Abstract. In this paper, we present the results of using a parallel computational tool, BeamBeam3D, developed at Lawrence Berkeley National Laboratory, for strong-strong/strong-weak modeling of the beam-beam effects in three hadron accelerators: RHIC, Tevatron and LHC. This tool calculates self-consistently the electromagnetic beam-beam forces for arbitrary distributions and separation during each collision when a strong-strong beam-beam interaction model is used. When a strong-weak model is used, the code has the option of using a Gaussian approximation for the strong beam. Using the strong-strong model, we have studied the effect of time modulated offset beam-beam interaction on the emittance growth in the RHIC and LHC. We observed an extra 0.04% emittance growth after 300,000 turns in the RHIC where the time-averaged beam-beam offset is one transverse rms beam size and the modulation frequency is 10 Hz. There is no significant additional emittance growth in the LHC after one million turns where the time-averaged offset is zero. Using the strong-weak model, we have also studied the antiproton lifetime subject to 72 long range beam-beam interactions at 150 GeV injection energy in the Tevatron. The simulation shows a qualitative agreement with the experimental observation of the smaller antiproton emittance having a longer lifetime.

INTRODUCTION

The beam-beam interaction puts a strong limit on the luminosity of the high energy hadron colliders. For example, in the Tevatron Run II experiment, long-range beam-beam forces significantly reduce the antiproton lifetime and is one of the major factors preventing the achievement of designed luminosity. To study the beam-beam interaction, an important approach is to use self-consistent macroparticle simulation. However, in the hadron accelerators, radiation damping is very weak for hadron particles. It requires to track the particles for many thousand turns to study the long-term emittance growth and particle losses. Using a parallel beam-beam computational tool will significantly reduce the study time. Meanwhile, it also provides the capability to include more complex physical process and to do the simulations with higher numerical accuracy.

COMPUTATIONAL MODEL

In the computational beam-beam model, we have used six dimensional phase space coordinates $(x, p_x, y, p_y, \Delta z, \Delta p_z/p_0)$ to describe the particle motion in the accelerator. Here, $p_{x,y}$ is the transverse

momentum normalized by the total momentum of a reference particle ($p_0 = E_0/c$), $\Delta z = s - ct$ (s with c the speed of light, and $\Delta p_z = |p| - p_0$). To calculate the electromagnetic force from the beam-beam interaction, we have used a multiple slice model. In this model, each beam bunch is divided into a number of slices along the longitudinal direction in the moving frame. Each slice contains nearly the same number of particles at different longitudinal locations Δz . The collision point between two opposite slices i and j is determined by

$$s_c = \frac{1}{2}(\Delta z_i^+ - \Delta z_j^-) \quad (1)$$

The transverse coordinates of the particles at the collision point are given by

$$x^c = x + s_c p_x \quad (2)$$

$$y^c = y + s_c p_y \quad (3)$$

The slopes of the particles are updated using the beam-beam electromagnetic forces at the collision point following

$$p_{x_{new}} = p_x + \Delta p_x \quad (4)$$

$$p_{y_{new}} = p_y + \Delta p_y, \quad (5)$$

where

$$\Delta p_{x_2} = \frac{2q_1q_2N_1}{\gamma_2 4\pi\epsilon_0 m_2 c^2} E_{x_1} \quad (6)$$

$$\Delta p_{y_2} = \frac{2q_1q_2N_1}{\gamma_2 4\pi\epsilon_0 m_2 c^2} E_{y_1}. \quad (7)$$

In the above equations, the subscripts 1 and 2 pertain to each of the two beams, the corresponding equations for the other beam are obtained from the above by the exchange $1 \leftrightarrow 2$, $\gamma = 1/\sqrt{1-\beta^2}$, $\beta_i = v_i/c$, $i = x, y, z$, c is the speed of light, ϵ_0 is the vacuum permittivity, q is the charge of the particle, m is the rest mass of particle, N is the number of particles in a bunch, and E_x and E_y are the transverse electric fields generated by the opposite moving beam. After the collision, the particles of each slice drift back to their original locations according to

$$x = x^c - s_c p_{x_{new}} \quad (8)$$

$$y = y^c - s_c p_{y_{new}} \quad (9)$$

The electric fields generated by the opposite moving beam can be obtained from the solution of Poisson's equation. The solution of Poisson's equation can be written as

$$\phi(x, y) = \int G(x, \bar{x}, y, \bar{y}) \rho(\bar{x}, \bar{y}) d\bar{x}d\bar{y} \quad (10)$$

where G is the Green's function and ρ is the charge density. For the case of transverse open boundary conditions, the Green's function is given by:

$$G(x, \bar{x}, y, \bar{y}) = -\frac{1}{2} \ln((x-\bar{x})^2 + (y-\bar{y})^2) \quad (11)$$

The convolution for ϕ in Eq. 10 can be computed efficiently using an FFT in the doubled computational domain as described by Hockney and Eastwood. [1].

In the FFT-based algorithm, the particle domain and the electric field domain are contained in the same computational domain. Here, the particle domain is the configuration space containing the charged particles, and the field domain is the space where the electric field is generated by the charged particles. In the beam-beam interaction, the two opposite moving beams might not overlap with each other. For example, in the long-range interaction, the two colliding beams could be separated by more than several σ , where σ is the rms size of the beam. Thus the field domain where the electric field is generated by one beam can be different from the particle domain containing the beam. In the beam-beam simulation, the origin of the field domain can be at an arbitrary location and varies from turn to turn. To apply Hockney's algorithm directly will require the computational domain to contain both the particle domain and the field domain, i.e. both beams. Since there is a large empty space between two

beams, containing both beams in one computational domain will result in a poor spatial resolution of the beams. This is also computationally inefficient because the electric fields in the empty space between two beams are not used.

To avoid this problem, we have defined a *shifted Green function* as

$$G_s(x, \bar{x}, y, \bar{y}) = -\frac{1}{2} \ln((x_c + x - \bar{x})^2 + (y_c + y - \bar{y})^2) \quad (12)$$

where x_c and y_c are the center coordinates of the field domain. The electric potential in the field domain is written as

$$\phi(x + x_c, y + y_c) = \int G_s(x, \bar{x}, y, \bar{y}) \rho(\bar{x}, \bar{y}) d\bar{x}d\bar{y}. \quad (13)$$

Using the shifted Green function, the center of the field domain is shifted to the center of the particle domain. The range of x and y cover both the particle domain and the field domain in one computational domain. The FFT can be used to calculate the convolution in Eq. 10 using the new Green function. A more detailed discussion of the shifted Green function method can be found in [2].

To summarize, using the shifted Green function:

- avoids the requirement that the particle domain and the field domain be contained in one big computational domain,
- leads to better numerical resolution for the charge densities and the resulting electric fields than the conventional method, because the empty space between the beams is not included in the calculation,
- is far more efficient, in terms of computational effort and storage, than the traditional approach of gridding the entire problem domain.

When the strong-weak beam-beam model is used, the program has the option to use the electric field from the numerical solution of Poisson's equation or from the Gaussian approximation of the strong beam. In the latter case, the electric field is calculated following a Gaussian code [3].

The effects of external fields can be represented, in the small-amplitude approximation, by a linear transfer map between collision points. A one-turn map is included to take into account the linear machine chromaticity effect. The effects of radiation damping and quantum excitation are represented using a localized stochastic map.

STRONG-STRONG SIMULATIONS OF BEAM-BEAM INTERACTION IN RHIC AND LHC

In the hadron colliders, the closed orbit of each bunch at interaction point can be perturbed due to the vibration of focusing magnets or due to parasitic beam-beam

TABLE 1. RHIC Physical Parameters for the Beam-Beam Simulations

beam energy (GeV)	23.4
protons per bunch	8.4×10^{10}

betatron tunes (ν_x, ν_y)	(0.22, 0.23)
chromaticity (q'_x, q'_y)	(2, 2)
synchrotron tune ν_z	$3.7e-4$
RMS bunch length (m)	3.6
momentum spread	$1.6e-3$
offset (sigma)	1
oscillation frequency (Hz)	10

interaction. This results in the bunches colliding at the interaction point with a small transverse offset. For example, in RHIC, there exists triplet vibration with frequency close to 10 Hz, which leads to offset of 5 – 10% of one σ at the interaction point [4]. For practical purposes, it is important to know if offsets (static and modulated) cause additional emittance growth. To study this effect, we have carried out a strong-strong beam-beam simulation of two proton beams colliding in RHIC. The major physical parameters used in the simulation are given in Table 1. Here, we have chosen an offset of one σ from the closed orbit in order to maximize its effect since the beam-beam force is strongest around one σ for a Gaussian density distribution. The initial distribution was Gaussian but was allowed to evolve freely. We first studied the proton emittance growth in RHIC with static offset beam-beam collision. Fig. 1 shows a comparison of the emittance evolution (averaged over horizontal and vertical plane) with and without offset beam-beam collision. We see that emittance growth after 300,000 turns

FIGURE 1. Emittance evolution (averaged over horizontal and vertical plane) with and without a one σ offset beam-beam collision in RHIC.

is about the same with and without the offset. This suggests that the static beam-beam offset collision will not cause an extra emittance growth. The averaged emittance has grown by about 0.05% after 300,000 turns. This emittance growth is driven by the nonlinear electromag-

TABLE 2. LHC nominal beam-beam parameters

beam energy (TeV)	7
protons per bunch	1.05×10^{11}

momentum spread	$1.11e-4$

netic forces during the beam-beam interaction. Next, we studied the emittance growth with time modulated offset beam-beam collision. Here, we have assumed 10% oscillation amplitude around one σ time-averaged offset in the horizontal direction. The oscillation frequency is set as 10 Hz to emulate the triplet vibration in RHIC. Fig. 2 shows a comparison of the averaged emittance evolution with and without offset beam-beam collision. With the time modulated offset beam-beam collision, the

FIGURE 2. Emittance evolution (averaged over horizontal and vertical plane) with and without a time-modulated offset beam-beam collision in RHIC.

averaged emittance growth is about 0.09% after 300,000 turns. There is about 0.04% extra emittance growth due to the effect of time modulated beam-beam collision. In this simulation for RHIC, we have assumed that time-averaged beam-beam offset is one σ to maximize the effect from time modulated offset beam-beam collision. In LHC, it is estimated that the time-averaged beam-beam offset is about zero but with about 0.1σ bunch-to-bunch closed orbit variation due to the parasitic beam-beam interaction [5]. We have done a strong-strong simulation using a set of nominal LHC physical parameters with 0.1σ oscillation amplitude and 1000 turn oscillation period. The nominal beam-beam parameters of the LHC are given in Table 2. Fig. 3 shows the emittance growth with and without the time modulated beam-beam collision. We see that there is about 0.05% emittance growth after one million turns with the nominal head-on collision. Even though the final emittance from the time modulated beam-beam collision is slightly higher than that without

FIGURE 3. Emittance evolution (averaged over horizontal and vertical plane) with and without offset beam-beam collision in LHC.

offset, the emittance growth rate is about the same. All the above simulations have been done using one million particles for each beam, 128×128 mesh points, and single slice model.

STRONG-WEAK SIMULATION OF LONG RANGE BEAM-BEAM INTERACTION IN TEVATRON

We have assumed a strong-weak beam-beam interaction model in the calculation of the antiproton lifetime since the antiproton intensity is much smaller than the proton intensity (typically a factor of 10). There are 72 long range beam-beam interaction points at the 150 GeV injection stage of the Tevatron. The linear transfer maps between collision points for antiproton particles are obtained from the MAD simulation of the Tevatron lattice. At the collision point, every antiproton receives a kick from the beam-beam force generated by the proton beam. The beam-beam force is calculated assuming a Gaussian distribution for the proton beam. After each turn, a linear chromaticity map and a random diffusion map are applied to all antiprotons. The random kick was added to simulate the effect of gas scattering which has a sizable influence on the emittance growth at injection. The simulations are run for 100,000 turns using one million particles. In the simulation, we have assumed an “aperture” size of 3.25σ , where the σ is the horizontal or vertical rms size at each collision point. The aperture is such that a particle is lost with a unit probability when it hits it. The antiproton lifetime τ is estimated from fitting the antiproton intensity with function $I_0 \exp(-t/\tau)$ using a least square method. Here, I_0 is the initial antiproton intensity.

Fig. 4 shows the antiproton lifetime as a function of the initial antiproton emittance. With a factor 2 increase of the antiproton emittance, the antiproton lifetime de-

FIGURE 4. Antiproton lifetime as a function of antiproton emittance at 150 GeV Tevatron.

creased drastically by more than a factor of 100. The strong antiproton emittance dependency of the lifetime may be due to the following two effects: On the one hand, the larger antiproton emittance gives a larger antiproton beam size and results in a faster loss to the aperture. On the other hand, the larger antiproton beam size reduces the distance between the proton beam and the antiproton particles, which results in stronger nonlinear beam-beam interactions.
