Precis: In this prospective cohort study, disc hemorrhages were associated with more severe central damage on 24-2 and 10-2 visual fields (VFs), and faster progression globally on 24-2 VFs and centrally on 10-2 VFs.

Purpose: To study the relationship between disc hemorrhage (DH) and the presence and progression of glaucomatous central VF damage.

Methods: Cross-sectional and longitudinal analyses were performed on data from the African Descent and Glaucoma Evaluation Study (ADAGES) cohort. Two masked investigators reviewed disc photographs for the presence and location of DH. 24-2 central VF damage was based on the number of test locations within the central 10 degrees of the 24-2 field pattern deviation and their mean total deviation (MTD). 10-2 central VF damage was based on pattern deviation and MTD. Main outcome measures were the association between DH and presence of central VF damage and between DH and worsening of VF.

Results: DH was detected in 21 of 335 eyes (6.2%). In the cross-sectional analysis, DH was significantly associated with more severe central damage on 24-2 [incidence rate ratio=1.47; 95% confidence interval (CI)=1.02-2.12; $P=0.035$] and 10-2 VFs (incidence rate ratio=1.81; 95% CI=1.26-2.60; $P=0.001$). In the longitudinal analysis, DH eyes progressed faster than non-DH eyes based on 24-2 global MTD rates (difference in slopes, $\beta=-0.06$; 95% CI=-0.11 to -0.01; $P=0.009$) and 10-2 MTD rates ($\beta=-0.10$; 95% CI=-0.14 to -0.06; $P<0.001$), but not 24-2 central MTD rates ($\beta=-0.02$; 95% CI=-0.078 to 0.026; $P=0.338$).

Conclusion: DH was associated with the presence and progression of central VF defects. DH identification should prompt intensive central VF monitoring and surveillance with 10-2 fields to detect progression.

Key Words: central visual field damage, disc hemorrhage, risk factors, glaucoma, progression

(*J Glaucoma* 2020;29:429–434)

Optic disc hemorrhage (DH) is a relatively specific diagnostic feature for glaucoma, occurring at rates of 4.0% to 5.7% in glaucoma patients compared with 0.2% in normal eyes.^{1,2} DH typically occurs in, or adjacent to, regions of localized retinal nerve fiber layer (RNFL) defects, neuroretinal rim notching, and parapapillary atrophy.^{2,3} Many studies have demonstrated that DH is a significant risk factor for development of glaucoma, as well as structural and functional progression.^{4–7} In RNFL and visual field (VF) regions corresponding to DH locations, there are faster rates of progression before and after the detection of DH.^{4,8} In fact, the rate of VF progression in eyes with DH can be as much as twice the rate of progression in eyes without DH.^{4,9}

There is substantial evidence that glaucoma may affect the central VF, even in early stages of disease.^{10–15} Regarding VF progression, Wu et al¹⁶ have recently reported that, for a

similar frequency of testing, duration of follow-up, and specificity, the 10-2 VF pattern had greater power than the central points of the 24-2 to detect statistically significant change. Furthermore, Park et al¹⁷ found a significantly higher incidence of DH in patients with functional damage detected only within 10 degrees of fixation, providing additional evidence for a relationship between DH and early damage to the central VF.

We aimed to assess the relationship between DH and the presence and progression of central VF damage. We tested this hypothesis in cross-sectional (detection) and longitudinal (progression) analyses. In the former, we hypothesized that DH eyes are more likely to have central VF damage than non-DH eyes. For the latter, we tested whether DH eyes experience more rapid global and central VF loss than non-DH eyes as measured with the entire 24-2 VF, central points of the 24-2 VF, and 10-2 VF test patterns.

METHODS

The multisite African Descent and Glaucoma Evaluation Study (ADAGES) collaboration (clinicaltrials.gov Identifier: NCT00221923) includes the Hamilton Glaucoma Center at the Department of Ophthalmology, University of California-San Diego (UCSD) (data coordinating center), Edward S. Harkness Eye Institute at the Columbia University Medical Center, and the Department of Ophthalmology, University of Alabama-Birmingham (UAB). The institutional review boards at all sites approved the study methodology, which adheres to the tenets of the Declaration of Helsinki and to the Health Insurance Portability and Accountability Act. All participants gave written informed consent. Participants of both African and European ancestry were included in this longitudinal cohort study of individuals with healthy eyes, glaucoma suspects, and established glaucoma. Methodological details have been described previously.¹⁸

Inclusion Criteria at Baseline

All participants had open angles, best-corrected visual acuity $\geq 20/40$, and refractive error <5.0 D sphere and 3.0 D cylinder. At baseline, we required at least 1 good-quality stereophotograph and 2 reliable standard automated perimetry Humphrey Field Analyzer Swedish Interactive Thresholding Algorithm (SITA) standard 24-2 field test results, defined as $<15\%$ false positives, $<33\%$ false negatives, and $<20\%$ fixation losses and without artifacts as assessed by the Visual Field Assessment Center (VISFact) at the University of California, San Diego. Both eyes were included, except in cases where only 1 eye met the study criteria. All participants were older than 18 years. Diabetic participants without evidence of retinopathy were included.

For the present study, only eyes who had glaucomatous optic neuropathy or were suspected to have glaucomatous optic neuropathy were included. Glaucomatous optic neuropathy was defined as excavation, neuroretinal rim thinning or notching, localized or diffuse RNFL defect, or vertical cup-disc ratio asymmetry >0.2 between eyes by at least 2 independent graders.

Exclusion Criteria

Participants were excluded if they had a history of intraocular surgery (except for uncomplicated cataract surgery), secondary causes of glaucoma (eg, iridocyclitis, trauma), other systemic or ocular diseases known to affect the VF (eg, pituitary lesions, demyelinating diseases, retinal

disease, etc.), significant cognitive impairment, history of stroke, Alzheimer disease or dementia, problems other than glaucoma affecting color vision, an inability to perform VF examinations reliably, or a life-threatening disease that precluded retention in the study.

For the cross-sectional analysis, eyes were excluded if they did not have 24-2 VFs from at least 2 dates. For the longitudinal analysis, eyes were excluded if they did not have at least five 24-2 and 10-2 VF tests on 5 visits.

Evaluation of the Optic Nerve Complex

Stereoscopic disc photographs were taken annually for up to 13 years. Disc photographs were reviewed for the presence of DH by 2 independent glaucoma specialists (C.G.D.M. and A.G.S.), who were masked to participant diagnosis, race, and all other identifying characteristics. Cases of disagreement were adjudicated by a third, experienced grader (J.M.L.).

DH was defined as a splinter or flame-shaped hemorrhage on or within the RNFL or neuroretinal rim with a proximal edge no further than $\frac{1}{2}$ disc diameter from the disc margin, or hemorrhages within the cup area.² The location of the DH was recorded as nasal, superonasal, superotemporal, temporal, inferotemporal, or inferonasal based upon the Garway-Heath structure-function map.¹⁹

Evaluation of the VF

All participants underwent VF testing every 6 months using the 24-2 strategy on the Humphrey Field Analyzer II with the SITA standard, 33 version 4.1 (Carl Zeiss Meditec Inc., Dublin, CA). Starting in 2013, given growing evidence of the importance of early macular damage in glaucoma, all participants were also tested with the 10-2 pattern at the same frequency as 24-2 tests, that is, every 6 months.¹⁰ Any unreliable test (as defined above) was excluded. Only 24-2 and 10-2 tests done on the same day were included in the analyses; therefore, all eyes had the same number of 24-2 and 10-2 tests, all equally spaced, and during the same time period. Testing order (administration of the 24-2 or 10-2 test first) was randomized at the patient level.

The number of abnormal test locations within the central 10 degrees of the 24-2 and in the 10-2 patterns were assessed. For the central 10 degrees of the 24-2 (ie, the 12 central-most test locations), abnormality was defined at $P < 5\%$ of the pattern deviation plot, as this area matches the macular region tested with the 10-2.¹⁰ For the 10-2, abnormal locations were also defined at $P < 5\%$ of the pattern deviation plot. VF progression was quantified for 3 different outcome variables: (i) 24-2 mean total deviation (MTD), which is the average of total deviation (TD) values of all 52 locations (54 minus the points above and below the blind spot); (ii) 24-2 central MTD, which is the average of TD values of the 12 central-most locations; and (iii) 10-2 MTD, which is the average of TD of all 68 locations. The 12 central points included in the 24-2 central MTD analysis are demonstrated in Figure 1.

Because 10-2 tests were included as part of ADAGES protocol after 2013, only the 24-2 tests performed thereafter were included in the present study. Had we included the 24-2 tests done before (without accompanying 10-2), the number of tests would not be balanced, potentially biasing the comparison between the 2 test patterns. Given the progressive nature of glaucomatous VF damage, to optimize the detection of VF abnormalities the cross-sectional analysis was

FIGURE 1. Map of the 24-2 test points and their spatial relationship to corresponding points on the retina. The points in the green box were included in the 24-2 central mean sensitivity deviation analysis. Modified from Hood et al.¹⁰ Adaptations are themselves works protected by copyright. based on the last (most recent) follow-up visit, when both 24-2 and 10-2 were performed. For the longitudinal analysis, we included eyes with at least 5 visits with both test patterns and included a similar number of 10-2 and 24-2 VF tests for each eye.

Statistical Analyses

Categorical variables were described by their percentages and compared using the Fisher exact test. Continuous variables were described by their means and SDs and compared with Mann-Whitney 2-sample statistic. For the cross-sectional analysis, Poisson mixed effects regression models were used to calculate the incident rate ratio (IRR) of central VF damage where the predictor was the presence of DH and the outcome the number of abnormal test locations as defined above. In the longitudinal analysis, linear mixed-effects models were used to test the difference in rates of abnormal test locations over time and MTD change over time (dB/y), respectively, between DH and non-DH eyes. This type of model adjusts for inter-eye correlation as well as the correlation between residuals in longitudinal data. Computerized statistical analyses were performed using commercially available software (STATA, version 14.0; StataCorp LP, College Station, TX). Statistical significance was defined at $P < 0.05$.

RESULTS

Cross-sectional Analysis

In total, 335 eyes of 215 participants were included in the cross-sectional analysis. A total of 145 (43.2%, 95% binomial confidence interval: 37.9% to 48.7%) were of

TABLE 1. Demographic Characteristics of the Larger Study Population (N = 335 Eyes)

	DH (n = 21)	Non-DH (n = 314)	P
Age (y)	75.5 (9.3)	68.4 (11.2)	0.002
Sex (female/male)	10/11	176/138	0.501
Race (African/European)	4/17	141/173	0.023
Spherical equivalent (D)	−0.00 (1.5)	−0.58 (1.8)	0.382
CCT (μm)	531.2 (48.4)	541.4 (37.5)	0.170
IOP (mm Hg)	14.6 (2.1)	15.3 (3.3)	0.186
24-2 MD (dB)	−5.7 (5.4)	−4.9 (6.2)	0.155
10-2 MD (dB)	−7.0 (6.3)	−4.3 (5.7)	0.032

CCT indicates central corneal thickness; DH, disc hemorrhage; IOP, intraocular pressure; MD, mean deviation.

African descent, and their mean (95% confidence interval of the mean) age was 68.8 (67.6 to 70.0) years. Baseline demographic characteristics of the study population are detailed in Table 1. Mean 24-2 and 10-2 MTD at the last visit were −5.0 (−5.7 to −4.3) and −4.5 (−5.1 to −3.8) dB, respectively. DH was detected in 21 of 335 eyes (6.2%; 3.9% to 9.4%) and was more common in eyes of participants of European descent (17/190, 8.9%; 5.3% to 13.9%) than African descent (4/145, 2.7%; 0.7% to 6.9%; $P = 0.023$, Fisher's exact test). A total of 17 of the 21 (81%; 58.0% to 94.5%) eyes with DH had an inferotemporal DH, 2 DHs were inferonasal, 1 nasal, and 4 superotemporal (note: 3 eyes had concurrent superotemporal and inferotemporal DH).

DH eyes had more abnormal test points within the central 10 degrees of 24-2 VFs from the last follow-up visit than non-DH eyes (Poisson's IRR = 1.42; $P = 0.032$). A similar relationship was seen when looking at the matching 10-2 fields (IRR = 1.67; 95% confidence interval = 1.42–1.98; $P < 0.001$).

Longitudinal Analysis

In the longitudinal analysis, 20 of 306 eyes (6.5%; 4.0% to 9.9%) had at least 1 DH, 16 of which were observed in the inferotemporal sector. Their mean (SD) age was 59.8 (58.6 to 61.1) years and mean 24-2 and 10-2 MTD at the baseline visit were −4.5 (−5.2 to −3.8) and −3.8 (−4.5 to −3.2) dB, respectively.

Over the follow-up period [mean of 7 (6.9 to 7.2) visits spanning 9 (8.9 to 9.1) y], DH eyes experienced more rapid global 24-2 progression than non-DH eyes (difference in slopes, $\beta = -0.06$; $P = 0.009$). However, a significant difference was not seen on the 24-2 central MTD (difference in slopes, $\beta = -0.02$; $P = 0.338$). With the 10-2, DH eyes experienced more rapid MTD progression than non-DH eyes (difference in slopes, $\beta = -0.10$; $P < 0.001$). Tables 2–4 detail the linear mixed-effects models describing the relationship between disc hemorrhage and rates of progression of 24-2 MTD, 24-2 central MTD, and 10-2 central MTD, respectively.

Figure 2 shows the distribution of mean TD values at baseline from 24-2 (A) and 10-2 (B) fields of all eyes with detected DH. Note that in both tests, areas in the superior arcuate region had worse sensitivities, which match the location of most detected DH (inferotemporal). Interestingly, while severe damage was noted within 10 degrees of fixation, damage did not clearly affect fixation.

TABLE 2. Linear Mixed-effects Model Testing the Relationship Between Disc Hemorrhage and Rates of 24-2 Mean Sensitivity Deviation Progression

24-2 MTD (dB)	Coefficient	95% Confidence Interval		P
DH (yes)	-0.445	-3.021	2.129	0.734

DH×Time	-0.063	-0.111	-0.015	0.009

DH indicates disc hemorrhage; MTD, mean total deviation.

DISCUSSION

The current study was undertaken to better understand the relationship between DH and central VF damage in eyes with glaucomatous optic neuropathy. We found that DH was significantly associated with the presence and progression of central VF damage. Because macular damage is associated with poorer vision-related quality of life,^{20–22} our study underscores the importance of monitoring the central field in DH eyes.

Based on data simulation, Wu et al¹⁶ recently suggested that 10-2 VFs could detect significant progression 6 months sooner than the 24-2 central MTD in eyes progressing at an average rate of -0.5 dB/y (which includes the majority of glaucomatous eyes²³). Our findings in a real-world population are consistent with their simulations given that—for a matched follow-up time and number of tests—10-2 fields detected differences in rates of progression between DH and non-DH. This difference in progression rate among DH and non-DH eyes was not reflected in central 24-2 MTD but was seen in the global 24-2 VF.

Little is known about the pathogenic mechanisms of DH. Vascular dysregulation seen in primary open-angle glaucoma,^{24,25} and a vascular event such as ischemia to the optic nerve head or damage to the blood-retinal barrier may lead to an arterial or venous spasm or occlusion.²⁶ In accordance with this, Kwon and colleagues found that nonphysiological drops in nocturnal blood pressure were a significant risk factor for the development of DH.²⁵ In another study, Kwon and colleagues reported that eyes with parapapillary deep-layer microvasculature dropout detected by OCT angiography—which is correlated with DH presence²⁷—had a significantly more rapid rate of VF progression than eyes without dropout.²⁸ In addition, a study by Chou and colleagues found that fundus densitometry profiles of DH resemble microaneurysms rather than retinal venous occlusions, suggesting that DH have an arterial origin. Deeper vasculature may be relevant to the development of DH, as regional microvasculature dropout in the deep parapapillary layer of the choroid around the optic

nerve head has been more frequently found in eyes with recurrent DH at the same site as previous DH.²⁹

A mechanical theory proposes that DH may be a result of changes in the morphology of the lamina cribrosa resulting in shearing of laminar capillaries and retinal ganglion cell axons as a result of structural loss.^{4,30} The matrix of collagenous beams that forms the lamina cribrosa acts as the load-bearing structural support for the optic nerve head and is hypothesized to be the primary site of retinal ganglion cell axonal glaucomatous damage.^{31–33} Mechanical alteration of the lamina cribrosa at its scleral insertion point occurs with changes in intraocular pressure or translaminal pressure gradients and may cause damage indicated by DH.^{34–36} Visualization of lamina cribrosa defects by swept source optical

FIGURE 2. Mean baseline total deviation values (in dB) on the 24-2 and 10-2 of eyes experiencing disc hemorrhage. 24-2 (A); 10-2 (B). Projections are in right eye view.

coherence tomography demonstrates a significant association with DH.³⁷ Finally, in agreement with the present report, Sharpe et al³⁸ found that most DH and laminar disinsertion were located in the inferotemporal and superotemporal sectors. More recently, Moghimi et al³⁹ reported that lamina cribrosa defects are an independent risk factor for structural progression, which was spatially consistent with the defect location and confirmed the findings of a previous retrospective study.⁴⁰ Disc hemorrhages,^{4,6} microvascular dropout,^{28,29} and lamina cribrosa defects^{39,40} tend to occur in the same location (inferotemporal peripapillary region) and could, therefore, represent different clinical manifestations of the same underlying mechanism associated with rapid, local glaucomatous progression.

Glaucomatous damage to the macula may occur in both early and late stages of disease.^{10–17} Thus, it appears that the presence of central VF damage, irrespective of severity of the global VF damage, may have significant implications on disease staging.⁴¹ In addition, our previous work has demonstrated that the presence of central VF damage is predictive of global VF progression independent of baseline 24-2 mean deviation.⁴² Importantly, central VF damage has been associated with poor vision-related quality of life outcomes even in early glaucoma.²⁰ Our study confirms numerous previous reports that showed more rapid 24-2 progression in DH versus non-DH eyes. The inferotemporal optic nerve region receives axons from the macular vulnerability zone¹⁰ as well as areas outside the macular region¹⁹; typically, damage to these fibers leads to para-central VF defects or nasal steps.¹⁰ Therefore, the 24-2 grid can detect damage outside the central 10 degrees, which would be missed with the 10-2. Nonetheless, the 12 central-most points of the 24-2 do not sample the macular region as densely as the 10-2 (with 68 points for the same area) which may explain why the central MTD failed to reveal a significant association with progression in our sample. Similar knowledge has long been used to justify the use of 10-2 fields to track progression in eyes with severe damage on the 24-2 in clinical practice. As shown in Figure 2, the 12 central-most points were significantly depressed at baseline, thus making it more difficult to measure progressive changes beyond that level. With more tested locations within the same area (10-2 grid), progressive changes may be more easily identified.

Strengths of the present report include its large number of participants and prospective design. Potential limitations of our study are related to the availability of photographs. For instance, optic disc stereophotographs were taken annually and therefore, the number of DHs identified in this study is likely lower than the true number of DH that occurred in the study population, as DH may have occurred in the time between photos. Notably, in the Early Manifest Glaucoma Trial (EMGT), stereophotographs were taken every 3 months⁶ and in the Collaborative Normal Tension Glaucoma Study (CNTGS) optic nerves were photographed every 3 to 6 months.^{43,44} These studies found a significantly higher incidence of DH than other studies with less frequent photographs.^{3,43,44} Because of the relatively small number of DH detected in this study (~6% of the eyes), were unable to perform subanalyses based on the location of hemorrhages (eg, inferotemporal vs. other regions) due to small sample sizes in each group, which decreased the statistical power of our analyses. Future studies with larger number of DH in each optic disc sector should investigate their relationship with central field damage. Finally, since this was not a

randomized controlled trial, the observation of a DH may have led to the addition of further IOP-lowering therapy. This may have potentially prevented further VF progression. As such, the impact of DH on progression rates may be larger than detected in this study.

Considering the increased prevalence of central as well as peripheral VF damage in patients with DH, clinicians should carefully scrutinize the central VF in any patient with DH, preferably with testing such as 10-2 fields. Heightened awareness of the implications of DH will allow for risk stratification of patients who may require escalation of treatment to prevent rapid central VF progression.
