Laser-sculptured ultrathin transition metal carbide layers for energy storage and energy harvesting applications

Xining Zang^{1,2}, Cuiying Jian¹, Taishan Zhu¹, Zheng Fan³, Wanlin Wang⁴, Minsong Wei², Buxuan Li², Mateo Follmar Diaz⁵, Paul Ashby⁶, Zhengmao Lu¹, Yao Chu², Zizhao Wang⁷, Xinrui Ding², Yingxi Xie², Juhong Chen², J. Nathan Hohman⁶, Mohan Sanghadasa⁸, Jeffrey C. Grossman¹ & Liwei Lin²

Ultrathin transition metal carbides with high capacity, high surface area, and high conductivity are a promising family of materials for applications from energy storage to catalysis. However, large-scale, cost-effective, and precursor-free methods to prepare ultrathin carbides are lacking. Here, we demonstrate a direct pattern method to manufacture ultrathin carbides (MoC_x , WC_x , and CoC_x) on versatile substrates using a CO_2 laser. The laser-sculptured polycrystalline carbides (macroporous, ~10–20 nm wall thickness, ~10 nm crystallinity) show high energy storage capability, hierarchical porous structure, and higher thermal resilience than MXenes and other laser-ablated carbon materials. A flexible supercapacitor made of MoC_x demonstrates a wide temperature range (–50 to 300 °C). Furthermore, the sculptured microstructures endow the carbide network with enhanced visible light absorption, providing high solar energy harvesting efficiency (~72 %) for steam generation. The laser-based, scalable, resilient, and low-cost manufacturing process presents an approach for construction of carbides and their subsequent applications.

Transition metal carbides (TMCs) have unique characteristics such as low resistivity (metallic), high melting temperature, and high electrochemical activities for energy storage and catalysis¹. Dimensional reduction of bulk TMCs to 0-, 1-, or 2-dimensional nanostructures (thickness vs lateral size < 1 %) ^{2,3} has attracted interest as a means to provide further control over a range of properties as well as to introduce new functionality^{4–6}. TMCs in particular have gained recent attention due to their intriguing physical, electrical, and catalytic properties. In general, the state-of-the-art fabrication process for ultrathin 2D-TMCs (MXenes)^{7–10} involves high temperatures (up to 1600 °C)¹¹ to generate the MAX phase ($M_{n+1}AX_n$, where M is a transition metal, A is a group 12–16 element, and X is C or N) precursor and then a hydrofluoric (HF) acid etching process to remove the A layer to form $M_{n+1}X_nT_x$ (T: OH, OOH and other surface terminations)^{9,12–14}. Fluoride-free methods for preparing ultrathin TMCs have been reported, notably chemical vapor deposition (CVD) on metal foils or graphene but the yield is extremely low^{3,15,16}. Therefore, development of a robust, mild temperature, versatile fabrication, and precursor independent method for ultrathin TMCs is required to enlarge the family of ultrathin-TMCs, expand the understanding of their properties, and enable cost-effective large-scale synthesis. Meanwhile, the etched MXenes sheets are terminated by rich surface functional groups such as –OH and –COOH, which could change the properties of intrinsic carbide. For example, $Ti_3C_2T_x$ decay at 200 °C due to the collapse of surface groups¹⁷ while the Ti_3C_2 shall survive up to 1000 °C. Synthesis of “purer” TMC beyond MXenes will empower researchers with wide opportunities to study their intrinsic physics and chemistry. Beyond the synthesis of the materials, their facile integration into devices represents another key challenge in realizing the potential of TMCs for applications. Devices made from chemically synthesized TMCs require further lithography steps; instead, a direct patterning method would enable roll-to-roll manufacturing of host of potential applications from energy storage devices¹⁸ to wireless communication¹⁹.

Herein, we demonstrate a versatile process to fabricate transition metal carbides in the form of ultrathin flakes with few-nanometer thickness. The approach utilizes laser ablation of a lamellar hydrogel/metal-ion matrix (metallo-hydrogel). Gelatin, commonly found in jelly desserts, can undergo a self-assembly process to form membranes in a layer-by-layer ordering^{20–22}. By selecting carbide-forming metal ions (Mo^{5+} , W^{6+} , and Co^{2+}), a nanostructured hydrogel can be prepared that is ablated for subsequent conversion into TMCs that retain their supramolecular layer-by-layer structure^{23,24}. When a hydrogel with embedded transition metal ions is heated, self-accumulation of polymeric phases of metal carbide degradation products occurs at the hydrogel air/liquid interface in a process described by the Buoyancy–Marangoni effect (Fig. 1a–d)^{25–27}. The self-assembly and ordering of gelatin can therefore macroscopically arrange precursors into structures that can be collapsed into dimensionally conserved nanostructures^{28,29}. When ablated by a CO_2 laser (Fig. 1e), metallo-gel absorbs IR energy which generates high temperatures (over 2000K, supporting information) within a rapid uptake time (sub millisecond timescale)³⁰. Residual solvent and carbon source from the gel “explosively” vaporizes and reacts with metal ions to form carbide structures (MoC_x , WC_x , and CoC_x) with macroporous (50–1000 nm pore size^{31,32}). The metallo-hydrogel can be easily spin coated onto a variety of substrates including glass (Supplementary Fig. 1). A common commercial cutter (VLS 2.30, Universal Laser) can directly pattern features (Fig. 1f) and integrate electrodes for microdevices with resolution of 25 microns. The laser-patterned carbide, using MoC_x as an example, performs as an energy storage interdigit supercapacitor electrode having a wide operational temperature

range (–50 °C to 300 °C in electrolyte). Furthermore, the single laser step not only produce ultrathin-TMC, but also pop up the ultrathin sheets into 3D microstructure with interconnected surface. As-sculptured structure provide more tunability in optical, electrical, and mechanical properties. For example, a membrane made of surface curved MoC_x can localize light with the to enhance solar energy harvesting (72% energy efficiency, evaporation total enthalpy over incident solar illumination energy). The exceptional thermal resilience of TMCs could enable a range of other applications such as carbide-based supercapacitors or solar-steam generation membranes operating in harsh environments.

Results

Materials characterizations and properties. The local high-temperature generated rapidly by the IR laser pulse³³ (Table S1), enables an instantaneously high carbon uptake and induces higher energy phases (Supplementary Fig. 2, Supplementary Fig. 3)³⁴. Within 30 μs the accumulated temperature can reach up to 2000 K in the Mo-gel thin film (Supplementary Fig. 3a–c) with a projected power of 4 W, using Mo-gel (2 molal, 60% wt) as an example. The rapid initial uptake leads to the formation of the carbon-deficient, metastable phase α - MoC_x instead of the thermodynamically stable Mo-C (α/β - Mo_2C) phases (Supplementary Fig. 2). A simplified heat transfer model was employed to estimate the temperature profile (Supporting Information), with approximate timescale within the range of μs to ms³⁵. The laser energy input produces this high energy α - MoC_x ($0 < x < 1$) phase of MoC_x (Supplementary Fig. 2), which has a threshold temperature of 1928 K in the phase diagram. The product of α - MoC_x/C has a much higher Gibbs free energy than the common α - Mo_2C and β - Mo_2C ^{36–38} and the 2D- Mo_2C achieved by CVD^{3,15,16}. Chemically exfoliated Mo_2CT_x ^{2,39} corresponds to β - Mo_2C , which is a lower energy phase compared to α - MoC_x . Confocal optical mapping of the laser-induced carbide (using MoC_x as an example), shows three-dimensional curved porous structure (Fig. 1g), and the slices of different confuse plane shows different cross section in the 3D tomography (Supplementary Fig. 4). Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) images show that the broken-down sheets of the porous structure have a thickness of 10–20 nm and are comprised of randomly orientated nanocrystals (Fig. 1h–j, Supplementary Fig. 4d–e). In comparison, for the cases of Mo-PEO and Mo-PVP, the temperature is much lower due to their lower IR absorption coefficients¹⁸, and the laser carbonized products are not recognized as any carbide phase (Supplementary Fig. 3d, e). Two other carbide phases β - W_2C/W and Co_2C/Co (Table 1, Supplementary Fig. 5), were not exfoliated from the corresponding MAX phases⁴⁰.

Further technical details regarding the laser power, spot size, temperature profile and product are discussed in supporting information, Supplementary Fig. 6. A 2 W laser with a scan speed of 200 $mm\ s^{-1}$ results in the smallest amount of amorphous carbon on Mo-gel (2 m, 60 wt%), and decent conductivity of $\sim 3.2\ S\ cm^{-1}$ for an 8- μm -thick spin-coated Mo-gel thin film (Fig. 1d), and is used as the standard protocol to pattern carbide devices in the rest of this paper. Electrical conductivities of laser-ablated carbides by different laser parameters are shown in Supplementary Fig. 7, and the optimized conductivities can reach $\sim 300\ S\ cm^{-1}$. Such conductivity, although not compatible with metal, is at a range of graphite (perpendicular to basal plane), amorphous carbon, carbon nanotube forest, and highly doped semiconductor⁴¹. The carbides hold BET surface area from ~ 10 –30 $m^2\ g^{-1}$ (Supplementary Fig. 8). The electrically conductive porous materials can perform as electrodes for many electrochemistry applications such supercapacitor and battery⁴². A few carbide

Zr(NO ₃) ₄ (2 m)	DI water	Gelatin	ZrC + ZrO ₂
Zn(NO ₃) ₂ (2 m)	DI water	Gelatin	NA
Tetrabutyl Titanate	NMP	Gelatin (<5 wt%)	TiC + TiO ₂

materials (Mo₂C, WC, and etc) show remarkable electrocatalysis activity such as hydrogen evolution reactions³². The laser direct printed carbide electrodes are promising to be implemented in Noble-metal free electrocatalytic nanodevices. As shown in Table 1 and Supplementary Fig. 9, the concentration of gelatin is essential for production of the carbide: above 10% all the products are in the form of carbide and carbon while below that concentration the product forms MoO₂ and lower energy Mo₂C. As revealed in Supplementary Fig. 10, the Mo-gelatin composite leads to the highest IR absorption at the typical wavelength of 10.6 μm compared to gelatin containing the same concentration of other metal ions^{43,44}. W⁶⁺ and Co²⁺ gelatin induced carbides with metal phases, and both were metal/carbide composites represented by MC_x (M = W, Co, Supplementary Fig. 5). The Ti⁴⁺ and Zr⁴⁺ in the gelatin hydrogel are converted to composite materials of carbides and oxides while Ni²⁺ and Fe³⁺ are converted to metal oxides with small portions of carbide. Zn²⁺ does not produce any crystalline phase (Supplementary Fig. 11).

Two critical parameters determine which mechanism and product are observed when forming laser-induced ultrathin TMC. The first key parameter is the “effectiveness” of energy absorbed by the metal-gelatin template, which is determined by the

absorption of the ion, polymer and metal-ligand interactions. An additional critical factor is the activation energy of carbonization. Using Mo^{5+} and Ti^{4+} as two examples, Mo-gelatin can be effectively converted to MoC_x at temperatures above 2000 K, while the ineffective energy conversion in the Ti-gelatin solution only activates the oxidation process to a more stable TiO_4 phase. Even with the same component of metal gel and similar input laser power, a UV laser-induced metal and metal oxide phases instead of carbide phases. One possible reason is the lower temperature generated by lower absorption of UV power in metallo-hydrogel (Supplementary Fig. 12).

Further characterization of laser-induced MoC_x is shown in Supplementary Fig. 13–14. We scratched off the as synthesized carbide and used high power ultrasonic processing to disperse flakes in ethanol ($\sim 20 \mu\text{m}$ in lateral size), which are then drop-cast onto silicon oxide. Atomic force microscopy (AFM) showed a thicknesses of carbide flakes between 10–20 nm, mostly $< 15 \text{ nm}$ (Supplementary Figure 14).

Flexible energy storage devices with wide operating temperature range. The nanocrystalline porous ultrathin flakes provide

exceptionally high surface area and exposed edges, which result in a high specific capacitance up to 55 F g^{-1} in 1 M LiCl and long-term stability of 10,000 cycles (Supplementary Fig. 15). Flexible, high performance MoC_x supercapacitor is patterned onto commercial Polyimide (PI) substrate. As shown in Fig. 2a, the Mo-gel is spin coated onto the PI tape, onto which interdigitated electrodes are then patterned. Unconverted Mo-gel is washed out, and highly concentrated PVA/LiTFSI electrolyte (20 molal) is coated. Supercapacitor device performance at different scanning rate is shown in Fig. 2b and Supplementary Fig. 16. The MoC_x supercapacitor shows over 90% maintenance of specific capacitance after 10,000 cycles (Fig. 2b). Lasing the commercial PI tape could induce porous graphene³³, which will benefit the binding between laser-sculptured-carbide (LSC) and the flexible substrate both mechanically and electrically. Although LIG electrodes have also been used in supercapacitor (Fig. 2c), their temperature resilience is not compatible as laser scribed carbide⁴⁵. As shown in Fig. 2c, LIG electrodes in electrolyte turned to black color and damage in elevated temperature, while the LSC electrodes remains well functioning up to 300 °C. TGA of ultrathin- MoC_x exhibits high-temperature stability up to 450 °C in air (Fig. 2c),

which outperforms the previously reported MXene thermal stability temperature of $\sim 200^\circ\text{C}$ in air¹⁷.

As shown in Fig. 2d, the electrolyte employed is a high concentration of 20 m LiTFSI/PVA with thermal stability up to 300°C . Based on the freezing point depression⁴⁶, which is positively correlated to the ion concentration, freezing point would possibly decrease to -74°C as estimated in Supporting Information. The LSC film achieved low electrical resistivity around $50\ \Omega\ \text{sq}^{-1}$ and the resulting micro supercapacitor prototype showed good specific capacitance ($2\ \text{mF cm}^{-2}$) at $100\ \text{mV s}^{-1}$ (Fig. 2e). This flexible supercapacitor showed stable operation under charge-discharge cycling over a wide range of temperatures from -50°C up to 300°C (Fig. 2e–f). The cyclic voltammetry (CV) measurements at 25°C before and after the harsh environment tests at 300°C clearly show no decrease in performance for the MoC_x -based supercapacitors (Fig. 2e). At low temperatures down to -50°C , the MoC_x -supercapacitor maintains functionality, with no perceptible irreversible damage to the electrodes according to the recovery of the CV curves after defrosting (Fig. 2f–h). Below -30°C a sharp decay in capacitance is observed due to the low ion mobility in the freezing electrolyte. Further modifications such as adding anti-freeze agents or changing the solvent could stabilize the electrolyte at such low temperatures.

Solar-energy harvesting membrane made of carbide. In contrast to chemically exfoliated MXenes and CVD synthesized ultrathin carbides, laser-sculptured carbide possesses a built-in interconnected curved surface, which could enable the tailored design of 3D morphologies consisting of interconnected ultrathin materials. One way to take advantage of such structures is in light capture; for example, the highly porous and curved carbide “walls” can efficiently harvest solar energy and transfer it to water for the generation of steam. Laser-sculptured carbide is sonicated in a water/ethanol mixture to detach from a glass substrate. Vacuum filtration yields a flexible membrane on versatile substrate support including Polytetrafluoroethylene (PTFE), Polyvinylidene (PVDF), and Polyethersulfone (PES) (Fig. 3a, Supplementary Fig. 17). The carbide membrane has strong absorption of a wide range solar spectrum, which induce local heating-driven evaporation at the water-air interface⁴⁷. The solar-driven energy conversion at the interface reduce the energy input for bulk evaporation, which improve the steam productivity as shown in Fig. 3b–c⁴⁸.

Under 3 sun illumination ($3\ \text{kW m}^{-2}$), enhanced solar-energy absorption generates a relatively higher temperature (60°C) at the water-air interface compared to other photo-absorbing membranes such as carbonized wood ($\sim 40^\circ\text{C}$)⁴⁹, wood-CNT composite ($\sim 50^\circ\text{C}$)⁵⁰, graphite-carbon foam double layer structure ($<40^\circ\text{C}$)⁴⁸ and etc. The evaporation rate and energy efficiency of solar-steam generation under different solar incident power is shown in Fig. 3c and Supplementary Fig. 18. Such energy efficiency is comparable to the membranes mentioned above, yet lower than a recently reported nano-hierarchical gel having an extremely high efficiency up to 90%⁵¹. No specific thermal management is deployed to decrease the thermal loss, which can be improved by adding an insulation layer^{47,48} to further increase the energy efficiency. Nevertheless, the high-temperature-resilience of the carbide enables steam generation in harsh environments that could burn or destroy many other polymer-based membranes⁵¹. The MoC_x reached $\sim 160^\circ\text{C}$ within 60 s (Fig. 3d), under 11 sun exposure (Fig. 3d, inset). Near identical X-ray photoelectron spectroscopy (XPS) of MoC_x Mo_3d orbital before and after 11 sun exposure for one hour implies the carbide is stable in extreme solar radiation (Fig. 3d, inset), while a MoS_2 membrane

(Supplementary Fig. 19)⁵² is oxidized shown from its XPS Mo_3d orbital (Supplementary Fig. 20) in comparison. From the water transport analysis that we add to Supplementary Fig. 20 and Supplementary Table 2, dry-out is not happening at the membrane-water interface. Capillary force can drive water to the membrane surface. Carbide membrane shows a permeability of $1973.4\ \text{LMH bar}^{-1}$, which falls to the range of membrane with pore size from hundreds of nanometers to micrometers⁵³.

We employ density function theory (DFT) and finite differential time domain (FDTD) simulation to understand the solar-energy localization within carbide porous structure. Due to the lack of available reference data for experimentally measured optical properties of MoC_{1-x} , we employ first principles simulations of the carbide dielectric constant and refractive index (Fig. 3e). The FDTD model is based on the SEM image in Fig. 3f, and a “gyroid-like” curved structure with variable unit cell is used to represent the porous carbide (Fig. 3g inset). The measured optical transmission for both $10\ \mu\text{m}$ and $20\ \mu\text{m}$ thick porous carbide membranes are shown in Fig. 3g, in good agreement with the computed optical transmission for the same wavelength range. All details of the DFT simulation and FDTD simulation are in the supporting information (Supplementary Fig. 21). Figure 3h is one example of optical absorption (500 nm incident light) projected onto the x-y plane in a unit cell ($1.6 \times 1.6\ \mu\text{m}$). Figure 3i shows the absorption intensity trend of different wavelength in different size carbide cells.

Discussion

In conclusion, we have developed a versatile approach for the synthesis of microporous ultrathin polycrystalline carbides ($\sim 10\ \text{nm}$ crystallinity) with ultrathin “wall” structures ($\sim 10\text{--}20\ \text{nm}$), using lamellar templated metal ion (Mo, W, and Co) containing gelatin (metallo-hydrogel) and processing with a low-cost and fast CO_2 laser cutter in ambient environment. The IR energy generates local high temperatures which induce a rapid carbon uptake to form carbon-deficient phases (MoC_x , WC_x , and CoC_x), and sculptured interconnected curved structures during the sub millisecond “explosive” carbonization process. The laser-induced MoC_x , as a conductive and refractory metallic material with hierarchical porosity (from microscale to nanoscale), was shown to be an appealing candidate for energy storage in lithium-based electrolyte ($55\ \text{F g}^{-1}$, discharged at $1\ \text{mV s}^{-1}$). Direct patterned MoC_x supercapacitor on PI tape shows a specific capacitance up to $20\ \text{mF cm}^{-2}$ at a discharge rate of $1\ \text{mV s}^{-1}$, and $2\ \text{mF cm}^{-2}$ at $100\ \text{mV s}^{-1}$. This work provides a general approach for a low cost, room temperature, high yield and exceptionally fast synthesis of transition metal carbides (Supplementary Table 3), which also enable large-scale devices and potentially roll-to-roll manufacturing. The non-decorated surface with less functional groups ($-\text{OH}$, $-\text{COOH}$) provide higher temperature resilience than surface-function-rich and chemical resilience (Table 2). The MoC_x interdigitated electrodes used in conjunction with a Li-rich electrolyte (for lower freezing point) was demonstrated to function over a temperature range of -50°C to 300°C with no significant degradation while the laser-induced graphene decay in the same electrolyte. Laser sculpturing also provide hierarchical structure in multiple scale (ultrathin 2D like to 3D, Table 2), which also potentially bring intriguing properties and tunability in light and phonon transport. A post vacuum filtered MoC_x membrane, exhibited effective solar-steam generation due to the size variable “gyroid-like” curved surface, which enhanced solar-energy harvesting. The direct write patterning and sculpturing process opens these materials up to a broader window of applications in flexible electronics, energy storage, energy harvesting, and water treatment applications.

Table 2 Summary and comparison among laser-induced graphene (LIG), MXenes, and laser-sculptured carbide (LSC)

Materials	LIG	MXene	LSC (this work)
Thermal stability (TGA in air)	Start burning over 200 °C ⁴⁵	-200 °C ¹⁷	450 °C
Resilience (in electrolyte)	<300 °C	NA	>300 °C
Dimension	2D->3D porous	Layered 2D	Ultrathin 2D like ->3D porous

Methods

Preparation of transition metallo-hydrogel. MoCl_5 , CoSO_4 , NiSO_4 , FeCl_3 , $\text{Zr}(\text{NO}_3)_4$, and $\text{Zn}(\text{NO}_3)_2$ (used as received from Sigma-Aldrich) were dissolved in deionized water, and WCl_6 was dissolved in N-Methyl-2-pyrrolidone (NMP, Sigma-Aldrich) with a concentration of 2 m (m is mass molality). The hydrogel was made by dissolving either gelatin, PVP or PEO with 60% wt concentration. Tetrabutyl titanate were mixed with NMP with a concentration of 2 m, which showed much lower solubility of gelatin (<5 wt%). Such Ti-NMP-gelatin mixture could only make suspension rather than uniform solution.

Synthesis of metal carbide by laser ablation. Metallo-gel precursor was spin coated onto glass and cured at 80 °C for 1 h to make a thin film, which was subsequently ablated by laser (IR 2 W; UV 1 W due to the limited of USB powered of UV laser). A commercial Universal VSL 2.30 was utilized to perform the laser ablation, with a CO_2 laser tube and all built-in optics. Laser spot is focused on the top surface of spin-coated gel film, and the height of the sample is controlled by tuning the z-position of the supporting cutting table. Designed pattern is imported to a vector drawing software and engraved by communicating with the laser cutter as a printer. Unablated gel can be easily removed by rinsing the whole device in DI water for 1 min and air dry before test.

Materials characterization. Scanning electron microscopy (SEM, FEI Quanta 3D), Transmission electron microscopy (TEM, FEI Tecnai) were employed to study the morphology and structure. X-ray diffraction (XRD, Bruker D8) is performed to study the crystallinity, and X-ray photoelectron spectroscopy (XPS) is used to study the surface element component of samples. Co source is used in the powder diffraction X-ray test.

Electrochemistry test. Ag/AgCl was used as the reference electrode to study majorly carbide performance in different electrolytes. Magnesium acetate solution (~1 M, volumetric concentration), was purchased from BioUltra. NaCl (≥99%wt, Sigma-Aldrich) and LiCl (≥99.99% wt, Sigma-Aldrich) were dissolved in distilled water to make solution with concentration of 1 M (volumetric molarity). Concentrated sulfuric acid is diluted by deionized water to a volumetric molarity of 1 M. Linear sweep voltammetry, cyclic voltammetry, chronopotentiometry, and EIS impedance tests were performed by an electrochemistry workstation (Gamry Ref 600) with different modules. Powdery MoC_x flakes are grinded with PAN (1 wt%) dissolved in N-Methyl-2-pyrrolidone (NMP, Sigma-Aldrich) as binder, which is casted onto hydrophobic carbon paper (Toray Carbon Paper 060, Wet Proofed).

Fabrication of supercapacitor of carbides on PI tape. Mo-gelatin (2 m MoCl₅, 60 wt%) hydrogel is spin coated onto Polyimide tapes to form a thin film, which is dried in the oven at 80 °C for 30 min. Gel-on-PI film is ablated by IR laser with 2 W power at a speed of 200 mm s⁻¹. Interdigit structure is patterned with the geometry design using CAD interface. Li-rich electrolyte (21 m LiTFSI) is dissolved in DI water with 10% PVA, which is deposited onto the interdigit electrodes to assemble a functional supercapacitor. WC_x and CoC_x supercapacitor are fabricated via the same process using W-gelatin (2 m WCl₆, 60 wt%) and Co-gelatin hydrogel (2 m CoCl₂, 60 wt%).

Fabrication of ultrathin-TMC membrane. Laser-sculptured MoC_x was scratched off subtracted, dispersed in DI water and ultrasonic for 2 h at 80 °C. The supernatant was vacuum filtered using a porous Polytetrafluoroethylene (PTFE, 47 mm diameter, 0.45 μm pore size, Fisher Scientific, Fair Lawn, NJ, USA) and dried in the air for 24 h. Same process is performed to vacuum filtrate carbide membrane onto Polyvinylidene (PVDF, 0.45 μm pore size, 47 mm diameter, Sterlitech Corp) and Polyethersulfone (PES, 0.45 μm pore size, 47 mm diameter, Sterlitech Corp) membrane filters.

Test of solar-thermal energy harvesting and steam generation. The experimental setup is equipped with a solar simulator (Newport 94023 A), and a balance, with data collection system (OHAUS, 420 g, with USB cable). The 47 mm membrane was exposed to solar illumination on the top of a baker (2 inch diameter) filled with DI water. IR camera was employed to record the temperature, with the balance to record mass loss.

Density functional theory simulation details for MoC_x optical properties. All ab initio calculations were performed using the Vienna Ab Initio Simulation Package (version 5.4.4.18Apr17⁵⁴). To obtain the dielectric tensor, the structure of MoC_{1-x} was first relaxed to ensure all the forces on the ions were smaller than 0.01 eV Å⁻¹. Then dielectric tensor was calculated using the independent particle approximation, and subsequently the local field effects were included using the random phase approximation. All calculations were performed using Perdew-Burke-Ernzerh (PBE⁵⁵) version of generalized gradient approximation with projected-augmented wave potentials^{56,57} and a wave function energy cutoff of 400 eV; the Brillouin zone was sampled with, respectively, 1728 and 4096, k-points, to confirm convergence. In calculating the frequency-dependent dielectric tensor, 2000 frequency grid points were used, and the actual number of bands (1280) was carefully chosen such that a considerable number of empty bands was included in the calculation.

Acknowledgements

This work was performed in part at the Molecular Foundry, a User Facility supported by the Office of Science, Office of Basic Energy Sciences, of the U.S. Department of Energy

under Contract No. DE-AC02-05CH11231. We gratefully acknowledge the computational resources from National Energy Research Scientific Computing Center (NERSC), a U.S. Department of Energy Office of Science User Facility operated under Contract No. DE-AC02-05CH11231. A few of authors get support from Berkeley Sensor and Actuator Center. We want to thank Dr. Anthony Straub from Grossman Group in Massachusetts Institute of Technology to help measure the permeability of carbide membrane. We specially thank Prof. Gang Chen from MIT to share facilities for solar-steam generation test, and Dr. Bruno Lorenzi from Prof. Chen’s group for training. The authors thank Dr. Morris Wang from Lawrence Livermore National Lab for inspiring discussions on ultrathin TMCs, Prof. Peng Tao and Prof. Tao Deng from Shanghai Jiao Tong university for facilities support to test the solar-steam generation and helpful discussions.

Author contributions

X.Z. designed, performed most of the experiments, and analyzed the results. X.Z., L.L. and J.C.G. wrote the paper. M.F., M.W., B.L., Y.C., J.C., Y.X. and Z.W. helped with the experiments; P.A. helped with the AFM measurements; Z.F. performed the TEM analysis of materials; C.J. and T.Z. performed DFT simulation; C.J. performed Molecular Dynamics simulations, which are not presented in current version but is crucial to design the carbide-based electrochemical supercapacitor presented; Z.L. helped with the water transport analysis of carbide membrane; W.W. and X.D. helped with FDTD optical simulations and temperature profile modeling; J.N.H. and M.S. helped to revise the paper; the paper and figures were prepared with input from all authors.
