29 Abstract

According to classic stomatal optimization theory, plant stomata are regulated to 30 maximize carbon assimilation for a given water loss. A key component of stomatal optimization 31 models is marginal water-use efficiency (mWUE), the ratio of the change of transpiration to the 32 change in carbon assimilation. Although the mWUE is often assumed to be constant, variability 33 of mWUE under changing hydrologic conditions has been reported. However, there has yet to be 34 a consensus on the patterns of mWUE variabilities and their relations with atmospheric aridity. 35 We investigate the dynamics of mWUE in response to vapor pressure deficit (VPD) and aridity 36 index using carbon and water fluxes from 115 eddy covariance towers available from the global 37 database FLUXNET. We demonstrate a non-linear mWUE-VPD relationship at a sub-daily scale 38 in general; mWUE varies substantially at both low and high VPD levels. However, mWUE 39 remains relatively constant within the mid-range of VPD. Despite the highly non-linear 40 relationship between mWUE and VPD, the relationship can be informed by the strong linear 41 relationship between ecosystem-level inherent water-use efficiency (IWUE) and mWUE using 42 the slope, m^* . We further identify site-specific m^* and its variability with changing site-level 43 aridity across six vegetation types. We suggest accurately representing the relationship between 44 45 IWUE and VPD using Michaelis-Menten or quadratic functions to ensure precise estimation of mWUE variability for individual sites. 46

48 Plain Language Summary

Plants use diverse strategies for water utilization during growth. Marginal water-use efficiency 49 (mWUE) quantifies how effectively plants gain carbon relative to the water they lose through 50 their leaves. A scientific debate exists regarding how mWUE responds to dry conditions. To 51 investigate this, we analyze data from various vegetation types worldwide, observing changes in 52 mWUE under dry conditions. Contrary to common assumptions, mWUE is not a constant; it 53 varies substantially based on moisture levels. Additionally, we show that a simpler measure 54 called inherent water-use efficiency (IWUE) can help explain this complicated relationship, 55 which is useful for predicting plant growth under different moisture conditions. 56

62 **Running title**

Response of mWUE and IWUE to changing aridity

64 **1. Introduction**

Terrestrial plants mitigate global warming by sequestering atmospheric carbon dioxide 65 (CO₂) through photosynthesis (Beer et al., 2010). However, photosynthesis is inherently linked 66 with plant water loss via transpiration, as CO₂ and water vapor share the same stomatal pathway. 67 Plants risk hydraulic damage during droughts if they maintain high stomatal conductance as soil 68 water availability decreases and atmospheric demand increases, resulting in low leaf water 69 potential and xylem cavitation. Therefore, plants must balance stomatal function to optimize 70 carbon uptake while minimizing transpirational water loss and hydraulic stress (Cowan & 71 Farquhar, 1977; Katul et al., 2010; Sperry et al., 2017; Wang et al., 2020). To predict plant 72 ecophysiological responses to projected changes in atmospheric CO₂ concentration, elevated 73 74 atmospheric water demand, and more severe and frequent drought events, we need a mechanistic understanding of how different ecosystems regulate the trade-off between photosynthetic carbon 75 assimilation and transpirational water loss. 76

Although carbon uptake is usually represented through mechanistic models of 77 photosynthesis (e.g., the Michaelis-Menten equation (Marshall & Biscoe, 1980; Michaelis & 78 Menten, 1913; Thornley, 1976); the Farquhar model (Von Caemmerer, 2000; Farquhar et al., 79 1980a)), water use (i.e., transpiration) is often described based on empirical relationships that 80 prescribe how stomatal conductance responds to environmental drivers and carbon uptakes. For 81 example, the Ball-Berry model (Ball et al., 1987) is one of the most widely used empirical 82 stomatal conductance models (Anderegg et al., 2017; Buckley, 2017; Katul et al., 2010), and has 83 been readily incorporated into many climate models (Bonan et al., 2014). It takes the form: 84

$$g_s = g_0 + g_1 \frac{A}{c_a} \text{RH} \qquad (1)$$

86 where g_s is stomatal conductance (mol m⁻² s⁻¹), *A* is carbon assimilation rate (μ mol m⁻² s⁻¹), c_a is 87 atmospheric CO₂ concentration (ppm), RH is relative humidity at the leaf surface, and g_0 and g_1 88 are empirically fitted parameters. To simulate the non-linear variation in g_s with changing 89 humidity, Leuning (1995) modified the Ball-Berry model by replacing relative humidity with a 90 vapor pressure deficit (VPD) response function as follows:

91
$$g_s = g_0 + g_1 \cdot \frac{A}{(c_a - \Gamma^*)\left(1 + \frac{\text{VPD}}{\text{VPD}_0}\right)}$$
(2)

where Γ^* is CO₂ compensation point for photosynthesis (ppm) and VPD₀ is the empirically determined coefficient, representing the slope of the relationship between g_s and VPD. These empirical models are relatively simple, easy to use, and work well for well-watered conditions (Bonan et al., 2014). However, they have an incomplete grounding in physiological theory, leading to uncertainty when they are extrapolated to predict plant function under unprecedented climate conditions (Franks et al., 2018; Knauer et al., 2015, 2018; Medlyn et al., 2012; Sabot et al., 2022).

An alternative way to enable the theoretical interpretation of leaf-level stomatal 99 conductance models is to adopt the principle of stomatal optimization theory (Anderegg et al., 100 2018; Bonan et al., 2014; Katul et al., 2009; Katul et al., 2010; Medlyn et al., 2012; Novick et al., 101 2016b; Sperry et al., 2017; Wolf et al., 2016). Stomatal optimization theory was originally based 102 103 on a hypothesis that stomata are regulated to maximize carbon assimilation (A) for a given water loss (transpiration, E). A key parameter in this class of models is the so-called "marginal water-104 use efficiency (mWUE)," here defined as the ratio of a change in E to a change in A $(\partial E/\partial A)$ 105 following Cowan and Farquhar (1977), although it is sometimes defined as the inverse form 106 $(\partial A/\partial E)$ (Katul et al., 2010; Manzoni et al., 2011). The optimality models often maintain the 107 mWUE constant over arbitrary time steps (e.g., daily), assuming abundant water at the canopy 108

(Buckley, 2017; Cowan & Farquhar, 1977; Makela et al., 1996). However, this may not hold true
at sub-daily timescales, where high atmospheric demand (i.e., VPD) during midday can decrease
water potential at the canopy level even when soil moisture is abundant (Anderegg et al., 2017;
Grossiord et al., 2020).

Understanding how mWUE changes under hydrologic stress is necessary for the 113 optimization models in a prognostic sense, yet no consensus on the magnitude or even direction 114 of these changes exists. For instance, Manzoni et al. (2011) and Zhou et al. (2013, 2014) 115 performed meta-analyses of leaf gas exchange measurements from previous studies that spanned 116 wide ranges of species and moisture conditions. A major difference in their approaches was the 117 proxy for plant water status; Manzoni et al. (2011) used mid-day leaf water potential, whereas 118 Zhou et al. (2013, 2014) used pre-dawn leaf water potential as a proxy for soil moisture 119 availability. Similarly, Lin et al. (2015) compiled a global database of leaf gas exchange 120 measurements spanning diverse plant functional types and estimated a slope parameter (g_1) 121 122 (Medlyn et al., 2012), which is analogous to the slope parameter from empirical models (Eqs. 1 & 2) and proportional to $\sqrt{\partial E/\partial A}$ (Medlyn et al., 2012). They further evaluated the relationship 123 between g_1 and a moisture index, defined as the ratio of mean annual precipitation to the 124 equilibrium evapotranspiration. Mäkelä et al. (1996) and Lu et al. (2016) took a theoretical 125 approach to examine short- and long-term optimal stomatal behavior, respectively, in response to 126 the soil moisture availability assuming that plants are adapted to the stochastic rainfall patterns of 127 their environments. More recently, alternative stomatal optimization perspectives have been 128 proposed, which presume stomata function to maximize carbon uptake while minimizing water 129 costs, including those linked to hydraulic damage during droughts (Anderegg et al., 2018; Sperry 130 et al., 2017; Wolf et al., 2016). Although promising, in contrast to the Medlyn et al. (2012) 131

model, these newer formulations have yet to be integrated into land surface model schemes (but refer to Kennedy et al., 2019, for a study implementing plant hydraulics in the Community Land Model). Although theoretical expectation and many studies indicate decreasing mWUE as water stress drives reductions to g_s , there is some evidence of increasing mWUE under water stress (Farquhar et al., 1980b; Grieu et al., 1988; Zhou et al., 2013), although reasons for this needed to be clarified.

It is also important to note that canopy water status and water potential are not 138 determined solely by the availability of water supply but by the balance between water supply 139 and demand, with VPD as a major force exerted on the canopy by the atmosphere (Manzoni et 140 al., 2011, 2013; Novick et al., 2019). Thus, it is reasonable to expect that mWUE needs to be 141 adjusted with changing atmospheric water demand unless other factors limit the plant response 142 (e.g., compromised hydraulic conductivity under water stress, limited soil moisture availability 143 to plants) (Brodribb et al., 2005; Medlyn et al., 2012). Different plants or ecosystems may adjust 144 145 differently, resulting in divergent responses of mWUE to changing VPD. Understanding the relationship between mWUE and VPD is important given that VPD is expected to keep 146 increasing in the future, which will exert further water stress on plants (Ficklin & Novick, 2017; 147 148 Grossiord et al., 2020; Novick et al., 2016a; Zhang et al., 2019). Furthermore, while soil moisture is a stochastic variable due to its dependency on intermittent rainfall, VPD is smoother 149 150 in time and easier to monitor through various meteorological or gas exchange measurement 151 techniques. Although VPD and soil moisture limit plants' carbon uptake and water use independently (Yi et al., 2019), VPD can be used as a proxy of water stress at a sub-daily scale 152 where VPD plays a primary role in regulating stomatal regulation unless severe soil moisture 153 154 deficiency, as indicated by the models with sub-daily timesteps (e.g., Ball-Berry model and its

155	variations), and in turn influencing the balance between carbon uptake and water loss (i.e., water-
156	use efficiency) at a sub-daily scale (Baldocchi et al., 2022; Grossiord et al., 2020; Novick et al.,
157	2016a). Therefore, examining the association between mWUE and VPD would add insight into
158	the predictability of soil moisture alone.
159	The objectives of this study are (1) to investigate the variation of mWUE at an hourly
160	timescale in response to changing VPD and (2) to explore approaches for estimating mWUE
161	explicitly from the modeled relationship between intrinsic water-use efficiency (iWUE, carbon
162	assimilation per unit stomatal conductance, representing water-use efficiency at leaf level) and
163	VPD. The Ball-Berry model (Eq. 1) reveals that the parameter g_1 , which is proportional to
164	$\sqrt{\partial E/\partial A}$ (Medlyn et al., 2012), is related to A/g_s (= iWUE at leaf level). The iWUE can be more
165	straightforwardly estimated from field measurements across various spatiotemporal scales,
166	including leaf gas exchange (daily to weekly at the leaf level), dendrochronology
167	(seasonal/annual at the tree level), and eddy covariance (hourly at the stand level) (more
168	discussion on iWUE at different scales is available from Beer et al., 2009 and Yi et al., 2019).
169	Notably, the inference of iWUE from tree-ring analyses provides an avenue for understanding
170	historical variations in iWUE and, potentially, mWUE. While iWUE has a mathematically
171	simpler form and thus facilitates modeling its response to water stress, the complex mathematical
172	expression of mWUE poses challenges in generalizing its variability at a sub-daily timescale. By
173	elucidating the correlation between iWUE and mWUE, we can gain insights into the response of
174	mWUE to water stress. Additionally, through site comparisons, we further explore whether there
175	is an emerging pattern in the correlation between iWUE and mWUE across different vegetation
176	types and aridity levels.

Term or symbol	Definition
A	Carbon assimilation rate
AI	Aridity index: the ratio of annual precipitation to annual potential evapotranspiration
c_{a}	Atmospheric CO ₂ concentration
Ε	Transpiration rate
ET	Evapotranspiration rate
g_0	Intercept parameter in Ball-Berry model (represents minimum leaf conductance)
g_1	Slope parameter in Ball-Berry model (represents marginal water-use efficiency, mWUE)
$g_{ m s}$	Stomatal conductance
$G_{ m s}$	Surface conductance
GPP	Gross primary productivity
iWUE	Intrinsic water-use efficiency; leaf-level water-use efficiency (= A / g_s)
IWUE	Inherent water-use efficiency; a proxy of intrinsic water-use efficiency at the ecosystem level (= GPP / ET × VPD / P_a , Beer et al., 2009)
<i>m*</i>	The slope of the linear relationship between $IWUE^{-1}$ and $mWUE$
mWUE	Marginal water-use efficiency, the ratio of a change in E to a change in A (= $\partial E / \partial A$)
P_{a}	Atmospheric pressure
VPD	Vapor pressure deficit

178 Table 1. A glossary of terms related to water-use efficiency.

179

180 **2. Materials and Methods**

181 **2.1. FLUXNET data**

182 We obtained half-hourly measurements of carbon and energy fluxes, along with ancillary

183 environmental data, from 115 flux towers across FLUXNET sites. These data were collected

- using the FLUXNET 2015 Tier 1 database (Table S1) (Pastorello et al., 2020). Eddy covariance
- records, which have the benefit of providing continuous meteorological and gas exchange data at

the high temporal resolution, are very well suited for investigating the relationship between gas
exchange dynamics, mWUE, and VPD at the ecosystem scale.

We selected the study sites from six vegetation types (grassland, cropland, shrubland, 188 savanna, broadleaf forest, and needleleaf forest, based on the International Geosphere-Biosphere 189 Programme (IGBP) land cover classification system; Loveland & Belward, 1997) based on the 190 191 data availability for the variables required for the analysis. For reliable and clear mWUE analysis, we only included the sites that had at least three years of data and a strong iWUE-VPD 192 correlation. Specifically, we selected the sites that had a coefficient of determination $(R^2) > 0.8$ 193 with any of the three model fits-linear, quadratic, or Michaelis-Menten, which was the case for 194 more than 70% of the sites over three years of data (refer to section 2.4 for more information 195 about the model fits). In addition, we only used the data where net ecosystem exchange (NEE), 196 latent heat flux (LE), and sensible heat flux (H) were either original measurements (quality 197 control flag = 0) or gap-filled data of good quality (quality control flag = 1) to ensure data 198 quality and make the most of the data. We only used daytime data when net radiation was greater 199 than 0 W m⁻² without precipitation. While we acknowledge the potential benefits of excluding 200 more days after rainfall (e.g., Lin et al., 2015), we believe that omitting only the precipitation 201 202 days is sufficient for our analysis. This is because iWUE had low variability under humid conditions, as evidenced by the low standard deviations of IWUE under low VPD levels in 203 204 Figure 2. Additionally, we implemented a procedure to remove outliers in soil water content and 205 relative humidity as described in the following paragraph, which would help mitigate the impact of periods after rainy days on our analysis. 206

We limited our analysis to the growing season, where daily GPP was larger than 10% of the 95th percentiles of daily GPP for each site with $> 5^{\circ}$ C air temperature. We used the GPP

partitioned based on the standard daytime method (variable name: GPP DT VUT REF, Lasslop 209 et al., 2010). Additional filtering criteria were applied for some key variables: atmospheric CO₂ 210 concentration between 350 ppm and 420 ppm, friction velocity (u^*) greater than 0.1 m s⁻¹, and 211 canopy conductance calculated by Penman-Monteith equation (Monteith, 1965) greater than 0.05 212 mol m⁻² s⁻¹. Lastly, we removed outliers of the environmental drivers and biological variables 213 214 (i.e., air temperature, relative humidity, atmospheric CO_2 concentration, latent heat flux, wind speed, VPD, atmospheric pressure, friction velocity, net radiation, soil water content, canopy 215 conductance, iWUE, and mWUE) by excluding data that were below the 5th or above the 95th 216 percentiles of each variable. Note that the purpose of data filtering was to remove exceptionally 217 low or high values of the variables, which we consider outliers. Our goal was to ensure that the 218 results, especially the variability of mWUE, were not unduly influenced by these outliers. We 219 carefully examined the histograms for the variables for each site to minimize data reduction 220 while retaining useful information. 221

222

223 **2.2. Two different approaches describing mWUE**

We used two different approaches for describing the mWUE: two optimization-theory-224 225 driven mWUE, the solution of " $\partial E/\partial A$ " suggested by Katul et al. (2010) and the "g₁" parameter proposed by Medlyn et al. (2012). The difference between the optimization-theory-driven 226 mWUE is based on their interpretation of stomatal optimization. Katul et al. (2010) assumed that 227 stomata are optimizing for photosynthesis limited by Rubisco activity (i.e., carbon-limited), and 228 229 plant stomatal optimality is subject to change (i.e., mWUE is not constant). On the other hand, Medlyn et al. (2012) assumed that stomata are optimized for photosynthesis limited by Ribulose-230 1,5-bisphosphate (RuBP) regeneration (i.e., light-limited). In either case, the optimization 231

objective should result in constant mWUE values at short timescales—Katul et al. (2010)

suggested approximately 10 minutes, whereas Medlyn et al. (2012) suggested daily or longer—

although it may change at longer timescales as hydrologic conditions evolve.

Following Katul et al. (2010), the $\partial E/\partial A$ emerges from an optimality condition

determined with a linearized variant of the Farquhar et al. (1980b) photosynthesis model, defined

237 as:

24

238
$$\frac{\partial E}{\partial A} = 1.6 \text{ VPD } c_a \left(\frac{A}{g_s}\right)^{-2} = \frac{1.6 \text{ VPD } c_a}{\text{iWUE}^2} \qquad (3)$$

where iWUE is defined as a ratio of A to g_s at the leaf-scale (Beer et al., 2009).

The other perspective on optimality proposed by Medlyn et al. (2012) takes an analogous form to an empirical model proposed by Leuning (1995) (Eq. 2):

242
$$g_s \approx g_0 + 1.6 \left(1 + \frac{g_1}{\sqrt{\text{VPD}}}\right) \frac{A}{c_a}$$
 (4)

This approach indicates that the parameter g_1 represents a slope between g_s and $A/c_a\sqrt{\text{VPD}}$ and is proportional to $\sqrt{\partial E/\partial A}$ (Lin et al., 2015; Medlyn et al., 2012). Therefore, to facilitate comparison between the two approaches, we compare $\partial E/\partial A$ with squared g_1 (i.e., g_1^2) throughout the results. Eq. 4 was rearranged with an assumption that g_0 , which represents cuticular conductance to water vapor, is negligible (but refer to Manzoni et al. (2011) and

Lanning et al. (2020) for discussion of the role of cuticle conductance under drier conditions):

$$g_1 = \left(\frac{g_s c_a}{1.6 A} - 1\right) \sqrt{\text{VPD}} = \left(\frac{c_a}{1.6 \text{ iWUE}} - 1\right) \sqrt{\text{VPD}} \quad (5)$$

Consequently, two different mWUE parameters,
$$\partial E / \partial A$$
 (mol H₂O · kPa · mol⁻¹ of dry air) and g_1
(mol H₂O · kPa^{0.5} · mol⁻¹ of dry air), were expressed as functions of iWUE, c_a , and VPD.
Assuming c_a is relatively stable over a short period, we focus on how iWUE (as a biological
factor) and VPD (as an indicator of water stress governing plant response at a short temporal
scale, e.g., sub-daily) affect both mWUE parameters (more details discussed in section 2.5). We

applied an approximation of iWUE at the ecosystem level, inherent WUE (IWUE), defined by Beer et al. (2009). IWUE (μ mol C mol⁻¹ H₂O) was particularly suitable for our study because IWUE can be calculated from the measurements of carbon and water fluxes by eddy covariance technique and ancillary meteorological data, i.e., gross primary productivity (GPP; μ mol m⁻² s⁻¹) from net ecosystem exchange representing canopy-level carbon assimilation, evapotranspiration rate (ET, mol m⁻² s⁻¹) from latent heat flux, VPD under the assumption of equal temperatures of leaves and atmosphere, and atmospheric pressure (P_a , kPa):

(6)

$$IWUE = \frac{GPP \cdot VPI}{ET \cdot P_a}$$

263

264 Several important assumptions for the definition of IWUE include (1) small and invariant soil evaporation (E) compared to plant transpiration (T) over the course of the day (hence $\Delta ET \sim \Delta T$) 265 especially during days without rainfall (conditions we used for our analysis), (2) thermal 266 equilibrium between leaf and air, which influences VPD, and (3) disregarding of aerodynamic 267 resistance through the boundary layer that can change depending on the vegetation structure 268 (refer to Beer et al. (2009) for more discussion about IWUE as a proxy of ecosystem-level 269 iWUE). We confirmed the robustness of IWUE as a proxy of iWUE at the ecosystem level by 270 comparing it with a few other definitions of iWUE (the comparison results are available in the 271 Supporting Information; Figs. S1 & S2). Note that IWUE and mWUE were computed using half-272 hourly FLUXNET data; hence, their variabilities discussed here represent plant physiological 273 response at a sub-hourly scale. 274

275

276 **2.3. Sensitivity of mWUE parameters to moisture condition**

277 Variations of mWUE parameters in response to moisture conditions (i.e., atmospheric

water demand and site-level aridity) were evaluated at the individual site level and across sites.

For the individual sites, mWUE parameters were partitioned into discrete bins spanning a range

of VPD. To avoid biases from unevenly distributed data points across the range of VPD (i.e.,

sample sizes at low and high VPD are smaller than those for the intermediate level of VPD), data

binning was performed in a way that the sample sizes were evenly distributed into 30 bins across

the range of VPD at each site. Then, mWUE-VPD relationships were produced based on the

mean mWUE values generated for the different VPD bins.

To compare across the sites, the relationships between site-specific mWUE and aridity

index (AI) were evaluated (refer to Fig. S3 in the Supporting Information for AI at all the study

sites). AI was defined as the ratio of annual precipitation (P) to annual potential

evapotranspiration (PET) and averaged over the observation period for each site (UNEP, 1992):

$$AI = \frac{P}{PET}$$
(7)

The annual PET was determined by summing up the half-hourly PET values over the course of a year, using the United Nations Food and Agriculture Organization (FAO) Penman-Monteith method as outlined by Allen et al. (1998):

293
$$PET = \frac{0.408\Delta(R_n - G) + \gamma \frac{900}{T_a + 273}u(e_s - e_a)}{\Delta + \gamma(1 + 0.34u)}$$
(8)

where Δ is the slope of vapor pressure curve (kPa °C⁻¹), R_n is the net radiation (MJ m⁻² hr⁻¹), G is the soil heat flux density (MJ m⁻² hr⁻¹), γ is the psychrometric constant (kPa °C⁻¹), T_a is the air temperature (°C), u is the wind speed (m s⁻¹), e_s is the saturation vapor pressure (kPa), and e_a is the actual vapor pressure (kPa). The estimation of AI is sensitive to gaps in precipitation data. Therefore, we used long-term mean annual precipitation provided on the site information page at the FLUXNET website (https://fluxnet.org/sites/site-list-and-pages/) rather than calculating mean
 annual precipitation from the FLUXNET2015 dataset. For the sites where annual precipitation
 records were not provided, the high-frequency precipitation record in the FLUXNET2015 dataset
 was used.

303

2.4. Assessing the relationship between mWUE and IWUE

As a first step to conceptually understand the relationship between mWUE and IWUE, 305 the relationship between IWUE and VPD was modeled by three hypothetical functions—linear, 306 quadratic, and the Michaelis-Menten functions-based on the observations across the sites. The 307 quadratic model of IWUE-VPD (hereafter IWUE₀) depicts the case where IWUE increases with 308 VPD until it reaches a maximum and then decreases afterward. In other words, when VPD is 309 low, increasing IWUE with increasing VPD reflects a faster decrease of g_s than A (due to the 310 high intercellular CO₂ concentration, c_i), whereas decreasing IWUE with increasing VPD at high 311 312 VPD reflects a faster decrease of A than g_s (low g_s at high VPD reduces c_i and eventually causes the steep decline of A). The linear model (hereafter IWUE_L), on the other hand, represents a 313 simplified IWUE-VPD relationship where IWUE would keep increasing with rising VPD 314 315 assuming IWUE is only limited by g_s but not by photosynthetic capacity. The Michaelis-Menten function (hereafter IWUE_M) represents the saturating IWUE under high VPD but does not 316 317 account for IWUE reduction. Thus, the linear and quadratic functions are considered plausible 318 "end members" describing the actual response of IWUE to VPD, while the Michaelis-Menten function is a more intermediate case. Mathematically, the IWUE_L, IWUE_M, and IWUE_Q take the 319 forms: 320

$$321 IWUE_L = m VPD + n (9)$$

$$IWUE_M = \frac{IWUE_{max} \cdot VPD}{k + VPD}$$
(10)

323
$$IWUE_Q = -a (VPD - b)^2 + c$$
 (11)

where *m* is the slope of IWUE_L, *n* is IWUE_L at VPD = 0, IWUE_{max} is the maximum potential IWUE, *k* is the VPD at which IWUE proceeds at half IWUE_{max}, *a* represents the curvature of IWUE_Q, *b* is the vertex, *c* is the maximum IWUE_Q at the vertex.

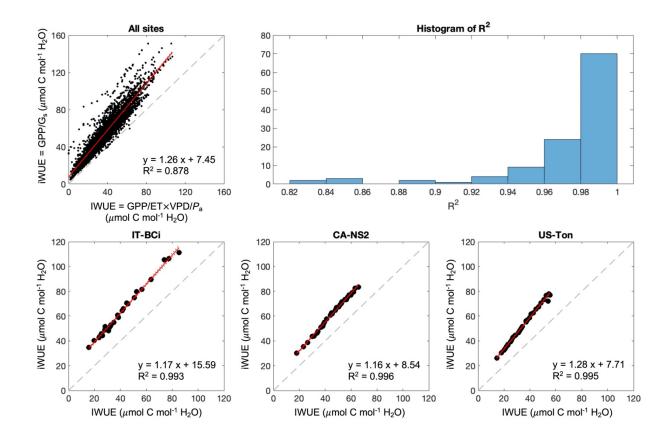

The expected dynamics of mWUE across the FLUXNET sites in response to changing 327 VPD were simulated based on an empirically driven IWUE-VPD model to understand how the 328 mWUE metrics would respond to changing VPD and IWUE. To generate possible patterns of 329 mWUE-VPD, the range of coefficients in the IWUE models was determined empirically from 330 the data across the sites. To facilitate interpretation, the patterns were simulated by changing the 331 curvature of the quadratic equation (Eq. 11), assuming the intercept is equal to zero. For the 332 simulation of mWUE, a constant c_a was applied by calculating its average across the sites to 333 focus on the interactions among VPD, IWUE, and mWUE (Eqs. 3 & 5). 334 Lastly, we investigated how IWUE (as a biological factor) and aridity index (as an 335 environmental driver) influence the variability of mWUE. Based on the Eqs. 3 and 5, we 336 hypothesized that a simple relationship between mWUE and the inverse of IWUE (IWUE⁻¹) 337 might emerge and would be affected by changing moisture conditions. Therefore, we identified a 338 relationship between mWUE and IWUE⁻¹ for each study site and examined whether the 339 relationship can be generalized across the sites based on the site-specific aridity index. 340 341

342 **3. Results**

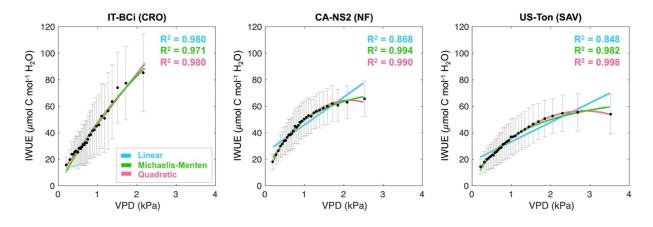

343 **3.1. Empirical response of IWUE to changing VPD or AI**

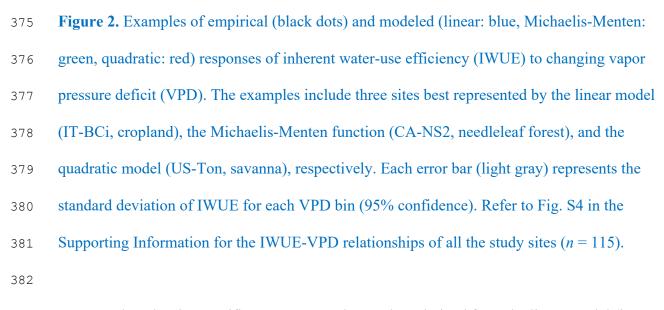

344	To test the robustness of IWUE as a proxy of intrinsic water-use efficiency at the
345	ecosystem level, we first compared the two different definitions of intrinsic water-use
346	efficiencies at stand level, GPP divided by surface conductance (G_s) (i.e., iWUE = GPP/ G_s) and
347	inherent WUE (i.e., IWUE = GPP/ET×VPD/ P_a). The two WUE definitions were linearly
348	correlated across the study sites (Fig. 1), and most sites had R ² values larger than 0.95 (Fig. 1b),
349	indicating the robustness of IWUE as a proxy of intrinsic water-use efficiency at the ecosystem
350	level (refer to the Supporting Information for an additional comparison of multiple definitions of
351	intrinsic water-use efficiency; Figs. S1 & S2). We also performed the entire analysis using these
352	two WUE definitions and observed similar results, which led to the same conclusion. Therefore,
353	we only show the results from using IWUE hereafter.

356	Figure 1. Comparison of two different definitions of water-use efficiencies at all sites (a) and at
357	three sample sites (c, d, e): inherent water-use efficiency at the ecosystem level, IWUE (=
358	GPP/ET×VPD/ P_a), and intrinsic water-use efficiency at the ecosystem level, iWUE (= GPP/ G_s).
359	Refer to Beer et al. (2009) for the comparison of different definitions of water-use efficiencies at
360	leaf and ecosystem-level. Individual dots in panels a, c, d, and e indicate WUE partitioned into
361	discrete bins spanning a range of VPD. Solid red lines indicate significant linear regressions (P \leq
362	0.05), and dashed red lines indicate 95% confidence interval. Dashed gray lines represent 1:1
363	lines. Panel b shows the histogram of coefficients of determination (R ²) of the linear fits between
364	IWUE and iWUE across the study sites.

When the site-specific IWUE-VPD slope values derived from the linear model (i.e., *m* in Eq. 9) were combined, we found increasing *m* with rising aridity index (P < 0.001, Fig. 3a). However, site-level aridity did not influence the intercept of IWUE-VPD relationship (P > 0.05, not shown here). When the sites were divided by their vegetation types, *m* increased with a rising aridity index in all vegetation types. However, the trend was only significant in grasslands, croplands, and shrublands (P < 0.05, Fig. 3).

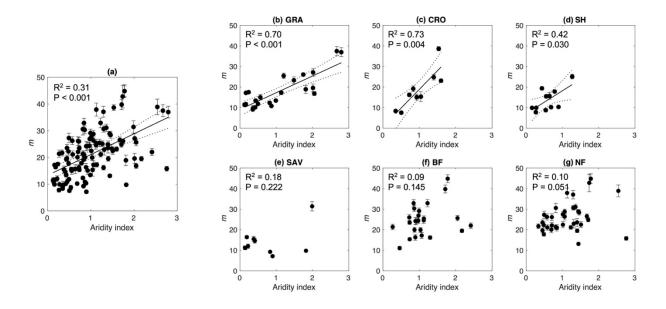

Figure 3. Relationship between the site-level aridity index and the regression slope of IWUE-VPD from individual sites (i.e., *m* in Eq. 9). Panel a shows the relationship when all sites were consolidated. The relationship is also illustrated separately for six different vegetation types in panels b to g (GRA: grassland, CRO: cropland, SH: shrubland, SAV: savanna, BF: broadleaf forest, NF: needleleaf forest). Each circle represents *m* from an individual site. Error bars represent standard errors of linear regressions. Solid lines indicate significant linear relationships (P < 0.05) and dashed lines indicate 95% confidence intervals.

399

3.2. Response of mWUE to changing VPD

Both of the mWUE indices, $\partial E/\partial A$ and squared g_1 (g_1^2), showed a very similar response to changing VPD and indicated that the directional change of mWUE can be interpreted differently depending on the pattern of IWUE-VPD (Fig. 4). When the iWUE-VPD relationship is strongly linear, mWUE decreased exponentially and became less variable as VPD increased (Brighter curves in Figs. 4b & 4c). However, as the iWUE-VPD relationship became more nonlinear, mWUE declined at lower VPD and then increased at higher VPD (i.e., concave-up),

rendering the mWUE-VPD relationship non-monotonic (darker curves in Figs. 4b & 4c).

407

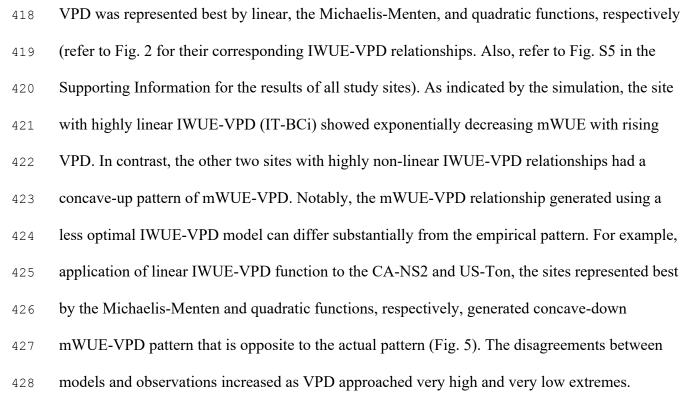

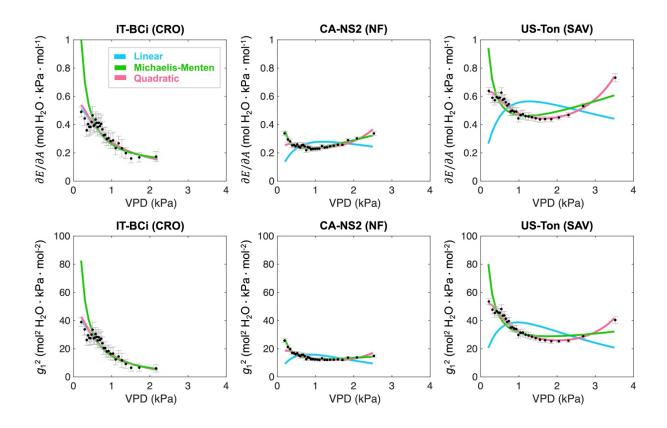

408

Figure 4. Hypothetical models of IWUE-VPD relationship (a), simulated $\partial E/\partial A$ -VPD (b) and g_1^2 -VPD (c) relationships based on typical cases, and their corresponding patterns illustrated using observations from all study sites (d, e, and f). The mWUE curves are the results of using the IWUE-VPD relationships of the corresponding colors. Note that IWUE-VPD relationships become more linear with lighter colors.

414

The simulated patterns of mWUE-VPD agreed well with the patterns from the empirical observation when the appropriate function for the IWUE-VPD relationship was applied. We show mWUE-VPD relationships from three study sites as examples (Fig. 5), of which IWUE-

Note that the reported percent increase was determined by excluding the upper and lower 10% of values. This step was taken to prevent exaggeration caused by extremely high $\partial E/\partial A$ at low VPD, which is commonly observed across the study sites (refer to Figure S5 in the

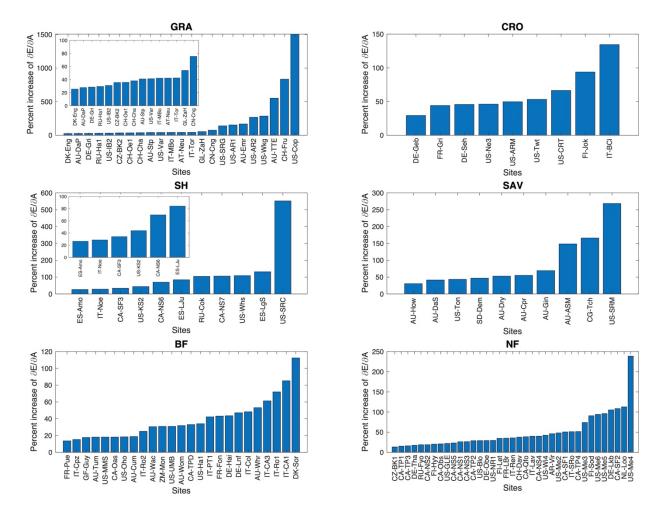

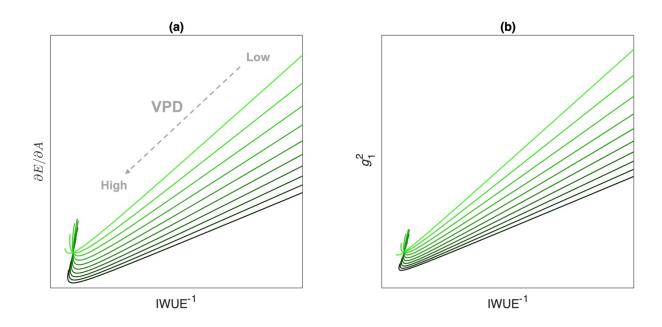

Figure 6. Sorted percent increase of $\partial E / \partial A$ (from the lowest $\partial E / \partial A$) (GRA: grassland, CRO: cropland, SH: shrubland, SAV: savanna, BF: broadleaf forest, NF: needleleaf forest). Embedded plots in GRA and SH are zoomed in for those sites where percent increases are lower than 100%. Note that the percent increases were calculated after removing values of the highest 10% and lowest 10% to avoid exaggeration due to very high $\partial E / \partial A$ at low VPD at some sites. Therefore, the reported percent increase values are conservative estimates for most sites.

451

459 **3.3. Correlation between mWUE and IWUE**

Although the trend of mWUE-VPD seems hard to generalize, the simulated mWUE had a clear linear relationship with IWUE⁻¹ for the majority of IWUE's range regardless of the linearity of the IWUE-VPD relationship except when IWUE is very high (i.e., under high VPD, Fig. 7).
Although limited to a small portion of the entire range, a sharp directional change in the variation
of mWUE was near a point where IWUE⁻¹ was smallest, and strong linearities between mWUE
and IWUE⁻¹ were found before and after the transitional point. Substantial hysteresis became
more evident as the IWUE-VPD pattern became more curved (darker curves in Fig. 4).

467

468

Figure 7. Simulated relationship between mWUE metrics $(\partial E / \partial A \text{ and } g_1^2)$ and IWUE⁻¹ (based on the hypothetical IWUE-VPD model in Fig. 4). The colors of the curves correspond to those used in Fig. 4: IWUE-VPD relationships become more linear with lighter colors. Dashed arrows in panel a represent the directional change of VPD from low to high VPD.

473

474 As predicted by the simulated mWUE-IWUE⁻¹ relationships (Fig. 7), the empirical 475 mWUE-IWUE⁻¹ relationship was strongly linear (P < 0.001 at all sites, Fig. 8). A sign of 476 hysteresis was noticeable for the site that showed decreasing iWUE under very high VPD (US- Ton, refer to Fig. 2 for its IWUE-VPD relationship). In contrast, hysteresis was less evident at the other sites. When the relationship was drawn by grouping data by different levels of IWUE (black dots in Fig. 8), hysteresis was not observed, and the mWUE-IWUE⁻¹ relationship was strongly linear.

481

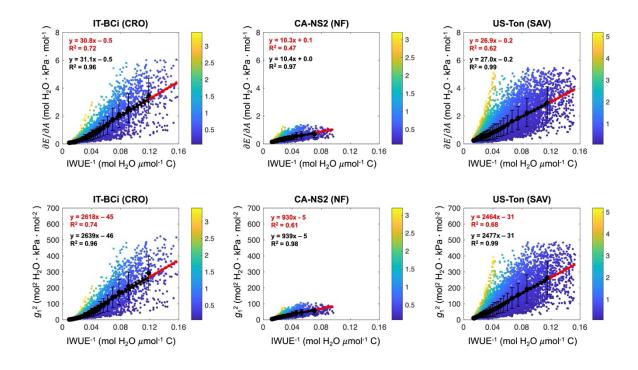

Figure 8. Examples of empirical relationship between mWUE metrics $(\partial E / \partial A \text{ and } g_1^2)$ and 483 IWUE⁻¹. The examples include three sites best represented by the linear IWUE-VPD model (IT-484 BCi, cropland), the Michaelis-Menten function (CA-NS2, needleleaf forest), and the quadratic 485 model (US-Ton, savanna), respectively. Refer to Fig. 2 for the IWUE-VPD relationships at the 486 corresponding sites. Colorful dots represent hourly data points shaded based on the level of VPD 487 (refer to color bars for the scale of VPD). Black dots represent data binned by IWUE⁻¹: Data 488 binning was performed to distribute sample sizes evenly across bins (~30 samples per bin). Error 489 bars represent standard deviations. The red and black solid lines indicate linear fits for hourly 490 and binned data, respectively. Dashed red lines represent confidence intervals for the slopes of 491 linear regressions. Note that red and black linear regressions and their confidence intervals 492 overlap. Refer to Fig. S6 in the Supporting Information for the $\partial E / \partial A$ - IWUE⁻¹ relationships at 493 the 115 study sites. 494

495

We investigated whether the relationship between mWUE and IWUE⁻¹ could be generalized across the sites based on the site-specific AI. Specifically, the linear IWUE⁻¹-mWUE slopes (hereafter m^*) from all study sites were merged, and their variability in response to changing AI was evaluated. We found a significant linear relationship between m^* and AI when both are scaled by log_{10} (P < 0.001, Fig. 9). The m^* was larger at the drier sites (i.e., sites of lower AI) than at the wetter sites (i.e., sites of larger AI). However, we did not find a significant relationship between the IWUE⁻¹ – mWUE intercept and AI (P > 0.05, not shown here).

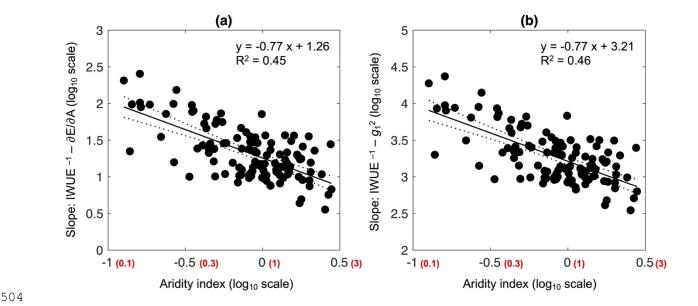

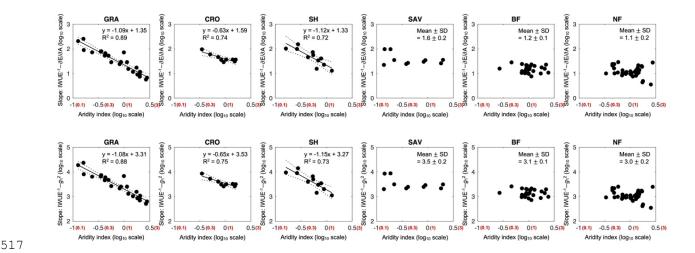

Figure 9. Relationships between IWUE⁻¹-mWUE slope and aridity index (= P/PET) derived from all the study sites (n = 115). Each circle represents the slope obtained from an individual site. Both the x and y axes are scaled by log₁₀. The numbers in parentheses next to the x-axis tick labels represent the aridity indices before the log transformation. The solid lines indicate linear regressions, and the dashed lines indicate confidence intervals (95% confidence interval).

We further tested whether we could find the similar relationship when the sites were grouped by the vegetation type. We found decreasing m^* with rising AI in grasslands, croplands, and shrublands (P < 0.01, Fig. 10). On the other hand, m^* was relatively constant across the range of AI in savannas, deciduous broadleaf forests, and evergreen needleleaf forests (P > 0.05, Fig. 10).

518Figure 10. Relationships between log-transformed IWUE-1-mWUE slope and aridity index in519different vegetation types (GRA: grassland, CRO: cropland, SH: shrubland, SAV: savanna, BF:520broadleaf forest, NF: needleleaf forest). Each circle represents the log-transformed slope521obtained from an individual site. The numbers in parentheses next to the x-axis tick labels522represent the aridity indices before the log transformation. Solid lines indicate significant linear523relationships (P < 0.05), and dashed lines indicate 95% confidence intervals.</td>

525 **4. Discussion**

Stomatal optimization theory, which originated with the work of Cowan and Farquhar 526 (1977), has experienced a recent surge in popularity as the vegetation modeling community 527 continually seeks ways to inject more theoretical rigor into Earth system models (Anderegg et 528 al., 2018; Bassiouni & Vico, 2021; Bonan et al., 2014; Feng et al., 2022; Katul et al., 2010; Katul 529 et al., 2009; Lin et al., 2018; Lin et al., 2015; Lu et al., 2020; Lu et al., 2016; Medlyn et al., 2012, 530 2017; Novick et al., 2016b; Sabot et al., 2022; Sperry et al., 2017; Wolf et al., 2016). The 531 marginal water-use efficiency (mWUE) is a key parameter in this type of model, but we still 532 need a clear understanding of how mWUE is regulated biologically and environmentally. Lin et 533

al. (2018) previously suggested suboptimal mWUE in response to VPD at a sub-daily scale by
estimating site-specific, best-fitted exponent for VPD based on the variation model of optimality
theory (Medlyn model), which inspired our study. In comparison, our study is unique in
analyzing the dynamics of mWUE observed at the half-hourly timescale in response to changing
VPD owing to the long-term continuous carbon and water flux data from the network of eddy
covariance towers.

Another motivation for our study was the conflicting arguments over the dynamics of 540 mWUE in response to water stress. Although mWUE is in general considered to be nearly 541 constant during a day under stable soil moisture conditions (Berninger & Hari, 1993; Fites & 542 Teskey, 1988; Hall & Schulze, 1980; Hari et al., 2000), several studies showed that mWUE 543 changed with different levels of water stress. For example, theoretical considerations indicate a 544 monotonic decrease of mWUE with higher water stress when the stochasticity of rainfall depths 545 is neglected (Cowan, 1982; Makela et al., 1996), although some empirical estimates showed that 546 547 mWUE increases under severe water stress (Farquhar et al., 1980b; Grieu et al., 1988). On the other hand, Manzoni et al. (2011) performed a meta-analysis of 50 species to estimate mWUE 548 from gas exchange observations along gradients of soil moisture and showed that mWUE 549 550 decreases under mild water stress but increases under severe water stress (note that they defined $\lambda = \partial A/\partial E$, which is inverse of the definition used by Cowan & Farquhar (1977) and this 551 study). 552

553

4.1. Relationship between IWUE and VPD

Based on the two equations of stomatal optimization theory (Eqs. 3 & 5), we first characterized the variability of mWUE based on the relationship between IWUE and VPD,

representing biological and environmental factors, respectively. We show that the variability of
IWUE needs to be modeled accurately to emulate the variability of mWUE in response to water
stress correctly. For example, as demonstrated in Fig. 5 (CA-NS2 & US-Ton), oversimplifying
the IWUE-VPD relationship by modeling it with a linear function can incorrectly interpret
mWUE variability.

The non-linear IWUE-VPD relationship is presumably driven by different rates of carbon 562 assimilation and water loss in response to changing VPD at an hourly scale, reflecting the 563 balance between stomatal and non-stomatal limitations to photosynthesis at the leaf level 564 (Farquhar, 1978; Jones, 2014). Under low to moderate VPD conditions, photosynthesis is less 565 sensitive to changing intercellular CO₂ concentration because stomatal conductance is high 566 enough to maintain the high intercellular CO₂ when VPD is low to moderate. Therefore, the 567 quantity of reduced water loss by stomatal closure (ET at an ecosystem level) outweighs the 568 quantity of reduced carbon assimilation (GPP at an ecosystem level) when VPD rises (i.e., 569 570 $|\Delta GPP| < |\Delta ET|$, resulting in the increasing phase of IWUE. As VPD keeps increasing, photosynthesis can be limited when the reduction of stomatal conductance under high VPD 571 conditions substantially reduces intercellular CO₂ concentration (i.e., $|\Delta GPP| \approx |\Delta ET|$), 572 resulting in the steady phase of IWUE. As VPD becomes excessively high, photosynthesis will 573 be further suppressed by high temperature (Yamori et al., 2014) and low leaf water potential 574 (Lawlor & Tezara, 2009) that are associated with dry conditions (i.e., $|\Delta A| > |\Delta g_s|$), leading to 575 the decreasing phase of IWUE. 576

577 Therefore, assuming a linear IWUE-VPD relationship may not only fail to emulate 578 observations but also oversimplify the physiological responses to water stress. Our analysis 579 recommends using the Michaelis-Menten function for most sites while utilizing a quadratic

580	function for sites exhibiting extreme cases where IWUE declines under high VPD conditions.
581	The Michaelis-Menten function can be beneficial to characterize the IWUE-VPD relationship
582	because the maximum potential IWUE and the rate of IWUE increase can be identified during
583	parameterization (Eq. 10). Although the quadratic function can emulate IWUE-VPD
584	relationships very well or performs even better than the Michaelis-Menten function in some
585	cases where IWUE decreases at high VPD, it is parameterized empirically and as a result, lacks
586	mechanistic information. Nevertheless, the quadratic function is preferable to the linear function.
587	It is also important to consider the definition of water-use efficiency for accuracy. We
588	used inherent water-use efficiency (IWUE) as a proxy of intrinsic water-use efficiency (iWUE)
589	at the ecosystem level as suggested by Beer et al. (2009), which can be estimated by GPP and ET
590	inferred from the flux tower observations. This approximation is particularly useful over a more
591	common ecosystem-level iWUE = GPP/G_s because IWUE requires fewer variables and is easier
592	to extrapolate to a larger scale. However, it is important to note that ET/VPD in the equation of
593	IWUE (Eq. 6) is a proxy of canopy conductance, assuming the canopy is well coupled to the
594	atmosphere, boundary layer resistance is small, and thermal equilibrium between leaf and air is
595	achieved (Beer et al., 2009). In other words, IWUE under non-equilibrium between canopies and
596	atmosphere can be overestimated due to the higher VPD than the vapor pressure gradient near
597	the canopy surface (i.e., the difference between intercellular vapor pressure (e_i) and atmospheric
598	vapor pressure (e_a), $e_i - e_a$). Difference between leaf and air temperature can also influence the e_i
599	$-e_{a}$; if leaf temperature is higher than air temperature (as it often is, e.g., Novick & Barnes,
600	2023; Yi et al., 2020), e_i will increase while e_a remains constant, resulting in larger $e_i - e_a$ than
601	measured VPD and consequently underestimate IWUE. Therefore, it is important to address this
602	potential bias to quantify iWUE accurately. According to our results, the correlation between the

two ecosystem-level iWUE proxies was strong at the site level (Fig. 1), implying that the choice 603 of ecosystem-level iWUE definition is unlikely to influence our interpretation of the iWUE and 604 mWUE variabilities substantially. Furthermore, our comparison of multiple definitions of iWUE 605 using a mechanistic model, CANVEG (refer to the Supporting Information for more details), 606 indicated that IWUE is a good proxy of leaf-level iWUE and meets the general assumptions to 607 608 address scaling issues. Thus, we conclude that eddy covariance observation of carbon and water fluxes is suitable to model the variability of intrinsic water-use efficiency in response to 609 changing VPD. 610

Of note, the linear relationship between the slope of IWUE-VPD and aridity index (Fig. 611 4) was stronger in the ecosystems characterized by lower vegetation types (e.g., grasslands, 612 croplands, and shrubland). In contrast, ecosystems with higher vegetation (e.g., savannas, 613 broadleaf forests, and needleleaf forests) exhibited a weaker relationship. This observation 614 implies a potential link between water-use efficiency and the vertical structure of vegetation, 615 616 although the exact underlying mechanism remains uncertain.

617

618

4.2. Modeling the variability of mWUE

619 We compared two solutions of mWUE by Katul et al. (2010) $(\partial E / \partial A)$ and Medlyn et al. 620 (2012) (g₁) developed based on different assumptions on stomatal optimality (carbon-limited versus light-limited) for more robust conclusion. Despite the difference in the assumption, both 621 solutions yielded very similar results throughout our analysis, confirming that the optimality 622 623 assumption had little effect on evaluating the variability of mWUE in response to changing moisture conditions. 624

625	We characterized the trend of mWUE by using VPD as an environmental driver (Figs. 4
626	& 5), where its variability in response to VPD was unique and not necessarily unidirectional,
627	thus making it hard to generalize with commonly available functions. Specifically, the variability
628	of mWUE was simpler and decreased exponentially with rising VPD when the IWUE-VPD
629	relationship was more linear, making it easy to model the mWUE-VPD relationship (Figs. 4 &
630	5). However, the variability of mWUE was not unidirectional when the IWUE-VPD relationship
631	was non-linear, as observed in most cases (Fig. S5 in the Supporting Information); high
632	variability in mWUE is usually observed at low- and high-ends of VPD. On the other hand, when
633	mWUE was calculated under conditions of moderate VPD level only, the variability of mWUE
634	can be overlooked and considered constant. This complex pattern signifies the importance of a
635	comprehensive view of IWUE and mWUE across the full potential range of VPD. Observation
636	under conditions of a partial range of environmental factors is common in many types of field
637	measurements that have coarser time resolution (hourly versus daily to weekly, e.g., eddy
638	covariance versus leaf gas exchange measurements) unless they are performed frequently over a
639	long period to cover non-typical conditions. We were able to estimate precise variability of
640	mWUE matching with the hypothetical models owing to the large amount of data
641	(FLUXNET2015) collected every half-hour over the long period throughout the network of flux
642	towers (total 1,036 site years with many sites offering data collected over more than a decade),
643	highlighting the value of long-term, continuous measurements. Overall, our result of the mWUE-
644	VPD relationship supports the results of Manzoni et al. (2011) among the various conflicting
645	results over the response of mWUE in response to water stress, which found decreasing mWUE
646	under mild water stress and increasing mWUE under severe water stress from a meta-analysis of
647	gas exchange observations.

As a solution to model unique patterns of mWUE, we attempt to address its variability 648 with information that can be obtained easily from various types of field measurements (e.g., eddy 649 covariance, gas exchange, and tree-ring cores) and modeled empirically-IWUE. The 650 relationship between mWUE and IWUE was inferred from the two equations of the optimization 651 theory (Eqs. 3 & 5). We found a strong linear correlation between IWUE⁻¹ and mWUE from both 652 empirical data (Fig. 8) and modeling exercise (Fig. 7). In other words, the variability of mWUE 653 in response to changing VPD can be characterized by (1) the function of IWUE-VPD 654 relationship and (2) the slope between IWUE⁻¹ and mWUE. The relationship between IWUE-655 VPD is relatively simple and can be identified with various field measurements. This raises the 656 question of whether a simple way exists to identify the slope between IWUE⁻¹ and mWUE. By 657 synthesizing the IWUE⁻¹-mWUE slopes across the sites, we found that the IWUE-mWUE slope 658 is highly correlated with the site-specific AI that can be characterized for different vegetation 659 types (Fig. 9). The correlation is conceivable from the equations of mWUE (Eqs. 3 & 5). If, for 660 instance, Eq. 3 is rearranged, 661

$$\frac{\partial E/\partial A}{\mathrm{IWUE}^{-2}} \propto \mathrm{VPD} \qquad (12)$$

indicating that the slope between mWUE and the inverse of IWUE is proportional to VPD,
which is commensurate with AI at a site-level. The correlation between the IWUE⁻¹-mWUE
slope and the AI at a site level implies that the aridity index is a good surrogate for the sitespecific IWUE⁻¹-mWUE slope.

We further illustrated how the correlations between the IWUE⁻¹-mWUE slope (m^*) and AI vary across vegetation types (Fig. 10). Among the vegetation types, GRA, CRO, and SH had strong correlations between m^* and AI, which indicated that using different m^* depending on the site-level dryness would be appropriate. On the other hand, the low variability of m^* observed in

SAV, BF, and NF indicates that constant m^* can generate a reasonably accurate mWUE-VPD 671 relationship regardless of the site-level dryness. Although the reasons for this difference are not 672 entirely clear, this empirical relationship can help more accurately model the variability of 673 mWUE in response to changing VPD across the sites and biomes. Growth in data availability 674 across the flux tower network helps ensure the coverage of the full potential range of 675 environmental factors. More data availability can be achieved by consistently collecting good-676 quality data from existing study sites and establishing new sites in underrepresented areas. 677 Furthermore, additional data would also help the development of m^* in detail, for instance, based 678 on the plant water-use strategies, with the aid of conjoined field measurements such as water 679 potential (Ψ) of soil and plant. 680

681

682 **4.3. Implications for future research**

It is important to note that plant response to water stress is not only determined by the 683 684 water demand (i.e., atmospheric dryness or VPD) but also by the availability of water sources (i.e., soil moisture). Although volumetric soil moisture content (θ) is often considered as a metric 685 686 of soil water available to plants, soil water potential (Ψ_s) is the driving force of water flows that becomes available to plants by moving along gradients of water potential through the plant (stem 687 and leaf) and eventually to the air. Moreover, Ψ_S is not only determined by the θ but also by soil 688 physical properties, and thus can differ even under conditions of the same θ (Campbell, 1974; 689 van Genuchten, 1980). Unlike Ψ_S , θ is widely measured and usually available with flux data, and 690 carbon and water fluxes are often explained as a function of θ (Green et al., 2019; Novick et al., 691 2016a). However, θ may not characterize soil moisture availability to plants properly, and its 692 relationship with carbon and water fluxes is usually nonlinear and threshold-driven (Feldman et 693

al., 2019; Novick et al., 2022; Stocker et al., 2018), making the modeling of the relationship between IWUE and soil moisture availability challenging. Therefore, enhanced accessibility to Ψ_S data by improving the ease and reliability of Ψ_S observations, for example, by building a centralized and standardized network of Ψ (Novick et al., 2022) would be a necessary step to better characterize the effect of soil moisture availability on plant responses such as IWUE and mWUE.

In this study, we tested the two stomatal optimization models (Katul et al., 2010; Medlyn 700 et al., 2012) that are elaborations of the original Cowan & Farquhar (1977) model with few 701 modifications because our goal was to characterize variability of mWUE in response to dryness 702 (VPD and aridity index) using IWUE that can be calculated from the extensive, long-term 703 704 continuous data from the network of eddy covariance. Meanwhile, more recent optimization models are incorporating additional physiological penalties than the water loss, for instance, 705 damage to the vascular system induced by water stress (Anderegg et al., 2018; Sperry et al., 706 707 2017; Wolf et al., 2016), which may enhance prediction of long-term plant responses to climate change. Although monitoring the integrity of the vascular system, which can be informed by the 708 709 dynamics of hydraulic conductivity, has not been widely conducted, recent advances in 710 psychrometric approaches allowing continuous measurements of plant Ψ (e.g., PSY1 711 manufactured by ICT International) and Ψ_s (e.g., TEROS 21 manufactured by Meter Group) are now enabling the monitoring the dynamics of hydraulic conductivity. Moreover, the relationship 712 between plant and soil Ψ can be used to identify plant water-use strategies (e.g., isohydry 713 framework; Martinez-Vilalta et al., 2014), which can help develop m^* based on plant water-use 714 715 strategies. The measurements of carbon and water fluxes using the eddy covariance technique with the aid of the centralized and standardized deployment of Ψ sensors (Novick et al., 2022) 716

will have a great potential to test models and theories of stomatal optimization and advance our
knowledge of it.

719

720 Acknowledgments

We thank FLUXNET/AmeriFlux community for managing their sites, collecting and 721 processing data, and making data available to public and broader scientific community. K.Y. and 722 G.B.S. acknowledge support from the NSF Division of Earth Sciences (Grant # 2012893) 723 through CUAHSI and the U.S. Geological Survey (USGS) John Wesley Powell Center for 724 Analysis and Synthesis. K.A.N and T.H. were supported by the NASA Carbon Science Program 725 (Grant # NNX17AE69G). K.A.N. also acknowledges support from the NSF Division of 726 727 Environmental Biology (Grant # 1552747), the NSF Division of Integrative Organismal Systems (Grant #2006196), and the AmeriFlux Management Project. L.W. was supported by the NSF 728 Division of Earth Sciences (Grant # 1554894). X.Y. was supported by the NSF Division of 729 Integrative Organismal Systems (Grant # 2005574). K.M. was supported by the INTER Mobility 730 Fellowship from the FNR Luxembourg (INTER/MOBILITY/2020/14521920/MONASTIC). 731 This article has been peer reviewed and approved for publication consistent with USGS 732 Fundamental Science Practices. 733

734

735 Author Contributions

- 736 K.Y., K.A.N., and D.B. conceptualized the research and developed the methodology.
- 737 K.Y., D.B., and M.B. analyzed the data, and K.A.N, Q.Z., L.W., T.H., X.Y., K.M., and G.B.S.

validated the analysis. K.Y. visualized the data analysis. K.Y. wrote the manuscript with input

and revisions from all authors.
