Supporting Information

ABSTRACT: Engineered nanoparticles (ENPs) are entering agricultural soils through land application of nanocontaining biosolids and agrochemicals. The potential adverse effects of ENPs have been studied on food crops and soil bacterial communities separately; however, how ENPs will affect the interacting plant–soil system remains unknown. To address this, we assessed ENP effects on soil microbial communities in soybean-planted, versus unplanted, mesocosms exposed to different doses of nano-CeO₂ (0–1.0 g kg⁻¹) or nano-ZnO (0–0.5 g kg⁻¹). Nano-CeO₂ did not affect soil bacterial communities in unplanted soils, but 0.1 g kg⁻¹ nano-CeO₂ altered soil bacterial communities in planted soils, indicating that plants interactively promote nano-CeO₂ effects in soil, possibly due to belowground C shifts since plant growth was impacted. Nano-ZnO at 0.5 g kg⁻¹ significantly altered soil bacterial communities, increasing some (e.g., *Rhizobium* and *Sphingomonas*) but decreasing other (e.g., *Ensifer*, *Rhodospirillaceae*, *Clostridium*, and *Azotobacter*) operational taxonomic units (OTUs). Fewer OTUs decreased from nano-ZnO exposure in planted (41) versus unplanted (85) soils, suggesting that plants ameliorate nano-ZnO effects. Taken together, plants—potentially through their effects on belowground biogeochemistry—could either promote (i.e., for the 0.1 g kg⁻¹ nano-CeO₂ treatment) or limit (i.e., for the 0.5 g kg⁻¹ nano-ZnO treatment) ENP effects on soil bacterial communities.

INTRODUCTION

As production and use of engineered nanoparticles (ENPs) rise, ENPs will increasingly enter the environment.¹ ENPs enter agricultural soils through land application of wastewater treatment plant biosolids or nanocontaining pesticides and fertilizers, and thus may pose risks to agricultural ecosystems.^{2,3} To assess soil exposure, experiments have used various ENPs (e.g., TiO₂, ZnO, CuO, Ag, and carbon nanotubes), but mainly in the absence of plants. Such experiments have either found limited effects of ENPs to soil bacterial communities (e.g., from fullerenes^{4,5}) or direct toxicity (e.g., TiO₂).^{6,7} ENPs can alter soil bacterial communities,^{8–10} including the abundance of some functionally significant bacterial groups (e.g., N₂-fixing bacteria).^{11–13} Metal oxide ENPs (e.g., CeO₂, ZnO, CuO, and FeOx) may also be bioavailable to soil-grown plants and may translocate from soils into plant tissues^{14–16} where they cause physiological and genetic damage.^{14,16–18} However, it is still unknown how plants cultivated in soils may change ENP impacts on soil microbial communities.

Plant roots alter soil processes in ways that may either change bacterial bioavailability of ENPs or modify ENP toxicity. For example, roots release low molecular weight organic

compounds (i.e., sugars, amino acids and organic acids), polymerized sugars (i.e., mucilage), and sloughed-off root cells.¹⁹ Plants allocate 30–60% of fixed carbon to their roots, and around 40–90% of this is ultimately released into soil.²⁰ Because soil organic matter can mitigate ENP toxicity by adsorbing and immobilizing some ENPs,^{4,21} the overall greater amount of available organic material in planted soils may further attenuate ENP toxicity. For example, roots secrete chelators that sequester metallic ions,¹⁹ and thus could reduce the bioavailability of toxic ions released from soluble metal oxide ENPs (e.g., ZnO).

To assess how plants alter the effects of ENPs on soil bacterial communities, we studied how nano-CeO₂ and nano-ZnO affect soil microbial communities and how those impacts are altered by the presence of growing soybean plants. Nano-CeO₂ is commonly used as a fuel additive to improve combustion efficiency, while nano-ZnO is widely used in

sunscreens, cosmetics, and coatings.²² Both ENPs are therefore increasingly being introduced into the environment.^{1,23} We exposed mesocosms containing either only soil or soils planted with soybean seedlings to a range of ENP concentrations (0.1, 0.5, 1.0 g kg⁻¹ for nano-CeO₂ and 0.05, 0.1, 0.5 g kg⁻¹ for nano-ZnO). We harvested mesocosm soils when the plants were mature and analyzed the soil bacterial community composition by two independent methods: terminal restriction fragment length polymorphism (T-RFLP) and PhyloChip analysis.

MATERIALS AND METHODS

Experimental Design. As described previously,¹⁴ surface soil (0–20 cm) was collected from an organic farm in Carpinteria, CA (N 34° 23' 40", W 119° 28' 40"), sieved to 2 mm and stored at 4 °C. This soil is mapped as grading between a Fluventic Haploxeroll (Goleta series) and an Aquic Xerothalic (Camarillo series). Soil pH (6.78), texture (sandy loam, 66% sand, 22% silt, and 12% clay), soluble salts (0.58 dS m⁻¹), cation exchange capacity (8.72 mequiv per 100 g), organic matter (1.44%), total C (0.71%), total N (0.07%), and other nutrients were characterized by the UC Davis Analytical Laboratory (Davis, CA; <http://anlab.ucdavis.edu/>) and were previously reported.¹⁴

The dry powder nano-CeO₂ (Meliorum, Rochester, NY, U.S.A.) used in this study was comprised of ceria with a primary rod shape (67 × 8 nm²); the dry powder specific surface area was 93.8 m² g⁻¹, isoelectric point 7.5, and purity 95%.²⁴ The nano-ZnO (Meliorum, Rochester, U.S.A.) was composed of zincite with a spheroid shape (24 nm); the specific surface area was 42.1 m² g⁻¹, isoelectric point 9.2, and purity 97%.²⁴ The ENP-amended soils were prepared approximately 24 h prior to use, by adding dry powder nanoparticles to sieved soils to achieve the target exposure doses (0.1, 0.5, and 1.0 g kg⁻¹ for nano-CeO₂, and 0.05, 0.1, and 0.5 g kg⁻¹ for ZnO). To homogeneously distribute the ENPs into the ENP-amended soils, a 10-fold dilution method was used, as described previously.¹⁴ In brief, powder nanoparticles were initially added to soil in doses of 10, 50, and 100 g kg⁻¹ for CeO₂, and 5, 10, and 50 g kg⁻¹ for ZnO, and mechanically mixed for 5 min with separate hand-held kitchen mixers. The nanoparticles were then diluted 10-fold twice to achieve the target doses by adding unspiked soils into each mixture, and homogenizing as described above. Soil without ENPs was used as the control.

For each of the seven ENP treatments, eight experimental pots were prepared with four receiving transplanted soybean seedlings and the remaining four serving as unplanted controls. The full details of the experimental pot preparation, the soybean seedling preparation, and the transplantation were reported previously.¹⁴ In brief, each experimental pot (4 L, polyethylene/polypropylene blend) contained 400 g of washed gravel (1.25–2.5 cm) underneath 2.4 kg of soil. To facilitate harvesting, the soil was contained within a polyethylene bag perforated with 5 mm holes ($n = 20$) to form a mesh. The mesh and gravel aided in water drainage and prevented root rot. Soybean seedlings were prepared by sowing the dwarf soybean seeds (variety: Early Hakuro, product #5555, Park Seed Company, Greenwood, SC, U.S.A.) in peat-filled seed starting pellets (4 cm diameter). Once the true leaves emerged (18 days after sowing), soybean seedlings were ranked into four size classes, and transplanted into half of the experimental pots such that each ENP treatment received one seedling from each size class. The transplanting time was referred to as "day 0" of the exposure experiment.

Both unplanted and planted pots were placed in a greenhouse for 48 days until soybean plants developed fully to the later stage of pod development (except for one replicate of the low dose nano-ZnO treatment in planted soils, because the plant died after transplantation). The greenhouse was under full sunlight, with temperatures ranging from 12 to 31 °C.¹⁴ During the experiment, the soil water content averaged 0.15 m³ m⁻³ by watering the experimental pots with tap water approximately every 72 h.¹⁴

As described previously,¹⁴ plant and soil samples were harvested after 48 days of ENP exposure and preprocessed within 2 days, including manually removing most roots then sieving (2 mm) out any remaining root material from the planted treatments. For planted treatments, aboveground plant tissues were first cut from the root systems with a razorblade and then divided into stems, leaves, and pods and weighed separately. The belowground plant tissues were harvested by carefully breaking apart the soils, rinsing roots in deionized H₂O three times, and removing nodules from the roots by using forceps. Subsamples of each tissue type were either analyzed immediately, refrigerated (4 °C), or oven-dried (70 °C for 72 h) to examine ENP effects on plant growth, nutritional value, and ENP translocation from the soil into plant tissues, as reported previously.^{14,15,25} Soils from the unplanted treatments were also homogenized and sieved to 2 mm. The sieved soil was subsampled, with portions stored at 4 °C for measuring soil enzyme activities, and the rest stored at -80 °C for later DNA extraction to characterize soil bacterial community structure and diversity.

Soil DNA Extraction. Total DNA was extracted from 0.3 g soil subsampled from each of the four end point replicates for each treatment (except for the low dose nano-ZnO treatment in planted soils where $n = 3$, Supporting Information (SI) Table S1) using the Powersoil DNA Isolation Kit (Mo Bio, Carlsbad, CA, U.S.A.) and quantified using the Quant-iT DNA Assay Kit High Sensitivity (Invitrogen, Eugene, OR, U.S.A.), according to the manufacturer's instructions. Besides end point soils, we also extracted DNA from subsampled soils when ENPs were just mixed with soils (0-day exposure), with one replicate per treatment (SI Table S1).

Polymerase Chain Reaction (PCR) and T-RFLP. Genes encoding 16S rRNA were amplified using the extracted DNA as template and using universal bacterial primers HEX-labeled 8F (AGA GTT TGA TCC TGG CTC AG) and 1389R (ACG GGC GGT GTG TAC AAG),²⁶ following the reaction chemistry and thermal cycling program described previously (see the SI for details).⁷

The *Hha*I digested PCR products (600 ng, see the SI for details) were shipped to Michigan State University (the Research Technology Support Facility) on dry ice for T-RFLP analysis using an ABI PRISM 3100 Genetic Analyzer (Applied Biosystems, Foster City, CA, U.S.A.). T-RFLP profiles were aligned using the crosstab Excel macro "treeflap"²⁷ and only those fragments between 50 and 1000 bp in size with relative peak heights >1% were included in the analysis. The relative abundance data, defined as the peak height proportions of specific restriction fragments in a whole community, were used to explore the response patterns of the overall community. Two T-RFLP outliers, one from the low dose nano-ZnO treatment in unplanted soils and another from the low dose nano-CeO₂ treatment in planted soils, were not included in the statistical analyses (SI Table S1).

PhyloChip Analysis and Data Preprocessing. In addition to T-RFLP analysis, extracted DNA was also concentrated and shipped on dry ice to Second Genome (San Francisco, CA) for PhyloChip analysis, using protocols described previously.²⁸ The mean fluorescence intensity of each operational taxonomic unit (OTU) was \log_2 transformed to generate hybridization scores for statistical analysis (see the SI for details). Hybridization scores were previously shown to correlate well with known concentrations of 16S rRNA genes in a mixture of twenty-six 16S rRNA genes (average correlation coefficient, $r = 0.941$), indicating the capacity of PhyloChip for quantitative community analysis.²⁸ An OTU was defined by a group of highly similar 16S rRNA gene sequences (a probe set), and assigned to a set of higher taxa (kingdom, phylum, class, order, family, and genus) based on the probe sequences, using a Bayesian method by Second Genome. The Bayesian annotation, as opposed to adopting the annotation from full-length reference sequences, prevents overspecification of the OTUs. The resulting sample-OTU matrix was used for community analysis. One PhyloChip outlier from the low dose of nano-ZnO treatment in planted soils was not included in the statistical analyses (SI Table S1).

Statistical Analyses. Distance-based redundancy analysis (dbRDA)²⁹ was performed to examine the Bray–Curtis distances within T-RFLP profiles and within PhyloChip profiles. In this way, two data sets (T-RFLP and PhyloChip) were separately used for determining community shift patterns. As a constrained ordination approach, dbRDA uses a multivariate regression-based model to correlate bacterial community variables with environmental variables.²⁹ Furthermore, as an extension of classical redundancy analysis which processes Euclidean distances between samples, dbRDA can analyze other types of community distance, e.g., Bray–Curtis.²⁹ For dbRDA, the T-RFLP profiles or PhyloChip profiles were used as community variables, and significant ($P < 0.05$ by the Monte Carlo permutation test with 999 permutations²⁹) environmental variables (plant treatment, nano-ZnO, and exposure time) were used as constrained variables.

To identify the OTUs sensitive to ENP exposure, we conducted regression analysis on the PhyloChip results to examine the relationship between the hybridization score of each OTU and the ENP exposure dose, and to define the sensitive OTUs as those whose hybridization scores significantly changed according to ENP exposure. To limit the potential high false discovery rate caused by multiple testing, we corrected the original P values using the Benjamini–Hochberg (BH) procedure.³⁰ If the statistical test on the regression equation was significant after Benjamini–Hochberg correction (adjusted $P < 0.05$), then the OTU was identified as a sensitive OTU with either a positive or negative correlation with ENP exposure. Regression analysis was also conducted to examine nano-CeO₂ and nano-ZnO effects on soil bacterial richness, defined as the number of different terminal restriction fragments (TRFs) or PhyloChip OTUs. Student's t test, coupled with Benjamini–Hochberg correction (adjusted $P < 0.05$), was conducted on the PhyloChip results to identify bacterial OTUs that differed in the presence or absence of soybean plants.

Analyses were conducted using CANOCO (Microcomputer Power, Ithaca, NY, U.S.A.), R (<http://www.r-project.org/>), or SigmaPlot (Systat Software, San Jose, CA, U.S.A.).

RESULTS AND DISCUSSION

Soil Bacterial Community Structure and Diversity. In the dbRDA graphs, bacterial community data from 0-day exposure samples clustered together (Figure 1 and SI Figure

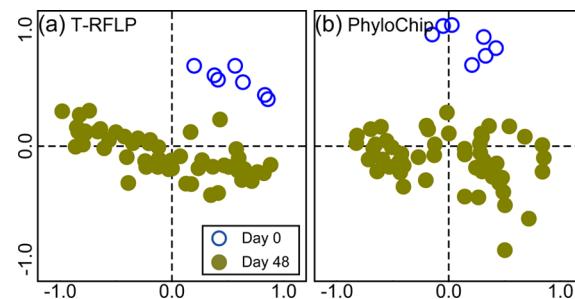

Figure 1. Exposure time effects on soil bacterial communities as analyzed by distance-based redundancy analysis (dbRDA), showing that soil microbial communities at day 0 were more similar to each other, irrespective of nanoparticle treatment, than to communities after 48 days of incubation. The x - and y -axis represent the first and the second ordination axis, respectively. Soil bacterial communities were independently characterized by both terminal restriction fragment length polymorphism (T-RFLP, a) and PhyloChip (b). In these graphs, the soil treatments (without or with ENPs at various doses, and with or without plants) are not distinguished. Open symbols are from day 0, i.e., immediately after soils and ENPs were mixed; closed symbols are after 48 days.

S1), indicating no ENP effects on either DNA extraction or further community analysis methods. In a prior study, exposure time was an important factor in ENP effects: with 0-day exposure, soil bacterial communities were unaffected by nano-TiO₂ and nano-ZnO, although soil DNA was reduced after 15 and 60 days.⁸ In the 48-day samples here, soil bacterial community data for the unplanted treatments distributed to the left side of the first axis that mainly differentiated plant effects, while data for the planted treatments distributed to the right side (Figure 2 and SI Figure S1), indicating that soybean plants overall changed soil bacterial communities. With T-RFLP analysis, although soil bacterial community data for the planted treatments were not totally separate from the unplanted treatments, the same trend of bacterial community shifts was observed (Figure 2a). For example, when we further examined plant effects for different ENP treatments, bacterial community data for unplanted versus planted treatments were mostly different (Figure 2c–e). With PhyloChip analysis, irrespective of the ENP treatments, soil bacterial communities differed between planted and unplanted treatments (Figure 2b). Plant roots are known to alter the composition and diversity of rhizosphere microbial communities.³¹ In this study, the soils in planted pots were mostly rhizosphere, since the rooting density was high and, thus, roots likely affected the entire soil volume.

We then examined nano-CeO₂ and nano-ZnO effects on the estimated richness of soil bacterial communities. T-RFLP analysis did not show measurable effects of nano-CeO₂ and nano-ZnO for either unplanted or planted soils ($P > 0.05$ for all combinations, Figure 3a,b). Also, nano-CeO₂ did not significantly change soil bacterial richness, as estimated by either T-RFLP or PhyloChip, in either unplanted or planted soils ($P > 0.05$ for all combinations, Figure 3a,c). However, in unplanted soils, bacterial community richness (as estimated by PhyloChip at the OTU level) exponentially decreased as a function of nano-ZnO dose ($P < 0.05$, Figure 3d). This pattern

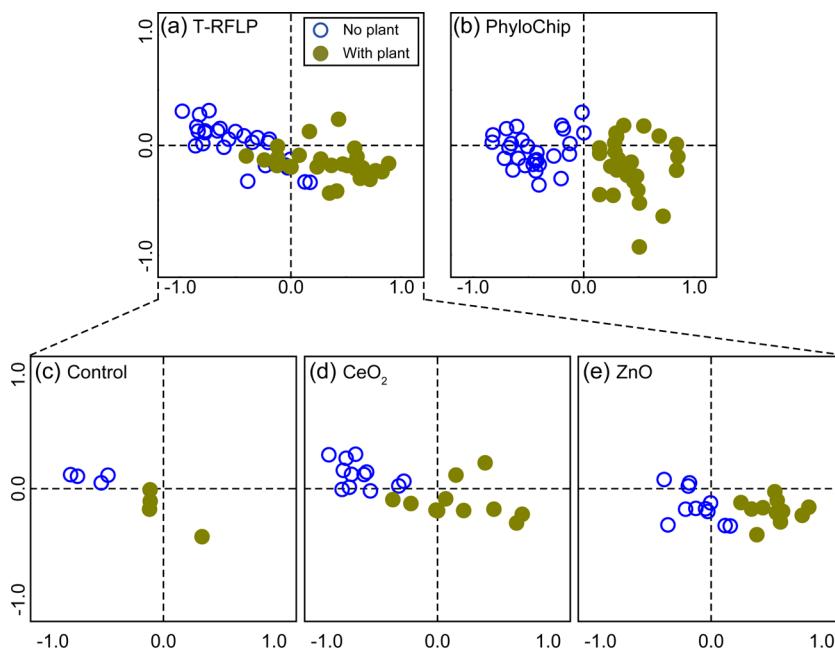

Figure 2. Plant effects after 48-days on soil bacterial communities analyzed by distance-based redundancy analysis (dbRDA). Time 0 data are shown in Figure 1 but not here. The x - and y -axis represent the first and the second ordination axis, respectively. Soil bacterial communities were independently characterized by both terminal restriction fragment length polymorphism (T-RFLP, a, c, d, and e) and PhyloChip (b). With T-RFLP analysis, plant effects at different ENP conditions, i.e., ENP-free control (c), nano-CeO₂ (d), and nano-ZnO (e), were separately plotted. Open symbols are for unplanted soils; closed symbols are for planted soils.

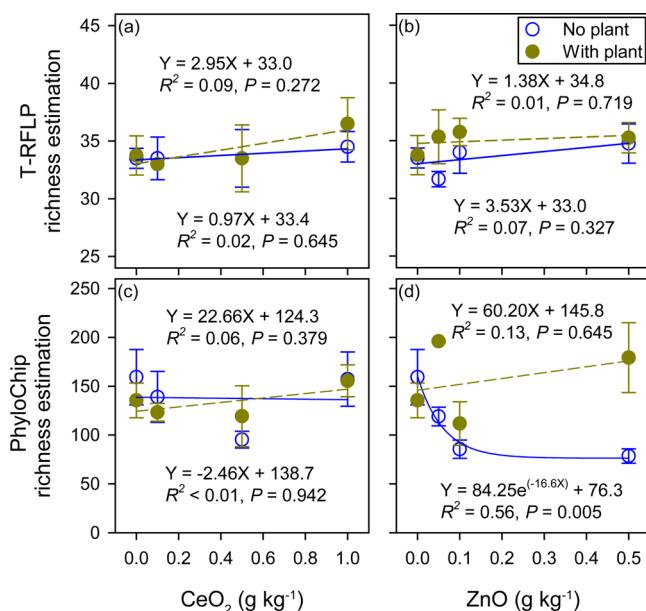

Figure 3. Effects of nano-CeO₂ (a and c) and nano-ZnO (b and d) on the number of terminal restriction fragments (a and b), and the number of bacterial OTUs estimated by PhyloChip analysis (c and d) in unplanted and planted soils after 48 days exposure. The x -axes display doses and not measures of actual exposure. Error bars indicate the standard error of the mean (with T-RFLP analysis, $n = 4$ except for the low dose of nano-ZnO treatments in unplanted and planted soils, and the low dose of nano-CeO₂ treatment in planted soils where $n = 3$; with PhyloChip analysis, $n = 4$ except for the low dose of nano-ZnO treatments in planted soils where $n = 2$). In each graph, the upper regression line equation corresponds to the "With plant" (closed symbols) soils, and the lower regression line equation corresponds to the "No plant" (open symbols) soils.

did not occur in planted soils ($P > 0.05$, Figure 3d), indicating that the presence of soybean plants may have reduced the nano-ZnO effects on soil bacterial diversity. The apparent contradiction between the PhyloChip and T-RFLP results could be attributed to the methodological difference between the two methods. Compared to T-RFLP that generally detects abundant bacteria (relative abundance $>1\%$), PhyloChip is more sensitive and is able to detect more rare bacterial taxa in environmental samples.²⁸

Similarity in community composition was plotted using distance-based redundancy analysis to illustrate nano-CeO₂ and nano-ZnO effects in more detail for with, versus without, plant treatments (Figure 4). There were no apparent effects on overall soil bacterial communities from nano-CeO₂ in unplanted soils since all three doses of nano-CeO₂ (0.1, 0.5, and 1.0 g kg⁻¹) resulted in overlapping similarity maps including with the ENP-free control, by both T-RFLP and PhyloChip analyses (Figure 4a and b). However, the low dose of nano-CeO₂ (0.1 g kg⁻¹) had a distinctively different effect in planted soils. With T-RFLP analysis, 0.1 g kg⁻¹ nano-CeO₂ resulted in distinctly separated similarity maps (Figure 4e); with PhyloChip analysis, there was more spread in the replicates for 0.1 g kg⁻¹ nano-CeO₂, yet the treatments were distinct (Figure 4f). Because 0.1 g kg⁻¹ nano-CeO₂ did not affect soil bacterial communities in unplanted soils (Figure 4a,b), the observed community shifts in planted soils in response to 0.1 g kg⁻¹ nano-CeO₂ were probably not related to the direct effects of nano-CeO₂. In a previous paper from this study, Priester et al. showed that, compared to the ENP-free control, 0.1 g kg⁻¹ nano-CeO₂ exerted the most pronounced effects on plant growth parameters, such as lower leaf count, lower leaf cover, and lower root biomass; in particular, plants harvested from 0.1 g kg⁻¹ nano-CeO₂ treatment were significantly shorter (final stem length; $P = 0.05$) than controls.¹⁴ Therefore, it is noteworthy that the previously

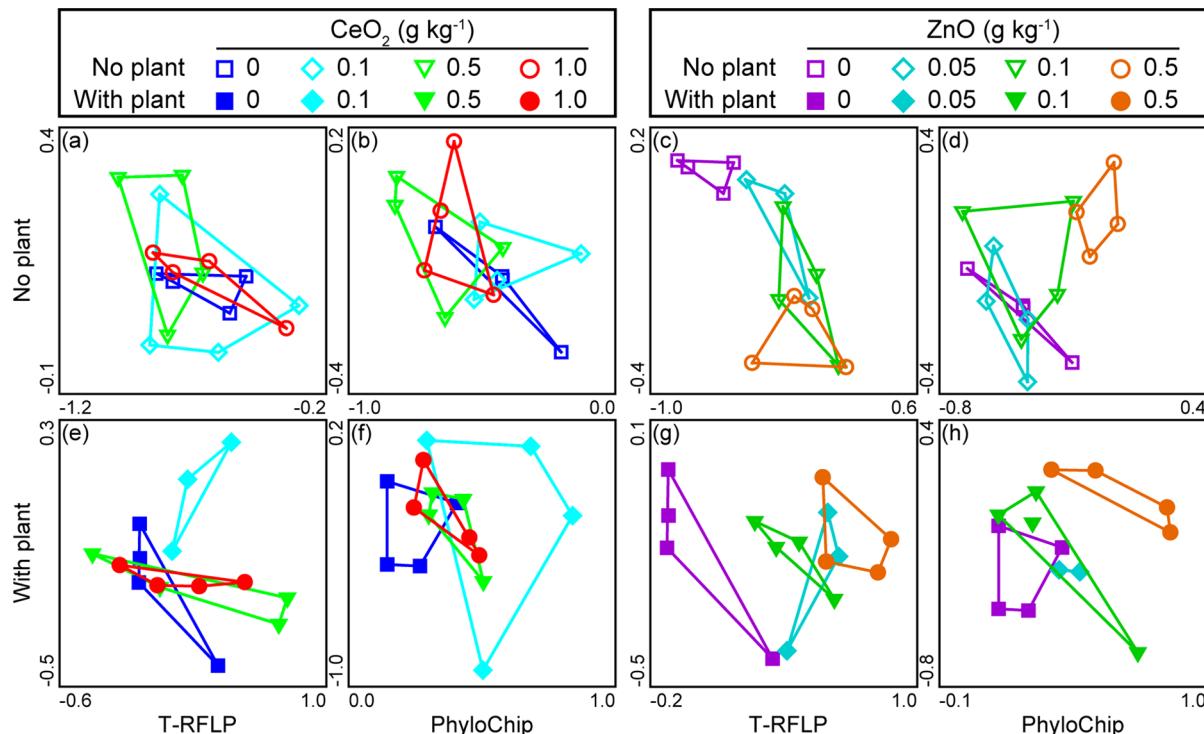

Figure 4. Effects of nano- CeO_2 (a, b, e, and f) and nano- ZnO (c, d, g, and h) on soil bacterial communities in unplanted (open symbols) or planted (solid symbols) soils, analyzed by distance-based redundancy analysis (dbRDA). The x- and y-axis represent the first and the second ordination axis, respectively. These data are also plotted in Figures 1 and 2 to display overall study effects of time or planting, respectively. Here, the data are separately displayed for each ENP, with (filled symbols) versus without (open symbols) plants, to examine detailed treatment effects. Soil bacterial communities were independently characterized by both terminal restriction fragment length polymorphism (T-RFLP, a, c, e, and g) and PhyloChip analysis (b, d, f, and h).

reported stunted plant growth at 0.1 g kg^{-1} nano- CeO_2 is accompanied herein by bacterial community shifts in planted soils in response to 0.1 g kg^{-1} nano- CeO_2 . Furthermore, higher concentrations of nano- CeO_2 had little effect on plant growth,¹⁴ which also accompanies the minimal effects of medium and high nano- CeO_2 on soil bacterial communities herein. Although we did not measure plant root exudates, they are likely to have been reduced due to the stunted growth when plants were grown in the presence of 0.1 g kg^{-1} nano- CeO_2 , since root exudates often correlate with root and shoot biomass (SI Figure S2).^{32,33} The quantity and composition of root exudates may also have been changed in the 0.1 g kg^{-1} nano- CeO_2 treatment as a result of plants mounting a defense against abiotic stress. Alternatively, damaged or stressed plants may be leakier. Perhaps relatedly, nano-Ag caused a significant release of dissolved organic carbon through affecting aquatic plants,³⁴ and nano-Ag toxicity to *Chlamydomonas reinhardtii* was mitigated by algal-produced organic compounds.³⁵ It is therefore conceivable that, although bacterial community richness was not significantly affected by nano- CeO_2 , 0.1 g kg^{-1} nano- CeO_2 impacted soil bacterial community composition indirectly through reducing plant growth and, thus, changing the quantity and composition of plant root exudates (SI Figure S2).

Differently from the effects of nano- CeO_2 , nano- ZnO resulted in dose-dependent effects on soil bacterial communities. For planted or unplanted soils, the high dose of nano- ZnO (0.5 g kg^{-1}) resulted in distinctly separated similarity maps from the ENP-free control, yet the similarity maps of low and medium nano- ZnO treatments (0.05 and 0.1 g kg^{-1}) tended to distribute between the control and high nano- ZnO data (Figure

3c, d, g, and h). The similarity maps from T-RFLP versus PhyloChip showed some differences: with T-RFLP analysis, the similarity maps of low and medium nano- ZnO treatments were more similar to the high nano- ZnO treatment, while with PhyloChip analysis the similarity maps of low and medium nano- ZnO were more similar to the ENP-free control. Our previous study using a California grassland soil also showed that nano- ZnO significantly altered soil bacterial communities in a dose dependent manner,^{8,11} indicating that nano- ZnO is bioavailable to soil bacteria.

Sensitive Bacterial OTUs. We defined sensitive bacterial OTUs as those whose hybridization scores showed significant relationships to the concentrations of either nano- CeO_2 or nano- ZnO (adjusted $P < 0.05$ after multiple testing corrections using BH procedure). Among the 514 bacterial OTUs that could be classified at the phylum level, no OTUs were significantly correlated with nano- CeO_2 (adjusted $P > 0.05$ for all), while 103 OTUs (20.0%) were significantly correlated with nano- ZnO in either unplanted or planted soils, or both (adjusted $P < 0.05$ for these 103 OTUs, SI Table S2). We also identified 261 OTUs that differed in the presence and absence of soybean plants (adjusted $P < 0.05$ for these 261 OTUs), with 68 OTUs sensitive to nano- ZnO (SI Table S3). We previously found a dose-dependent effect of nano- CeO_2 on nodule N_2 fixation potential,¹⁴ while here we did not find dose-dependent nano- CeO_2 effects on soil rhizobia. Because nodule N_2 fixation could be modulated by multiple processes (e.g., nodule formation, bacteroid infection of nodules, or fixation rates),³⁶ reduced N_2 fixation potentials in root nodules does not require decreased rhizobia populations in soils.

Among the 103 OTUs sensitive to nano-ZnO, 15 OTUs were positively correlated with nano-ZnO, while 88 OTUs were negatively correlated with nano-ZnO (Table 1), indicating a

mainly adverse effect of nano-ZnO on soil bacteria. Our previous study using a different soil also showed that more native soil bacterial taxa within communities showed negative, versus positive, responses to nano-ZnO exposure.¹¹

Interestingly, fewer bacterial OTUs showed significant responses to nano-ZnO in planted versus unplanted soils (41 versus 85, Table 1), indicating that the cultivation of soybean plants during ENP exposure may reduce ENP effects on some individual taxa. The mitigation effects could be partially attributed to the additional input of organic materials introduced by plant roots in the form of root exudates and sloughed root cells, although this was not directly tested. The newly introduced organic materials may attenuate ENP toxicity by immobilizing ENPs or sequestering metallic ions released by soluble metal oxide ENPs.^{4,19} Perhaps relatedly, nano-CuO and nano-ZnO were more toxic to bacterial community growth (by the leucine incorporation method) in mineral soil (40 g kg^{-1} organic-C) than in organic-matter-rich soil (154 g kg^{-1} organic-C).³⁷ Furthermore, soil sorption reduced the bioavailability and antibacterial activity of fullerene (C_{60}) and the sorption capacity increased with soil organic matter content,²¹ indicating the role of soil organic matter in attenuating ENP toxicity. In our experimental system, there was more aboveground and belowground biomass when plants were grown in the presence of nano-ZnO, and belowground biomass was significantly higher in the high nano-ZnO treatment than in the control ($P < 0.05$, Student's *t* test).¹⁴ The stimulated plant growth could be attributed to the increased Zn uptake in the presence of dissolvable nano-ZnO, since Zn is a micronutrient that is needed for plant photosynthesis.²⁵ It is conceivable that the stimulation of plant growth by nano-ZnO could have caused more belowground exudation.^{32,33}

ENP translocation from the soil into the plant is an unlikely explanation for the attenuated ENP effects herein, since less than 1% of the total applied Zn was translocated into the plants.¹⁴ However, given the abundant root biomass in the pots, the root surface area could have been high enough to sorb Zn ions and thus decrease their bioavailability and related effects to soil bacteria. Therefore, in addition to exudates and root cell sloughing, the sorption to root surfaces might be a mechanism by which bioavailable Zn is decreased. However, this mechanism was not studied directly, e.g., by measuring Zn associated with the roots before, versus after, root washing.¹⁴

The taxonomic affiliations (kingdom, phylum, class, order, family, and genus) of the 103 sensitive OTUs to nano-ZnO are summarized in SI Table S2, showing that the phylum *Proteobacteria* contains the highest number of sensitive OTUs

(35), followed by *Firmicutes* (17), *Cyanobacteria* (14), *Acidobacteria* (8), *Planctomycetes* (8), *Bacteroidetes* (6), *Gemmatimonadetes* (5), *Actinobacteria* (3), *Verrucomicrobia* (3), WS3 (2), OP11 (1), and *Synergistetes* (1). On the basis of the taxonomic affiliations, some of the sensitive OTUs are potentially significant to terrestrial N and C cycling. For example, OTU569 (the genus *Ensifer*, also called *Sinorhizobium*), known as a symbiotic N₂-fixing bacterium, negatively correlated with nano-ZnO in unplanted soils (adjusted $P < 0.05$, SI Table S2). However, OTU112 (the genus *Rhizobium*), another symbiotic N₂-fixing bacteria, positively correlated with nano-ZnO in planted soils (adjusted $P < 0.05$, SI Table S2). We also found that two bacterial groups, the family *Rhodospirillaceae* (OTU048 and OTU499) and the genus *Clostridium* (OTU454), which contain free-living N₂-fixing bacteria,^{38,39} negatively correlated with nano-ZnO in unplanted soils (adjust $P < 0.05$ for all, SI Table S2). Furthermore, OTU147 and OTU550 (the genus *Azotobacter*), another free-living N₂-fixing taxa,⁴⁰ negatively correlated with nano-ZnO in both unplanted and planted soils (adjusted $P < 0.05$ for all combinations, SI Table S2). Besides the OTUs involved in N₂ fixation, we also found some sensitive OTUs, i.e., OTU127 and OTU356 (the genus *Sphingomonas*, SI Table S2), that are known to be associated with the degradation of a variety of recalcitrant organic compounds.⁴¹

Previous bacterial population studies have reported greater toxicity of nano-ZnO to *Sinorhizobium meliloti* relative to nano-CeO₂,⁴² and the detrimental effects of nano-WO₃ (<10 mg L⁻¹) and nano-Ag (around 10 mg L⁻¹) on *Azotobacter vinelandii*,^{40,43} which partially support our observations regarding N₂-fixing bacteria. In soil exposure experiments without plant cultivation, *Bradyrhizobium canariense* was reported to be sensitive to nano-Ag;¹² *Flavobacteriales* and *Sphingomonadales* were suppressed by nano-Cu and nano-ZnO;⁴⁴ *Rhizobiales* and *Sphingobacteriaceae* were negatively affected by nano-CuO.¹³ Our previous soil microcosm experiment also found that both nano-TiO₂ and nano-ZnO affected bacterial taxa associated with nitrogen fixation (the order *Rhizobiales*), methane oxidation (the family *Methylobacteriaceae*), and recalcitrant organic compound decomposition (families *Sphingomonadaceae* and *Streptomycetaceae*).¹¹ Because of the indigenous community dissimilarities between soils, some identified sensitive taxa differed across studies and soils. However, some functionally significant bacterial groups, i.e., the group associated with N₂ fixation and the group associated with recalcitrant organic matter decomposition, were repeatedly identified as sensitive bacteria by multiple studies, suggesting potential ecosystem consequences of ENP exposure.

In conclusion, our results demonstrate that, although nano-CeO₂ did not affect soil bacterial communities in unplanted soils, 0.1 g kg⁻¹ nano-CeO₂ had a distinctive effect in planted soils, probably due to its previously reported effects on plant growth¹⁴ which may have indirectly affected soil bacterial communities through changed root exudates. In contrast, nano-ZnO, apparently, directly impacted soil bacterial communities, with 0.5 g kg⁻¹ nano-ZnO significantly altering communities in both unplanted and planted soils. However, the number of sensitive bacterial OTUs to nano-ZnO was reduced by around 50% in planted soils in comparison with unplanted soils (Table 1), indicating that the presence of soybean plants reduced nano-ZnO effects on soil bacterial communities. The mitigation effects of soybean plants on nano-ZnO toxicity could be from Zn ion sorption to plant roots, which would reduce Zn

availability to soil bacteria; it could also be from carbon that is introduced into soils by plant roots in the form of root exudates and sloughed root cells. Such plant-derived compounds could also modify the bioavailability and toxicity of nano-ZnO, e.g., by immobilizing ENPs and sequestering toxic ions released from dissolving nanoparticles. This is in contrast to the results with 0.1 g kg⁻¹ nano-CeO₂, whereby the plant response to nano-CeO₂ could have created, not ameliorated, a soil bacterial community shift. Thus, plants—likely through their effects on belowground biogeochemistry—can either promote (i.e., for the 0.1 g kg⁻¹ nano-CeO₂ treatment) or limit (i.e., for the 0.5 g kg⁻¹ nano-ZnO treatment) ENP effects on soil bacterial communities. As ENPs increasingly enter the soil environment, they will alter how soils function and may therefore affect agricultural plants and possibly the food we harvest from them. But the effects of ENPs will be altered by those very plants, creating feedbacks that alter the functioning of the plant–soil–ENP system. Developing effective policies to address the new field of nanotoxicology requires understanding both the direct toxicological effects of ENPs on humans and other sensitive species of plants and animals, but also the indirect effects on environmental systems. Assessing these requires integrating focused laboratory experiments with whole system microcosms as presented here.

Materials and Methods

Polymerase Chain Reaction (PCR) and T-RFLP. Negative controls, containing all PCR components except DNA templates, were included to test for contamination. For each sample, PCR products from duplicate reactions were pooled to reduce random PCR bias. The size and quality of PCR products were verified by 1.2% agarose-gel electrophoresis (Flashgel DNA system; Lonza, Allendale, NJ, USA). PCR products were purified using the QIAquick PCR Purification Kit (Qiagen, Valencia, CA, USA), and quantified using the Quant-iT dsDNA Assay Kit, Broad Range (Invitrogen, Eugene, OR, USA), according to the manufacturer's instructions.

The purified PCR products (600 ng) were digested at 37°C for 16 h using the *HhaI* restriction enzyme (New England BioLabs, Ipswich, MA, USA), deactivated at 65°C for 20 min, and purified again using the QIAquick Nucleotide Removal Kit (Qiagen, Valencia, CA, USA), according to the manufacturer's instructions.

PhyloChip Analysis and Data Preprocessing. To calculate the overall fluorescence intensity of each probe set that represents a specific OTU, the central nine pixels of individual probes were ranked by intensity, and the 75th percentile intensity values were used. Probe intensities were background-subtracted, i.e. scaled to the quantitative standards,⁴ and collected as integer values ranging from 0 to 65,536 (2^{16}). Fluorescence intensities of individual probes within each probe set were averaged after discarding the highest and lowest values, and the mean was \log_2 transformed and rounded to decimal numbers ranging from 0 to 16. For compatibility with the statistical analysis, the mean was multiplied by 1000 then rounded to the nearest integer, allowing a range of 0 to 16,000. The mean was referred to as the hybridization score of a specific OTU.⁴

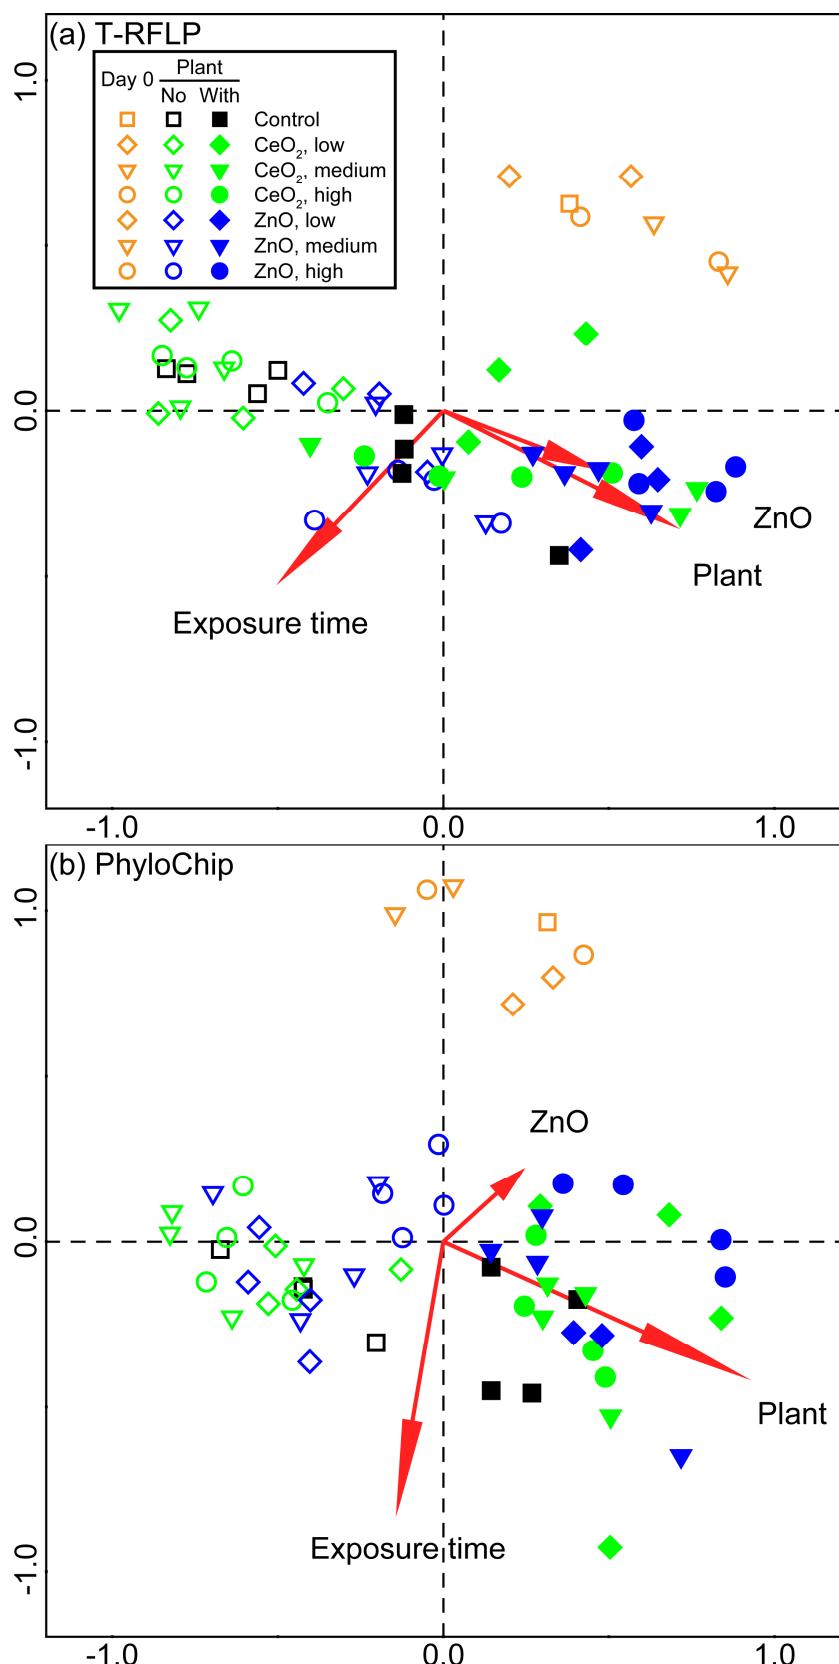

Figure S1. Distance-based redundancy analysis (dbRDA) to illustrate the effects of different environmental variables (plant, ENP dose, and exposure time) on soil bacterial communities. The x- and y-axis represent the first and the second ordination axis, respectively. Soil bacterial communities were independently characterized by both terminal restriction fragment length polymorphism (T-RFLP, a) and PhyloChip analysis (b). Control: ENP-free control; Low: low dose of nano-CeO₂ (0.1 g kg⁻¹) or nano-ZnO (0.05 g kg⁻¹); Medium: medium dose of nano-CeO₂ (0.5 g kg⁻¹) or nano-ZnO (0.1 g kg⁻¹); High: high dose of nano-CeO₂ (1.0 g kg⁻¹) or nano-ZnO (0.5 g kg⁻¹). The red arrows point to microbial communities whose treatments were significantly related to the variable (arrow label); the lengths of the arrows indicate the variables' effects magnitudes on soil microbial community composition.

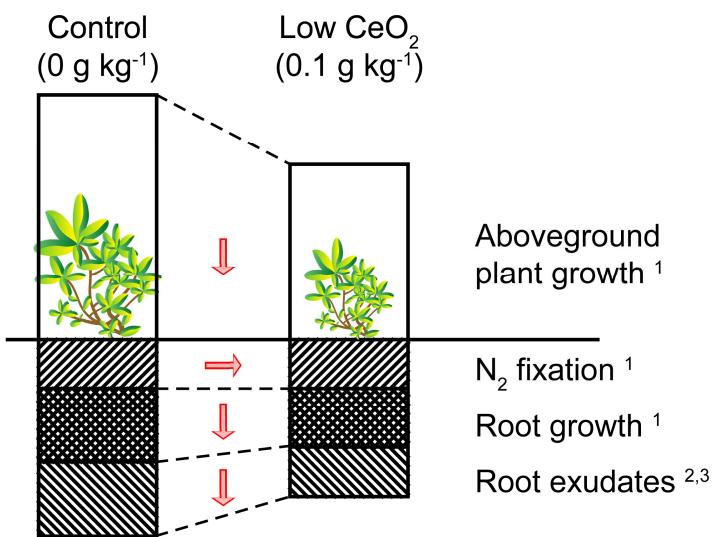

Figure S2. Conceptual illustration of the possible effects of 0.1 g kg^{-1} nano- CeO_2 on N_2 fixation, aboveground and belowground soybean biomass, and root exudates. In a previous paper from this study regarding plant growth and N_2 fixation potential, Priester et al. showed that, compared to the ENP-free control, 0.1 g kg^{-1} nano- CeO_2 did not alter N_2 fixation, but stunted aboveground and belowground plant growth.¹ Although not quantified, plant root exudates are likely to have been reduced due to stunted plant growth when plants were grown in the presence of 0.1 g kg^{-1} nano- CeO_2 , since it has been reported in other studies that root exudates positively correlate with root and shoot biomass.^{2,3} Our prior interpretation regarding N_2 fixation at this low nano- CeO_2 dose was that the plants preferentially allocated photosynthate to root nodules so that the N_2 fixation apparatus was functional.¹ Decreased root growth and aboveground plant biomass would support the interpretation, and would support that root exudates also would have been decreased. With less, or even compositionally different, bioavailable plant-derived C compounds entering planted soils, it is logical that bacterial communities in the low nano- CeO_2 treatment would vary from the communities in planted control soils.

Table S1. The number of independent DNA extracts, T-RFLP profiles, and PhyloChip runs.

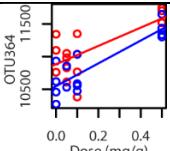

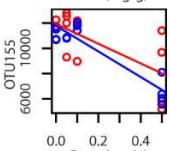

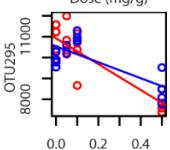

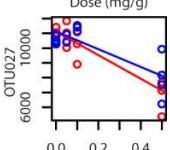

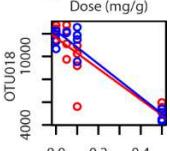

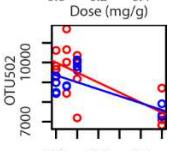

Dose (g kg ⁻¹)	Control	CeO ₂			ZnO		
	0	0.1	0.5	1	0.05	0.1	0.5
DNA extracts*

No plant	4	4	4	4	3	4	4
With plant	4	3	4	4	3	4	4
PhyloChip runs ***							
Day 0	1	1	1	1	1	1	1
No plant	4	4	4	4	4	4	4
With plant	4	4	4	4	2	4	4

*One replicate of the low dose nano-ZnO treatment in planted soils was not included in DNA extraction and the following T-RFLP and PhyloChip analyses, since the plant died after transplantation.

**Two T-RFLP outliers, one from the low nano-ZnO treatment in unplanted soils and another from the low nano-CeO₂ treatment in planted soils, were not included in the statistical analyses.

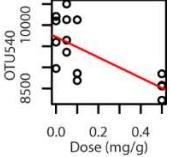

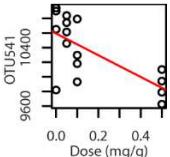

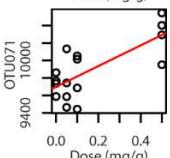

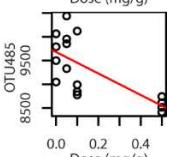

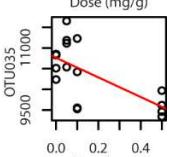

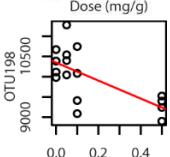

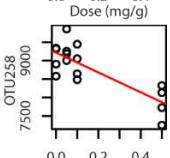

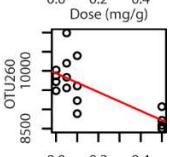

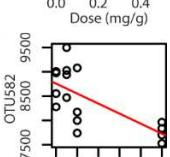

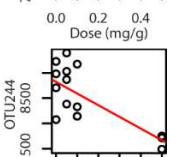

***One PhyloChip outlier from the low nano-ZnO treatment in planted soils was not included in the statistical analyses.

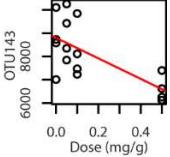

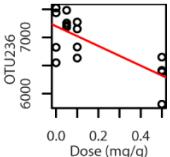

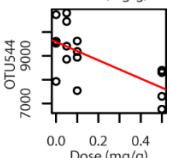

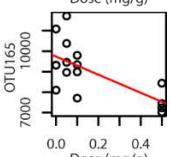

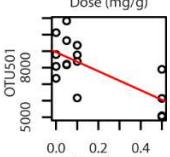

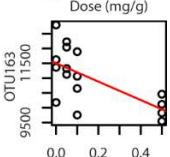

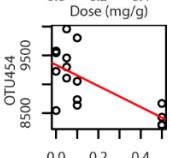

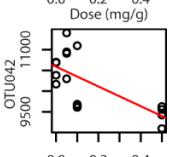

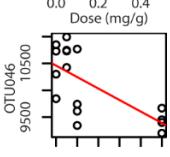

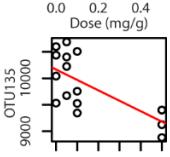

Table S2. The bacterial taxa (103 of 514 classified OTUs) identified as sensitive to nano-ZnO exposure through linear regression ($Y = aX + b$). The hybridization score of bacterial OTU determined by PhyloChip was used as the dependent variable, and the exposure dose of nano-ZnO was the independent variable. The red lines represent unplanted treatments, and the blue lines represent planted treatments. Because the OTU is a lower level than the genus, and can be further grouped to higher taxonomic levels (kingdom; phylum; class; order; family; genus), the same genus may contain different OTUs, with some increasing and others decreasing, in the presence of nano-ZnO.

OTU	Plant	Linear regression: $Y = aX + b$					Taxonomic affiliation (kingdom; phylum; class; order; family; genus)

Table S3. The bacterial OTUs that differed in the presence and absence of soybean plants. The hybridization scores of bacterial OTUs determined by PhyloChip were compared using Student's *t* test, coupled with Benjamini-Hochberg correction (adjusted *P* < 0.05).

OTU	No plant		With plant		Adjusted <i>P</i>	Sensitive to ZnO	Taxonomic affiliation (kingdom; phylum; class; order; family; genus)
