $\theta_4 = 0.09$  for model (1). On the other hand, the range of values we chose for the model (2) seem appropriate because the mean response is not negative over the range of doses we studied.

From the two tables, we observe that the design  $\xi_D^*(\theta)$  for model (1) always requires the 0 dose (placebo) and the largest admissible dose  $\overline{d}$  (= 12.5). However, for model (2), the design  $\xi_D^*(\theta)$  always contains the 0 dose but the largest dose may not be at  $\overline{d}$ . The two interior doses  $d_2$  and  $d_3$  in the *D*-optimal designs for model (1) are approximately 3 and 8.5 respectively. We note that one of the interior doses in the implemented design (3) is 3.12, which is close to one of the interior doses of the *D*-

optimal designs. The intermediate doses of the locally *D*-optimal designs for model (2) are more variable; for instance,  $d_2$  varies between 2.6 and 4.2. We also observe that the locally *D*-optimal design  $\xi_D^*(\theta)$  for model (2) depends slightly on  $\theta_1$  or  $\theta_2$ ; this suggests that a slight mis-specification of the nominal values of these parameters is unlikely to cause a big drop in *D*-efficiencies.

The last two columns of Tables 1 and 2 show the *D*-efficiency of the implemented design  $\xi_p$  which is approximately 0.82 for model (1) and in the range 0.735 – 0.864 for model (2). We report other efficiencies of this design later on and show that optimal design theory can provide us with a more efficient design for estimating parameters and also a design which is more robust to model assumptions and optimality criteria than the implemented design.

Tables 1 and 2 also show the *D*-efficiencies of the locally *D*-optimal design for the nominal value  $\theta^0$  for other nominal values of the parameters  $\theta$ . We observe that, *D*-optimal designs for model (1) varies when values of  $\theta_4$  are close to  $\theta_4^0$  but efficiencies remain close to 1. We note that in performing such a robustness study to ascertain sensitivities of the optimal design to nominal values, it is important to choose meaningful values of the parameters. If we evaluate the robustness of the locally *D*-optimal when  $\theta_4^0$  is 0.09 but the true nominal is 0.15, we obtain a *D*-efficiency of 0.996. While this may seem reassuring, we recall that the choice of  $\theta_4 = 0.15$  is unacceptable.

Further, we observe that the *D*-efficiencies of  $\xi(\theta^0)$  from Table 2 are close to 1 for different values of  $\theta_1$  and  $\theta_2$  when  $\theta_3$  and  $\theta_4$  are constant. This confirms that the *D*-optimal design depends only slightly on  $\theta_1$  and  $\theta_2$  for model (2) and are robust against small deviations of nominal values; in other words, small deviations from the real value of  $\theta_1$  or  $\theta_2$  do not seem to have an impact on the efficiency of the optimal design.

#### 3.2 Locally *τ*-optimal designs

Numerical calculations show that for each model, the locally  $\tau$ -optimal design  $\xi_{\tau}^*(\theta)$  is a two-point design concentrated at the placebo dose, 0, and the ZEP dose  $\tau(\theta)$  (see Table 3). Such a specific form of  $\xi_{\tau}^*(\theta)$  was also observed for the other models in Dette et al. (2011).

The last column in Table 3 report the  $\tau$ -efficiencies of the implemented design  $\xi_p$ . It has low  $\tau$ -efficiencies, under 0.465 for model (1) and under 0.497 for model (2) for the nominal values of  $\theta$  considered in this work. This may not be surprising since we are comparing the equally weighted two-point optimal designs at the placebo dose and at the ZEP dose with a design supported at five different doses spread over the same dose interval.

#### 3.3 Locally *h*-optimal designs

Tables 1 and 2 show 4-point locally *h*-optimal designs  $\xi_h^*(\theta)$  for the two models. We observe their optimal doses are close with those of the locally *D*-optimal designs. For example, for model (1) the doses for the *h*-optimal design when  $\theta_4 = 0.09$  are 0, 2.710, 8.917 and 12.5, which are very close to the *D*-optimal design doses: 0, 3.009, 8.557

|                                               |         |     |    |      |                |                        |

and 12.5 for the same nominal parameter values. From our examples, we observe that the locally *h*-optimal designs  $\xi_h^*(\theta)$  for model (1) always include the 0 dose and the largest possible dose  $\bar{d}(= 12.5)$ . For model (2), the locally *h*-optimal design  $\xi_h^*(\theta)$  always contains the 0 dose but may not include the largest admissible dose  $\bar{d}$ .

Unlike *D*-optimal designs, the *h*-optimal designs are not equally weighted, i.e. not every dose in the *h*-optimal design requires the same number or proportion of observations. For the nominal values considered, the *h*-optimal designs for both models require roughly 80% or more of the total observations be at the two lowest doses,  $d_1$  and  $d_2$ . The optimal design for model (2) requires fewer than 9.5% observations at its largest dose,  $d_4$ , and the optimal design for model (1) requires fewer than 5.5% observations at its largest dose.

Tables 1 and 2 also show *h*-efficiencies of the implemented designs  $\xi_p$  and the *h*-optimal design when some of the nominal values are mis-specified and the assumed vector of the nominal values is  $\theta^0$ , and more specifically, only  $\theta_4^0$  in the model (1). From both tables, the implemented design  $\xi_p$  has low *h*-efficiencies for all the nominal values of the tables, around 50% for model (1) and in the range 37%–61% for model (2). The design  $\xi_p$  has higher *h*-efficiencies than  $\tau$ -efficiencies, suggesting it performs better for detecting hormesis than for estimating the ZEP dose. The tables also show  $\xi_p$  has higher *D*-efficiencies than *h*- and  $\tau$ -efficiencies, implying that the implemented design  $\xi_p$  is best for estimating the model parameters among the three objectives.

We observe that the *h*-efficiencies of  $\xi_h^*(\theta^0)$  seem robust with respect to misspecification of the nominal values of the parameter  $\theta_4$  in model (1) because these efficiencies are generally very high. The same is not true for model (2). The *h*efficiencies can drop to as low as 33% when nominal values of  $\theta_3$  vary. A similar but smaller effect is observed when  $\theta_4$  varies, with the *h*-efficiency dropping to about 60%. The *h*-efficiencies remain close to 1 when nominal values for the parameters  $\theta_1$  and  $\theta_2$  vary, suggesting that h-optimal designs seem to be robust to mis-specification of these parameters.

#### 4 Robustness properties of optimal designs

In previous sections, we assumed nominal values are available and optimal designs were constructed assuming they are correct. In practice, the nominal values may be unknown or unreliable and mis-specifications of their nominal values can result in sub-optimal designs with possibly very low efficiencies. It is therefore advisable that before a design is implemented, researchers should undertake a robustness study that investigates sensitivities of the design to various model assumptions. In this section, we evaluate optimal designs for the various models when there is uncertainty in the nominal values. Ideally, we want a design that remains relatively efficient when the model is slightly mis-specified in various ways.

Tables 1 and 2 display various types of efficiencies for models (1) and (2) when some nominal values of their parameters are mis-specified. Such an investigation is always helpful because it informs us which parameters are more important to be accurately specified before constructing an optimal design. Those parameters that are less influential means that when their nominal values are slightly mis-specified, the resulting optimal designs are not very different from the optimal design and, therefore, there is a slight drop in efficiency.

We next consider the design issue when there is model uncertainty. To fix ideas, suppose models (1) and (2) are two plausible models. Figure 1 shows the mean responses from the two models for a selected choice of their model parameters . We construct and compare the optimal designs when one of the two models is postulated and is mis-specified. Rows 1–3 in Table 4 show the *D*-efficiencies of the optimal design for the assumed model (1) when the true model is model (2) for several sets of parameter values for both models. Rows 4-6 show the corresponding results when model (1) is the true model and the working model is (2).

| Table 4       D-efficiencies of         locally D-optimal designs for         model (1) with various nominal                          | $\frac{(\theta_3^{(2)}, \theta_4^{(2)})}{\theta_4^{(1)}}$ | (8,4)  | (7,4)  | (9,4)  | (8,3.6) | (8,4.4) |

Table 4 shows the *D*-efficiencies of the locally *D*-optimal designs under a misspecified model can vary wildly from a low of about 36% in *D*-efficiency to a high of about 95% *D*-efficiency, depending on which parameters in each of the model are mis-specified. On the other hand, *D*-optimal designs have similar *D*-efficiencies for different values of the parameter  $\theta_4^{(1)}$  when values of the parameters in model (2) are fixed, regardless whether model (1) is the assumed or the true model.

Analogous tables can be constructed to ascertain *h*-efficiencies when the model is mis-specified. In general we observe low *h*-efficiencies for some locally *h*-optimal designs when either one of these models is mis-specified when the other holds. As a matter of fact, all the *h*-efficiencies are lower than 80%. In particular, we observe that when the true model is model (1), the *h*-optimal designs for model (2) with parameters  $(\theta_3^{(2)}, \theta_4^{(2)}) = (7, 4)$  have *h*-efficiencies around 50%. In contrast, when the true model is model (2) with parameters  $(\theta_3^{(2)}, \theta_4^{(2)}) = (7, 4)$ , the *h*-optimal designs for model (1) have very low *h*-efficiencies: 0.113, 0.0984 and 0.1262 when  $\theta_4^{(1)}$  is 0.09, 0.08, and 0.10, respectively. For space consideration, we do not present the corresponding results in a tabular form.

We note that the above calculation is illustrative in the sense that we have somewhat arbitrarily picked nominal values for the two models in this discussion. In practice, the nominal values should be appropriately selected based on available data or from a pilot study.

#### 5 An interactive web-based tool

Practitioners and researchers in toxicology and pharmacology may not be able to easily compute the optimal designs for their problems. To facilitate use of the proposed optimal designs, we have created a website that generates the sought optimal design for the models discussed in this paper. This website can be freely assessed through the link http://areaestadistica.uclm.es/oed/index.php/computer-tools/. It contains tools for finding different types of optimal designs for various scenarios. One of the tools is OED-hormesis, which was used to generate the optimal designs reported in this paper. Our algorithms are all based on the R software (R Core Team 2015) and are available on the user-friendly interactive web app, which was created using the library Shiny (Chang et al. 2016). The navigation bar on the app allows users to choose one or two models for comparison purposes.

To find an optimal design, the user first inputs a predefined set of design parameters for the selected model (Fig. 2 top). For instance, when there is only interest in one model, the user selects the model from the given list, the dose space and the nominal values of the parameters for the model. The app also evaluates the efficiency of any generated design relative to one of the predefined designs that include the design for the WET test, the design for the toxicity study of the chemical diethylhexl phthalate (DEHP), a carcinogen, on mice given by Dette et al. (2011) or any desired design that the user inputs in the corresponding box.

Upon execution, the app uses the nominal values and constructs a plot of the mean response of the model in the first tab. The graph is helpful to ascertain whether the

| commas)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  | lin-logistic                                                                                                              |                                |                      |              |            |              |             |                   |
|                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          | In-logistic   Parameter values (separated by                                                                              |                                |                      |              |            |              |             |                   |

Fig. 2 Interactive web app with default values showing different types of optimal designs (top) and efficiencies of optimal designs for two models (bottom)

mean response has the shape that the user wants from the nominal values. In the second tab, the app displays the locally D-, h- and  $\tau$ -optimal designs showed in Tables 1 and 2 (Fig. 2 top). The app computes the best 4-point  $\tau$ -optimal design to avoid numerical errors caused by the singularity of the information matrix when designs have fewer points than the number of parameters (see Sect. 3.2). The last line of the output shows various efficiencies of the user-supplied design and the estimated  $\tau(\theta)$  value or ZEP dose.

The app facilitates comparison of the efficiencies of various optimal designs for the two models discussed in our paper and those studied in Dette et al. (2011). The tab "Models to compare" allows the user to modify the predefined comparison (Fig. 2 bottom). For particular cases, the user has to select the design interval meaningfully, choose the two models among the five available models, and carefully modify the nominal values for the model parameters. The efficiencies in Tables 1 and 2 and in Sect. 4 can all be obtained using this app.

#### 6 Conclusions

Our work is an attempt to investigate a hitherto unaddressed problem in toxicology. While the phenomenon of hormesis seems to occur in various degrees across many areas in toxicology and beyond, the issue of finding an informed and efficient design to detect hormesis or accurately estimate ZEP or the threshold dose has not been sufficiently addressed from the statistical viewpoint. We show that our proposed designs have advantages over currently used designs in terms of saving resources and improved precision for estimating the threshold and model parameters.

We have also shown that the design implemented in practice,  $\xi_p$ , has several doses in common (or similar) with the *D*-optimal or *h*-optimal designs for model (1). This includes the placebo dose, a dose around 3.12 (in the case of *D*-optimal design) and largest admissible dose. For model (2) the optimal designs have only the placebo dose in common with those of  $\xi_p$ . However  $\xi_p$  has lower efficiencies for testing the presence of hormesis than to estimate the model parameters. The performance of this design is even worst for estimating the ZEP dose when compared with the  $\tau$ -optimal designs. For the nominal values considered in this work, the *D*-efficiency of  $\xi_p$  is higher than 73.5% for model (2) and around 82% for model (1). The *h*-efficiencies of  $\xi_p$  are all lower than 61% and in some cases lower than 40%. The  $\tau$ -efficiencies of  $\xi_p$ are consistently unacceptably low.

Our results indicate that the proportion of observations to be taken at each dose is different from one criterion to other. For example, we have the equally weighted *D*-optimal designs to *h*-optimal designs that require less than 10% of observations at its largest dose,  $d_4$  and more than 80% in its first and second dose,  $d_1$  and  $d_2$ .

A limitation of our approach is that we consider models with a single independent variable. In practice, models may have two or more variables plus interaction terms. Such models will make it more difficult for us to determine the optimal designs of interest. Another limitation is that we assume that there is a single set of nominal values for the model parameters. The alert researcher should conduct a sensitivity analysis to ascertain whether the locally optimal design is sensitive to meaningful misspecifications in the nominal values. Sometimes, in practice, there are multiple possible values for the model parameters or there are different opinions on the values of the nominal values. More sophisticated designs can be constructed using optimal design theory to incorporate the additional information. For example, if a joint distribution of the possible values of the model parameters is available, we may adopt a Bayesian approach. Usually such a joint distribution is elicited from all available information that may come from experts, pilot studies or similar studies. The construction of a Bayesian optimal design is more complicated because multiple integration is required to solve the optimization problem. Examples of Bayesian optimal designs can be found in Baek et al. (2006), Rodríguez et al. (2015), Zhu and Wong (2001).

Alternatively, we may be willing to specify an interval of possible values for each parameter and find a design that is efficient no matter which value in each of these intervals is the true value for the parameter. Such optimal designs are variously called maximin or minimax optimal designs, depending on the problem formulation. They are difficult to find because we have a nested bi-level optimization problem and techniques to search for them are beyond the scope of this paper. Some recent work in constructing minimax or maximin approach using various techniques for different types of design problems are Duarte et al. (2018) and Chen et al. (2015, 2017).

We conclude by noting that some practitioners could be interested to find an optimal design to discriminate between two or more models using the T or KL-optimality criterion. Details of this more complicated approach can be found in Atkinson and Fedorov (1975), López-Fidalgo et al. (2007) and Amo-Salas et al. (2016) and are beyond the scope of this paper.
