# TRAVEL-TIME UNCERTAINTY, DEPARTURE TIME CHOICE, AND THE COST OF THE MORNING COMMUTE 

#### Abstract

We extend existing models of the commuting time-of-day choice in order to analyze the effect of uncertain travel times. Travel time includes a time-varying congestion component and a random element specified by a probability distribution. We compare results from the uniform and exponential probability distributions and derive the optimal "head start" time that the commuter chooses to account for travel time variability; i.e., a safety margin that determines the probability of arriving late for work. Our model includes a one-time lateness penalty for arriving late as well as the per minute penalties for early and late arrival that other investigators have included. It also generalizes earlier work by accounting for the time variation in the predictable component of congestion, which interacts with uncertainty in interesting ways. A brief numerical analysis of the model reveals that uncertainty can account for a large proportion of the costs of the morning commute.

KEYWORDS: Reliability, Congestion, Time-of-day, Scheduling, Travel-time variation

## Introduction

The choice of home departure time for commuters is an important element of determining how congestion levels will vary during the morning peak. This choice has been related empirically to the cost of early or late arrival relative to some preferred work arrival time $(1,2)$. The planning of on-time arrivals is, however, complicated by the presence of uncertainty in actual travel times.

This paper describes a model in which commuters simultaneously trade off costs of inconvenient schedules, lateness penalties, and the desire to minimize time spent in congested traffic. Like Gaver (3) and Polak (4), we assume that commuters face a probabilistic distribution of travel times, and choose departure time to minimize an expected cost function. In contrast to these authors, our cost function includes a discrete lateness penalty as well as per minute penalties for both early and late arrival; it also accounts for variation over time in the predictable component of congestion. Furthermore, we derive analytically the optimized expected cost function (i.e., the costs resulting after an optimal departure time is chosen). We do this for both a uniform and an exponential distribution for uncertain travel time.

The results show how changes in the uncertainty of travel time affect both the departure time decision and the resulting expected costs. For example, as uncertainty increases, commuters shift their departure schedules to earlier hours to compensate for the increased probability of late arrival; in some cases they overcompensate in the sense that the probability of late arrival decreases as uncertainty increases. As for the resulting expected costs, the functional relationship that we derive relating costs to the underlying parameters of the model is of great interest for empirical studies of traveler behavior under uncertainty ( $5,6,7$ ). We find, for example, that only when we disregard lateness penalties is that functional relationship linear in the standard deviation of travel time as is frequently assumed.

Changes in the level of congestion over the course of the peak period also play an important role in commuter decisions. Rapidly rising congestion shifts the commuter to earlier departure times, but also lowers the probability of late arrival. The opposite is true when congestion levels are falling. These type of trade-offs are fully accounted for in our model.

We begin with a review of the literature on departure time and route choice, especially previous work dealing with uncertain travel times. We then present and solve our analytical model. Next we give some numerical examples that provide quantitative information about the possible importance of various components of the model. We conclude by briefly discussing some implications for both research and policy.

## Literature Review

The reliability of arriving at a destination on time is a key component in the decisions made by commuters for their morning trips. Prashker (8) attempts to classify some perceived components of reliability into a measurable framework using factor analysis. More recently, researchers have produced direct empirical estimates of how travelers respond to reliability $(5,6,7)$. Much of this work has been aided by the development of stated preference survey techniques.

It is useful to begin with an understanding of how travelers choose departure time choice under certainty. Most research has focused on schedule delay, defined as the difference between the actual time of arrival and some ideal time, usually identified with an official work start time. Typically the commuter is assumed to receive some disutility from schedule delay as well as from travel time (1,2,9). In Small's specification (2) this disutility is piecewise linear in schedule delay, i.e., disutility rises linearly in either the early or late direction. In addition, there is a discrete penalty for being late. In all these studies scheduling disutility is traded off against the possible advantages, due to variation in congestion over the rush hour, of shifting one's schedule to take advantage of lower
congestion. In Cosslett's (1) continuous model, this tradeoff appears as a maximization condition involving the slope of the congestion function.

Scheduling models such as these have been incorporated into equilibrium analyses of congestion formation. Basic models for a single link (10-15) have been extended to a variety of circumstances including elastic demand (16,17), networks (16, 18, 19), heterogeneous commuters including arbitrary population distributions for desired arrival times ( 19,20 ), and uncertain capacity or demand (21,22,23). See (24) for a more complete review. Although most of these analyses use deterministic models of the traveler's choice of departure time, a few $(16,25)$ use a discrete-choice model analogous to Small's (2).

Other researchers have incorporated a simpler version of this utility specification into models analyzing uncertain travel times. Gaver (3), Polak (4), and Bates (5) all consider the piecewise linear disutility specification when travel time is uncertain, but none consider congestion that is varying over the rush hour. Hence they examine only the trade-offs inherent in trying to minimize the expected disutility from given arrival times given the randomness in travel times.

Mahmassani and associates (23,26,27,28) simulate time of day departure choices using hypothetical data collected from actual commuters and fed through a traffic simulation model. These papers focus on day to day variations in travel time as commuters gain experience with the system. While travel times may be uncertain, these simulations emphasize how people learn about the shape of the congestion profile as opposed to uncertainties due to non-recurrent events.

Mannering (29) and Abdel-Aty et al. (7) investigate how likely commuters are to make changes in their departure time and/or route choices. Mannering finds that those commuters with longer travel times are more likely to make changes and speculates that these trips may have larger variances. His results also indicate that non-recurrent events may not allow a steady-state equilibrium to evolve, which may have implications for
simulating traffic congestion.
Mannering and Hamed (30) find empirical evidence that work-to-home departure decisions are influenced by similar factors. Such decisions may not be independent of home-to-work departure decisions: for example, some commuters may delay the morning departure with the intent of staying at work until evening congestion levels have fallen. Neither our model nor any other of which we are aware attempts to deal with this dependence.

Mahmassani and Herman (26) and Mahmassani et al. (31) show that commuters tend to adjust departure times more readily than they do routes. In fact, route switches tend to occur when commuters are continually dissatisfied with the outcomes from departure time switches alone (28,31). The lower likelihood of route switching adds credibility to models that examine only the choice of departure time, which can have important impacts on the development and timing of peak congestion levels.

## Analytical Derivation of Model

We now describe a model which explains how uncertainty in travel time affects the expected cost of the morning commute. First we specify the basic components of the cost model, including how changes in congestion levels are accounted for. We then formulate and solve the commuter's scheduling problem using both a uniform and an exponential probability distribution. The solution is then inserted into the expected cost function to determine how total commuting cost depends on the parameters describing the commuter's travel environment. This cost consists of various components that enable us to better understand how significant unreliability is as a contribution to travel cost.

## Cost Model

We assume the following cost function for the morning commute:

$$
\begin{equation*}
\mathrm{C}=\alpha \mathrm{T}+\beta(\mathrm{SDE})+\gamma(\mathrm{SDL})+\theta \mathrm{D}_{\mathrm{L}} \tag{1}
\end{equation*}
$$

where T is travel time, SDE and SDL are schedule delay early and late, respectively (defined below), and $\mathrm{D}_{\mathrm{L}}$ is equal to 1 when $\mathrm{SDL}>0$ and 0 otherwise. $\alpha$ is the cost of travel time, $\beta$ and $\gamma$ are the costs per minute of arriving early and late, respectively, and $\theta$ is an additional discrete lateness penalty.

The variables SDE and SDL are defined with respect to the official work start time, $\mathrm{t}_{\mathrm{w}}$, and the home departure time, $\mathrm{t}_{\mathrm{h}}$. Let $\mathrm{SD} \equiv \mathrm{t}_{\mathrm{h}}+\mathrm{T}-\mathrm{t}_{\mathrm{w}}$ be "schedule delay," the difference between actual arrival time and official work start time. Define

$$
\begin{align*}
& \mathrm{SDL}= \begin{cases}\mathrm{SD} & \text { if } \quad \mathrm{SD}>0 \\
0 & \text { otherwise }\end{cases}  \tag{2}\\
& \mathrm{SDE}= \begin{cases}-\mathrm{SD} & \text { if } \quad \mathrm{SD}<0 \\
0 & \text { otherwise }\end{cases} \tag{3}
\end{align*}
$$

This formulation of costs is that of Small (2), table 2, model 1. It could result if pay is docked for late arrival, or if in some other way the frequency and magnitude of late arrival are costly to one's career. Many analyses of time-of-day decisions have used the first three terms of (1); others have implicitly added the fourth term with $\theta$ set to infinity by excluding the possibility of late arrivals. A more complex model formulation could also vary the amount of time spent at work and thus account for evening travel conditions as additional determinants of the morning commute decision.

The total commute time, T , consists of three elements. $\mathrm{T}_{\mathrm{f}}$ is the free flow travel time when there is no congestion. $\mathrm{T}_{\mathrm{x}}$ is the extra travel time due to congestion which the traveler is sure to encounter; it is a function of $t_{h}$, the home departure time. $T_{r}$ is the extra travel time due to non-recurrent congestion, and is modeled formally as a random variable. Following the standard classification of congestion delays into recurrent and incident-related delays $(32,33)$ we call $\mathrm{T}_{\mathrm{X}}$ "recurrent delay" and $\mathrm{T}_{\mathrm{r}}$ "incident delay."

For simplicity we assume that the probability distribution of $\mathrm{T}_{\mathrm{r}}$ is independent of recurrent congestion and of the time of day of travel. This assumption has the advantage
that it enables us to isolate the impact of exogenous changes in travel time uncertainty. Although the assumption may appear unrealistic, there is a surprising absence of clear-cut empirical evidence for alternative assumptions. Satterthwaite (34), in a review, finds no reported relations between congested traffic and accidents (which are a primary cause of non-recurrent congestion). Hendrickson et. al. (35) analyzed data in Pittsburgh and concluded that variance of travel times is independent of departure times. Richardson and Taylor (36) posit a relationship between congested traffic and increases in travel time variability, but do not derive an explicit relationship.

To simplify the analysis, define the variable $\mathrm{T}_{\mathrm{e}}$ to be the amount one would arrive early if there were no incident-related delays:

$$
\begin{equation*}
\mathrm{T}_{\mathrm{e}}=\mathrm{t}_{\mathrm{w}}-\mathrm{t}_{\mathrm{h}}-\mathrm{T}_{\mathrm{f}}-\mathrm{T}_{\mathrm{x}} . \tag{4}
\end{equation*}
$$

Following Gaver (3), we call $\mathrm{T}_{\mathrm{e}}$ the "head start." Polak's (4) "safety margin" is equal to $\mathrm{T}_{\mathrm{e}}-E\left(\mathrm{~T}_{\mathrm{r}}\right)$, where $E\left(\mathrm{~T}_{\mathrm{r}}\right)$ denotes the expected incident delay. Note that $\mathrm{T}_{\mathrm{e}}>0$ implies the possibility of early arrival (if recurrent congestion turns out to be nil), whereas $\mathrm{T}_{\mathrm{e}}<0$ implies certain late arrival. Schedule delay can now be written as $S D=T_{r}-T_{e}$ and the lateness dummy, $\mathrm{D}_{\mathrm{L}}$, is equal to 1 if $\mathrm{T}_{\mathrm{r}}>\mathrm{T}_{\mathrm{e}}$ and 0 otherwise.

These definitions enable the cost function to be written as follows:

$$
\begin{equation*}
\mathrm{C}\left(\mathrm{~T}_{\mathrm{r}}\right)=\alpha\left[\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{X}}+\mathrm{T}_{\mathrm{r}}\right]+\beta\left(1-\mathrm{D}_{\mathrm{L}}\right)\left[\mathrm{T}_{\mathrm{e}}-\mathrm{T}_{\mathrm{r}}\right]+\gamma \mathrm{D}_{\mathrm{L}}\left[\mathrm{~T}_{\mathrm{r}}-\mathrm{T}_{\mathrm{e}}\right]+\theta \mathrm{D}_{\mathrm{L}} \tag{5}
\end{equation*}
$$

We specify two alternative probability distribution functions for $\mathrm{T}_{\mathrm{r}}$. First we will consider a uniform distribution, which assumes that the likelihood of a delay is equal for any level in the domain. Then we will consider an exponential distribution, as in Gaver (3), which allows lower levels of delay to have a greater likelihood than longer levels of delay. Many authors, including Richardson \& Taylor (36), have fit log-normal curves to travel-time variance data; Giuliano (37) has found specifically that non-recurrent
congestion follows a log-normal distribution. Unfortunately we find the log-normal distribution to be intractable in this model, so do not pursue it here.

## Changes in Congestion Levels

Before proceeding with the derivation of expected cost functions, it is convenient to describe how congestion levels change with the choice of departure time, $t_{h}$. First, we can describe the commuter's choice of departure time by head start time, $T_{e}$, instead of departure time, $t_{h}$. In order to do this, we assume that $T_{x}$, the travel time due to congestion, is a differentiable function of $t_{h}, T_{x}\left(t_{h}\right)$. Differentiating the implicit definition $t_{h}=t_{w}-T_{f}-T_{x}\left(t_{h}\right)-T_{e}$, we find that

$$
\begin{equation*}
\frac{\mathrm{dt}_{\mathrm{h}}}{\mathrm{dT}_{\mathrm{e}}}=-\left(\frac{\mathrm{dT}_{\mathrm{x}}}{\mathrm{dt}_{\mathrm{h}}}\right) \cdot\left(\frac{\mathrm{dt}_{\mathrm{h}}}{\mathrm{dT}_{\mathrm{e}}}\right)-1 \tag{6}
\end{equation*}
$$

or, solving,

$$
\begin{equation*}
\frac{\mathrm{dt}_{\mathrm{h}}}{\mathrm{dT}_{\mathrm{e}}}=\frac{-1}{\left(1+\mathrm{T}_{\mathrm{x}}^{\prime}\right)} \tag{7}
\end{equation*}
$$

where $\mathrm{T}_{\mathrm{x}}{ }^{\prime} \equiv \mathrm{dT}_{\mathrm{x}} / \mathrm{dt}_{\mathrm{h}}$. We impose the requirement $\mathrm{T}_{\mathrm{x}}{ }^{\prime}>-1$ in order to rule out "overtaking," in which a person can arrive earlier by leaving later (24, 38). This condition guarantees that (7) is well defined and negative. Using equation (7), the functional relationship between $T_{x}$ and $T_{e}$, defined by $T_{x}\left[t_{h}\left(T_{e}\right)\right]$, has total derivative

$$
\begin{equation*}
\frac{\mathrm{dT}_{\mathrm{x}}}{\mathrm{dT}_{\mathrm{e}}} \equiv \mathrm{~T}_{\mathrm{x}}^{\prime} \cdot\left(\frac{\mathrm{dt}_{\mathrm{h}}}{\mathrm{dT}_{\mathrm{e}}}\right)=\frac{-\mathrm{T}_{\mathrm{x}}^{\prime}}{\left(1+\mathrm{T}_{\mathrm{x}}^{\prime}\right)} \equiv-\Delta \tag{8}
\end{equation*}
$$

The quantity $\Delta$ is a measure of how steeply congestion increases if departure is delayed; more precisely, $\Delta$ is the rate at which congestion increases as the "planned" arrival time, $\mathrm{t}_{\mathrm{h}}+\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{x}} \equiv \mathrm{t}_{\mathrm{w}}-\mathrm{T}_{\mathrm{e}}$, is made later. It has the same sign as $\mathrm{T}_{\mathrm{x}}{ }^{\prime}$. If $\Delta>0$, conditions worsen as planned arrival time is delayed, thus favoring earlier schedules; whereas $\Delta<0$ favors later schedules. Note that the restriction $T_{x}{ }^{\prime}>-1$ implies $\Delta<1$.

Henceforth we regard $T_{x}$ as a function of $T_{e}$, with well-defined derivative $-\Delta$. As it turns out, making $T_{x}$ a function of traffic volume at $T_{e}$ rather than that at $t_{h}$ is necessary for consistency in an important equilibrium model of endogenous scheduling choice due to Henderson (10,11); see Chu (38) for a demonstration. If $\mathrm{T}_{\mathrm{x}}$ has a kink so that $\Delta$ is undefined, corner solutions in addition to those described below become possible.

We now solve the model for two alternative probability distributions for $T_{r}$. In each case we compute expected cost given scheduling choice $\mathrm{T}_{\mathrm{e}}$, then compute the choice of $\mathrm{T}_{\mathrm{e}}$ that minimizes the expected cost and insert this chosen value into the expected cost equation. The resulting expected cost is then a function solely of those parameters which the commuter faces in choosing the schedule for a morning commute trip.

## Uniform Distribution

A uniform probability distribution is defined for the domain [ $0, \mathrm{~T}_{\mathrm{m}}$ ]. The probability density function is defined as $f\left(T_{\mathrm{r}}\right)=1 / \mathrm{T}_{\mathrm{m}}$ for $0 \leq \mathrm{T}_{\mathrm{r}} \leq \mathrm{T}_{\mathrm{m}}$, and 0 otherwise. The mean of $\mathrm{T}_{\mathrm{r}}$ is $1 / 2 \mathrm{~T}_{\mathrm{m}}$, and its standard deviation is $\mathrm{T}_{\mathrm{m}} / \sqrt{12}$. The mean and standard deviation for the total travel time are $\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{x}}+1 / 2 \mathrm{~T}_{\mathrm{m}}$ and $\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{x}}+\left(\mathrm{T}_{\mathrm{m}} / \sqrt{12}\right)$, respectively.

The expected cost for the morning commute is:

$$
\begin{equation*}
\mathrm{EC}=\frac{1}{\mathrm{~T}_{\mathrm{m}}} \int_{0}^{\mathrm{T}_{\mathrm{m}}} \mathrm{C}\left(\mathrm{~T}_{\mathrm{r}}\right) \mathrm{d} \mathrm{~T}_{\mathrm{r}} \tag{9}
\end{equation*}
$$

Substituting equation (5) into (9), there are three possible cases: (a) $0<\mathrm{T}_{\mathrm{e}}<\mathrm{T}_{\mathrm{m}}$; (b) $T_{e} \geq T_{m}$; and (c) $T_{e} \leq 0$. For case (a), the chosen departure time can lead to either early or late arrival depending on the realization of the random variable $T_{r}$; equation (9) becomes:

$$
\begin{equation*}
E C=\alpha\left(T_{f}+T_{x}+\frac{T_{m}}{2}\right)+\frac{1}{T_{m}} \int_{0}^{T_{f}} \beta\left(T_{e}-T_{r}\right) d T_{r}+\frac{1}{T_{m}} \int_{T_{\mathrm{e}}}^{T_{\mathrm{m}}}\left[\gamma\left(T_{r}-T_{c}\right)+\theta\right] d T_{r} \tag{10}
\end{equation*}
$$

$$
\begin{align*}
& =\alpha\left[\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{x}}+\frac{\mathrm{T}_{\mathrm{m}}}{2}\right]+\frac{1}{\mathrm{~T}_{\mathrm{m}}}\left[\theta\left(\mathrm{~T}_{\mathrm{m}}-\mathrm{T}_{\mathrm{e}}\right)\right]+\frac{1}{2 \mathrm{~T}_{\mathrm{m}}}\left[\beta \mathrm{~T}_{\mathrm{e}}^{2}+\gamma\left(\mathrm{T}_{\mathrm{m}}-\mathrm{T}_{\mathrm{e}}\right)^{2}\right]  \tag{11a}\\
& =\alpha E(\mathrm{~T})+\theta \mathrm{P}_{\mathrm{L}}+\beta E(\mathrm{SDE})+\gamma E(\mathrm{SDL}) \tag{12}
\end{align*}
$$

In equation (11a), the first term is merely the expected travel time multiplied by its cost. The second term is the probability of arriving late, $\mathrm{P}_{\mathrm{L}}$, multiplied by the lateness penalty, $\theta$. The last two terms are the expected cost associated with the amounts of schedule delay early and late.

The other cases result in simple modifications of equations (10) and (11a). For case (b), where $T_{e} \geq T_{m}$ (implying the commuter is early with probability one), the limit of integration $T_{e}$ is replaced by $T_{m}$ in (10); the result is

$$
\begin{equation*}
\mathrm{EC}=\alpha\left[\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{x}}+\frac{\mathrm{T}_{\mathrm{m}}}{2}\right]+\beta\left[\mathrm{T}_{\mathrm{e}}-\frac{\mathrm{T}_{\mathrm{m}}}{2}\right] \tag{11b}
\end{equation*}
$$

For case (c), where $T_{e} \leq 0$ (implying the commuter is late with probability one), then $T_{e}$ is replaced by 0 as a limit of integration in (10) and the result is:

$$
\begin{equation*}
\mathrm{EC}=\alpha\left[\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{X}}+\frac{\mathrm{T}_{\mathrm{m}}}{2}\right]+\theta+\gamma\left[\frac{\mathrm{T}_{\mathrm{m}}}{2}-\mathrm{T}_{\mathrm{e}}\right] \tag{11c}
\end{equation*}
$$

In cases (b) and (c) the per-minute scheduling cost is simply that associated with the expected arrival time, since there is no uncertainty as to whether the commuter will arrive late. Equation (12) continues to apply, with appropriately modified expressions for the probability $\mathrm{P}_{\mathrm{L}}$ and for the expectations of SDE and SDL. As we will see, cases (b) and (c) can occur when the cost parameters and the rate of change in the level of congestion have specified ranges; for example, if $\theta$ is very large or if congestion is increasing rapidly in departure time, one may choose to always arrive early (case b).

We now seek the value of $T_{e}$ which minimizes the expected cost. For case (a), we set the derivative of equation (11a) equal to zero, while regarding $T_{x}$ as a function of $T_{e}$ as in equation (8). Solving for $\mathrm{T}_{\mathrm{e}}$ gives the following result:

$$
\begin{equation*}
\mathrm{T}_{\mathrm{e}}^{*}=\frac{1}{(\beta+\gamma)}\left(\theta+\gamma \mathrm{T}_{\mathrm{m}}+\alpha \Delta^{*} \mathrm{~T}_{\mathrm{m}}\right) \tag{13}
\end{equation*}
$$

where $\Delta^{*}=-\mathrm{dT}_{\mathrm{x}} / \mathrm{dT}_{\mathrm{e}}$ evaluated at $\mathrm{T}_{\mathrm{e}}{ }^{*}$. The second-order condition requires that $\mathrm{d} \Delta / \mathrm{dT}_{\mathrm{e}}<(\beta+\gamma) /\left(\alpha \mathrm{T}_{\mathrm{m}}\right)$, which may be interpreted as requiring that congestion be convex, or at least not be too strongly concave, in planned arrival time $\left(\mathrm{t}_{\mathrm{w}}-\mathrm{T}_{\mathrm{e}}\right)$. If $\mathrm{T}_{\mathrm{x}}$ is a concave function of $\left(\mathrm{t}_{\mathrm{w}}-\mathrm{T}_{\mathrm{e}}\right)$, then $\mathrm{d}^{2} \mathrm{~T}_{\mathrm{x}} / \mathrm{dT}_{\mathrm{e}}{ }^{2}<0$, i.e., $\Delta \equiv-\mathrm{dT}_{\mathrm{X}} / \mathrm{dT}_{\mathrm{e}}$ is increasing in $\mathrm{T}_{\mathrm{e}}$. This solution is valid only if it is consistent with case (a) as an interior solution, which therefore requires that $0<\mathrm{T}_{\mathrm{e}}{ }^{*}<\mathrm{T}_{\mathrm{m}}$, i.e., $-\gamma \mathrm{T}_{\mathrm{m}}<\left(\theta+\alpha \Delta^{*} \mathrm{~T}_{\mathrm{m}}\right)<\beta \mathrm{T}_{\mathrm{m}}$.

To evaluate the expected cost when $T_{e}$ is chosen optimally, we substitute (13) into (11a), yielding:

$$
\begin{equation*}
E C^{*}=\alpha E\left(\mathrm{~T}^{*}\right)+\theta \mathrm{P}_{\mathrm{L}}^{*}+\mathrm{C}_{\mathrm{s}}^{*} \tag{14}
\end{equation*}
$$

where

$$
\begin{align*}
& E\left(\mathrm{~T}^{*}\right)=\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{x}}\left[\mathrm{t}_{\mathrm{h}}\left(\mathrm{~T}_{\mathrm{e}}^{*}\right)\right]+\frac{1}{2} \mathrm{~T}_{\mathrm{m}}  \tag{15}\\
& \mathrm{P}_{\mathrm{L}}^{*}=\frac{\mathrm{T}_{\mathrm{m}}-\mathrm{T}_{\mathrm{e}}^{*}}{\mathrm{~T}_{\mathrm{m}}}=\frac{\left(\beta-\alpha \Delta-\frac{\theta}{\mathrm{T}_{\mathrm{m}}}\right)}{(\beta+\gamma)}  \tag{16}\\
& \mathrm{C}_{\mathrm{s}}^{*}=\frac{1}{2} \delta \mathrm{~T}_{\mathrm{m}}+\frac{\left(\theta+\alpha \Delta \mathrm{T}_{\mathrm{m}}\right)^{2}}{2(\beta+\gamma) \mathrm{T}_{\mathrm{m}}} \tag{17}
\end{align*}
$$

and

$$
\begin{equation*}
\delta=\frac{\beta \gamma}{(\beta+\gamma)} \tag{18}
\end{equation*}
$$

When $\theta=\Delta=0$, equations (14) - (17) are especially easy to interpret. The probability of being late is then chosen independently of travel time variance, and is decreasing in $\gamma / \beta$. In addition, the uncertainty of travel time creates a cost $\mathrm{C}_{\mathrm{S}}{ }^{*}=1 / 2 \delta \mathrm{~T}_{\mathrm{m}}$,
which is proportional to the standard deviation $\left(\mathrm{T}_{\mathrm{m}} / \sqrt{12}\right)$ of travel time and also to the coefficient $\delta$, which is a kind of geometric average of the two schedule delay cost parameters; this cost arises because the commuter is unable to eliminate the likelihood of some schedule delay, either early or late. When $\theta=\Delta=0$, the probability of being early is $1-\mathrm{P}_{\mathrm{L}}{ }^{*}=\gamma /(\beta+\gamma)$ in agreement with Gaver eq. (3) 2.3, Polak (4) eq. 3.8 (with notation $\mathrm{c}_{\mathrm{E}}=\beta$ and $\mathrm{c}_{\mathrm{L}}=\gamma$ ), and Bates (6) eq. 17 (with notation $l=\gamma$ and $\mathrm{e}-\mathrm{h}=\beta$ ).

The last term in $\mathrm{C}_{\mathrm{S}}{ }^{*}$ may be regarded as the scheduling-cost consequences of shifts in $T_{e}$ that are made to reduce congestion (if $\Delta \neq 0$ ) or to reduce the likelihood of a discrete lateness penalty (if $\theta>0$ ). For example, when $\Delta \neq 0$, indicating that some congestion can be avoided by changing the head start, the commuter does so; expected travel time is thereby reduced and $\mathrm{C}_{\mathrm{S}}{ }^{*}$ increased. When $\theta>0$, indicating an extra penalty for being late by any amount, $\mathrm{T}_{\mathrm{e}}^{*}$ is increased so as to reduce $\mathrm{P}_{\mathrm{L}}{ }^{*} ; \mathrm{C}_{\mathrm{S}}{ }^{*}$ will go up unless a negative $\Delta$ was already causing a tendency toward lateness.

Consider now case (b) of an individual who arrives early with probability one; this occurs if, in (13), $\mathrm{T}_{\mathrm{e}}{ }^{*}>\mathrm{T}_{\mathrm{m}}$, i.e., if

$$
\begin{equation*}
\alpha \Delta^{*} \geq \beta-\frac{\theta}{\mathrm{T}_{\mathrm{m}}} \tag{19}
\end{equation*}
$$

This case can occur when $\theta$ is high, or when congestion is increasing at a rapid rate. In this case, the commuter seeking to minimize cost will choose $\mathrm{T}_{\mathrm{e}}$ to minimize (11b). An interior solution occurs when

$$
\begin{equation*}
\alpha \Delta=\beta \tag{20}
\end{equation*}
$$

which requires $\Delta>0$; the second-order condition requires that $\mathrm{d} \Delta / \mathrm{dT}_{\mathrm{e}}<0$. Hence the congestion function must have a region where it is a rising convex function of planned arrival time $\mathrm{t}_{\mathrm{w}}-\mathrm{T}_{\mathrm{e}}$. At solution (20) the consumer trades off the extra schedule-delay costs of still earlier arrival $\left(\beta \mathrm{dT}_{\mathrm{e}}\right)$ against the saving in travel-time cost due to less congestion $\left(\alpha \Delta \mathrm{dT}_{\mathrm{e}}\right)$; this is the same tradeoff that forms the basis for determination of
early-side arrival times in the models of Vickrey (12), Cosslett (1), Fargier (13), Hendrickson and Kocur (14), Arnott et al. (15), and others. Alternatively, case (b) may lead to the corner solution $T_{e}=T_{m}$. This will occur if (19) is satisfied but (20) cannot be, as could easily happen if $\theta / \mathrm{T}_{\mathrm{m}}$ is large. The interpretation here is that the discrete lateness penalty is large enough for the commuter to eliminate entirely the possibility of late arrival, but variation in congestion, $\Delta$, is not large enough to cause a desire for still earlier planned arrivals.

Consider finally case (c) of an individual who decides to arrive late with probability one, i.e. who chooses $T_{e} \leq 0$. This occurs if $T_{e}{ }^{*} \leq 0$ in (13), i.e., if

$$
\begin{equation*}
\alpha \Delta^{*} \leq-\left[\gamma+\frac{\theta}{\mathrm{T}_{\mathrm{m}}}\right] \tag{21}
\end{equation*}
$$

This requires that $\Delta^{*}$ be negative, i.e., congestion is decreasing, and also that neither $\gamma$ nor $\theta$ be too large. In such a situation, the commuter chooses to incur the relatively mild lateness penalties in order to take advantage of lessening congestion. Expected cost (11c) has a local minimum where

$$
\begin{equation*}
\alpha \Delta=-\gamma \tag{22}
\end{equation*}
$$

provided again that $\mathrm{d} \Delta / \mathrm{dT}_{\mathrm{e}}<0$ (convex congestion function). Again, there could also be a corner solution $\mathrm{T}_{\mathrm{e}}=0$. Note that (21) and (22) are compatible only if $\Delta$ changes considerably over the range of possible values of $\mathrm{T}_{\mathrm{e}}$. This could happen if, for example, the interval $\left[\mathrm{t}_{\mathrm{w}}-\mathrm{T}_{\mathrm{m}}, \mathrm{t}_{\mathrm{w}}\right]$ occurs near the end of the rush hour, so that $\Delta^{*}$ is strongly negative (representing rapidly falling congestion at $\mathrm{T}_{\mathrm{e}}{ }^{*}$ ); the commuter may then choose a later time than $\mathrm{T}_{\mathrm{e}}{ }^{*}$ when both congestion $\mathrm{T}_{\mathrm{x}}$ and its rate of change, $\Delta$, are smaller in magnitude, making (22) possible. In fact, if $\Delta^{*}$ is strongly negative there must be a later region where $|\Delta|$ is smaller since $T_{\mathrm{x}}$ cannot fall below zero.

A practical difficulty is to find a reasonable congestion profile which allows one to solve these equations for the optimal head start. A linear congestion profile will work for
equation (13a) but not for (20) and (22). Conversely, other functional forms work for (20) and (22) but will not give analytic solutions for (13a). We do not define any explicit congestion profile; additional research is examining simulations which endogenously generate congestion profiles (39).

## Exponential Distribution

The exponential distribution for $\mathrm{T}_{\mathrm{r}}$ is defined by the probability density function,

$$
\begin{equation*}
f\left(T_{r}\right)=\frac{1}{b} e^{\left(-T_{r} / 6\right)}, \tag{23}
\end{equation*}
$$

which applies for $0 \leq T_{r}$. The parameter $b$ is the mean and the standard deviation of the distribution (this differs from the uniform distribution where the mean is $\sqrt{3}$ times larger than the standard deviation). The exponential distribution more accurately reflects the actual probability of the occurrence of an incident by allowing short delays to have a higher probability of occurrence than longer delays.

Following the same procedures as described above, we derive an expected cost for the exponential distribution. Assuming that $\mathrm{T}_{\mathrm{e}}>0$, in order to guarantee an interior solution,

$$
\begin{equation*}
E C=\frac{1}{b} \int_{0}^{\infty} \alpha\left(T_{f}+T_{x}+T_{r}\right) e^{-T_{r} / b} d T_{r}+\frac{1}{b} \int_{0}^{T_{e}} \beta\left(T_{e}-T_{r}\right) e^{-T_{r} / b} d T_{r}+\frac{1}{b} \int_{T_{e}}^{\infty}\left[\gamma\left(T_{r}-T_{e}\right)+\theta\right] e^{-T_{r} / b} d T_{r} \tag{24}
\end{equation*}
$$

Note that we can now specify an infinite range for the distribution function. Integration yields the following result:

$$
\begin{equation*}
E C=\alpha\left(T_{f}+T_{x}+b\right)+\beta\left(T_{e}-b\right)+e^{-T_{f} / b}(\theta+b \beta+b \gamma) \tag{25}
\end{equation*}
$$

which can be rewritten as,

$$
\begin{equation*}
E C=\alpha\left(T_{f}+T_{x}+b\right)+\beta\left(T_{e}-P_{E} b\right)+P_{L}(\theta+b \gamma), \tag{26}
\end{equation*}
$$

where $P_{L}=e^{-T / 6}$ is defined as the probability of arriving late, and $P_{E}=1-P_{L}$ is the
probability of arriving early, given $\mathrm{T}_{\mathrm{e}}>0$. This can again be put in the form of equation (12), where in this case $E(\mathrm{~T})=\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{x}}+\mathrm{b}, E(\mathrm{SDE})=\mathrm{T}_{\mathrm{e}}-\mathrm{P}_{\mathrm{E}} \mathrm{b}$, and $E(\mathrm{SDL})=\mathrm{bP}_{\mathrm{L}}$. These expectations can be verified by direct calculations from equations (2) - (4).

We now seek the value of $\mathrm{T}_{\mathrm{e}}$ that minimizes expected cost. Taking the derivative of (25) with respect to $T_{e}$, setting it equal to 0 and solving for $T_{e}{ }^{*}$ gives the following result:

$$
\begin{equation*}
\mathrm{T}_{\mathrm{e}}^{*}=\mathrm{b} \cdot \ln \left[\frac{\theta+\mathrm{b}(\beta+\gamma)}{\mathrm{b}(\beta-\alpha \Delta)}\right] \tag{27}
\end{equation*}
$$

where $\ln$ denotes the natural logarithm. When $\theta$ and $\Delta=0$, implying no late penalty and no change in congestion levels, this formula corresponds to that of Gaver (3), eq. (2.5). The second-order condition requires that $\mathrm{d} \Delta / \mathrm{dT}_{\mathrm{e}}<-1 / \alpha \mathrm{b}^{2} \cdot \exp \left(-\mathrm{T}_{\mathrm{e}} / \mathrm{b}\right) \cdot[\theta+\mathrm{b}(\beta+\gamma)]$, which can simplify to $\mathrm{d} \Delta / \mathrm{dT}_{\mathrm{e}}<(\alpha \Delta-\beta) / \alpha b$. The probability of being late, $\mathrm{P}_{\mathrm{L}}{ }^{*}=\mathrm{e}^{-\mathrm{T}_{\mathrm{c}} / / 6}$, can be rewritten as:

$$
\begin{equation*}
P_{L}^{*}=\frac{b(\beta-\alpha \Delta)}{(\theta+b \beta+b \gamma)} \tag{28}
\end{equation*}
$$

Lateness is favored by small values of $\theta$ and $\gamma$, and by a large negative slope to the congestion function. Equation (27) will have no solution where $\alpha \Delta \geq \beta$, but this is not a problem because if $\Delta$ is large enough for this to occur at some head start, then the commuter will seek larger head starts and must eventually find a region where $\Delta$ is small. Such a region must exist since $\mathrm{T}_{\mathrm{x}}$ cannot be negative.

The interior solution of (27) is valid only when it is compatible with $\mathrm{T}_{\mathrm{e}} \geq 0$, the range under which it was derived. That condition is violated if the term in square brackets is $\leq 1$, i.e., if

$$
\begin{equation*}
\alpha \Delta^{*} \leq-\left(\gamma+\frac{\theta}{\mathrm{b}}\right) \tag{29}
\end{equation*}
$$

This condition is the same as equation (21), except $T_{m}$ is replaced by $b$ (recall that the standard deviation in the uniform distribution is $\mathrm{T}_{\mathrm{m}} / \sqrt{12}$, while for the exponential distribution it is equal to $b$ ). If it holds, the commuter chooses to always be late; expected cost is found by replacing $T_{e}$ by 0 in the limits of integration in (24), resulting in:

$$
\begin{equation*}
\mathrm{EC}=\alpha\left(\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{x}}+\mathrm{b}\right)+\theta+\gamma\left(\mathrm{b}-\mathrm{T}_{\mathrm{e}}\right) \tag{30}
\end{equation*}
$$

which is equivalent to equation (11c) for the uniform distribution. Headstart, $\mathrm{T}_{\mathrm{e}}$, would be chosen either at the corner solution, $\mathrm{T}_{\mathrm{e}}=0$, or at a point where $\alpha \Delta=-\gamma$, just as in (22). This is analogous to case (c) of the uniform distribution; there is nothing analogous to case (b) because the exponential distribution has no upper limit and therefore there is no way to set $T_{e}$ so that one always arrives early.

Returning to the interior solution (27), the optimized value of expected cost can be calculated by substituting equation (27) into (25):

$$
\begin{equation*}
E C^{*}=\alpha\left(\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{x}}+\mathrm{b}\right)-\mathrm{b} \alpha \Delta+\mathrm{b} \beta \cdot \ln \left(\frac{\theta+\mathrm{b}(\beta+\gamma)}{\mathrm{b}(\beta-\alpha \Delta)}\right) \tag{31}
\end{equation*}
$$

The first term is the expected cost of travel time. This can be rewritten to compare with equation (14):

$$
\begin{equation*}
\mathrm{EC}^{*}=\alpha\left(\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{x}}+\mathrm{b}\right)+\theta \mathrm{P}_{\mathrm{L}}^{*}+\mathrm{C}_{\mathrm{s}}^{*} \tag{32}
\end{equation*}
$$

where $P_{L} *$ is given by (28) and

$$
\begin{equation*}
C_{s}^{*}=b\left\{\beta \cdot \ln \left[\frac{\theta+b(\beta+\gamma)}{b(\beta-\alpha \Delta)}\right]-\frac{\theta(\beta-\alpha \Delta)}{\theta+b(\beta+\gamma)}-\alpha \Delta\right\} \tag{33}
\end{equation*}
$$

The equations derived above describe the expected cost functions associated with uncertainty in travel times. These can be used to evaluate the relative proportion of expected cost associated with travel time uncertainty. The analyses in the next section provides some useful examples showing the relative importance of travel time variance for
the cost of commuting.

## Numerical Examples

In order to analyze the "head start" times and expected costs due to travel variance, we need estimates of the cost coefficients in the models. We use empirical estimates by Small (2) of the ratios $\beta / \alpha$ and $\gamma / \alpha$, in combination with a value of time of $\$ 6.40 /$ hour. These values are also used by Arnott et al. (15). The result, using $\alpha=6.40 /$ hour, is $\beta=$ $3.90 /$ hour and $\gamma=15.21 /$ hour (rescaled to minutes for our calculations). We also use $\theta=$ 0.58 , from Small (2).

Table I shows the values of $\mathrm{T}_{\mathrm{e}}{ }^{*}$ for standard deviations of travel time between 5 and 30 minutes and for the congestion slopes, $\Delta$, between -0.1 and 0.1 . The optimal head start time is always larger with the uniform distribution than the exponential distribution; this is due to its higher probability weighting for large delays. The head start is larger (earlier departure) when the standard deviation is larger and when congestion is increasing. Table II shows the corresponding optimal values of $\mathrm{P}_{\mathrm{L}}{ }^{*}$, the probability of arriving late, which is smaller when congestion is increasing.

If a hypothetical commuter has scheduling flexibility, then we can assume that $\beta=$ $\gamma$, i.e., the commuter is indifferent between schedule delay early and schedule delay late. In addition, this hypothetical commuter would have no lateness penalty, $\theta$. This can be considered a form of flextime. A commuter with flextime may still have some preferred arrival time, perhaps determined by constraints on the work departure time or personal preferences, such that $\beta$ and $\gamma$ are not zero. Table III shows the head start times chosen by such a commuter (with $\beta=\gamma=3.90$ ). In all cases the commuter still desires a head start time to avoid congestion, although these values are significantly less than in Table I. Note that the head start times increase linearly with respect to the standard deviation since $\theta=0$. In the case with no change in congestion levels, $\mathrm{T}_{\mathrm{e}}=\sqrt{3} \cdot \mathrm{~b}$ with the uniform distribution, and $T_{e}=b \cdot \ln (2)$ with the exponential distribution.

Our analytical derivations have separated the costs associated with travel time, $E\left(\mathrm{~T}^{*}\right)$, from those associated with the uncertainty of travel time, $\mathrm{C}_{\mathrm{s}}{ }^{*}+\theta \mathrm{P}_{\mathrm{L}}{ }^{*}$. How important are the relative contributions made by these terms towards the total expected cost of travel, EC*? Table IV provides a breakdown for each distribution for different levels of travel time uncertainty and Table $V$ for different levels of $\Delta$, excluding the cost of certain travel time, $\alpha\left(\mathrm{T}_{\mathrm{f}}+\mathrm{T}_{\mathrm{x}}\right)$. The total EC* does not differ much between the two distributions, the largest difference being about $\$ 0.73$ (when $\mathrm{SD}=30$ ). However, $\mathrm{C}_{\mathrm{s}}{ }^{*}$, the expected cost of schedule delay, is much larger under the exponential distribution than the uniform distribution. For large standard deviations of travel time, $\mathrm{C}_{\mathrm{s}}{ }^{*}$ from the uniform distribution becomes virtually insignificant regardless of the level or direction of changes in congestion. However, under the exponential distribution, the proportion of expected costs attributable to $\mathrm{C}_{\mathrm{s}}{ }^{*}$ remains relatively stable at about $46-48 \%$ of the total expected costs for each level of standard deviation. This is about the same contribution made by the expected value of uncertain travel time, $\alpha \mathrm{b}$ or $1 / 2 \alpha \mathrm{~T}_{\mathrm{m}}$, which in the case of the uniform distribution accounts for virtually all of the expected costs of commuting. In both distributions the proportion of expected cost associated with the probability of arriving late, $\theta \mathrm{P}_{\mathrm{L}}{ }^{*}$, decreases as the standard deviation increases; apparently the shifts in head start time shown in Table I more than compensate for the increases in standard deviation.

## Conclusions

This research has analyzed the costs associated with uncertain travel times. We have followed the work of Gaver (3) and Polak (4) but with some new contributions, focusing primarily on scheduling considerations. We have explicitly separated the effects of congestion that the commuter encounters everyday from the non-recurrent congestion that accounts for day-to-day variability in travel times. We have also introduced a discrete lateness penalty, which was originally detected empirically by Small (2).

Using one set of empirically estimated parameters, the expected cost of schedule
delay is found to be a relatively minor component of costs when the uniform distribution is used, but quite large when the exponential distribution is assumed. In both cases the residual probability of being late is set by the commuter at a small enough value that the expected discrete lateness penalty is only a small fraction of the total costs.

Our model enables the analyst to predict the expected cost of schedule delay, including penalties for lateness, taking into account how the traveler adjusts the trip schedule in response to the travel environment. Our numerical example suggests costs of several dollars per trip arising from standard deviations of travel time varying from 10 to 30 minutes. Furthermore, if the exponential distribution applies, about half this cost is due purely to the variance of travel times (the other half being the expected value of the incident delay).

If expected cost of schedule delay is indeed a major cost of unreliable commute trips, as this suggests, then policies that reduce travel time variance may be preferable in many cases to policies that reduce travel times, especially when the latter are very costly. Policies that decrease the response time needed to clear incidents, for example, may be much cheaper than and provide cost savings comparable to capacity expansion.

The information the commuter has about congestion will influence the departure time decision and ultimately the expected cost of commuting. Future work will analyze the impact of providing commuters with accurate information about changes in congestion levels and travel time variance. For example, how will changing information affect head start times when combined with a supply-side congestion model? What are the impacts on congestion when commuters have varying degrees of information about both congestion and reliability? The model presented here offers a starting point for addressing such questions which are central to the evaluation of intelligent vehicle highway systems.
