The sensory and cognitive abilities of the mammalian neocortex are underpinned by intricate columnar and laminar circuits formed from an array of diverse neuronal populations. One approach to determining how interactions between these circuit components give rise to complex behavior is to investigate the rules by which cortical circuits are formed and acquire functionality during development. This review summarizes recent research on the development of the neocortex, from genetic determination in neural stem cells through to the dynamic role that specific neuronal populations play in the earliest circuits of neocortex, and how they contribute to emergent function and cognition. While many of these endeavors take advantage of model systems, consideration will also be given to advances in our understanding of activity in nascent human circuits. Such cross-species perspective is imperative when investigating the mechanisms underlying the dysfunction of early neocortical circuits in neurodevelopmental disorders, so that one can identify targets amenable to therapeutic intervention.

**Key words:** brain organoids; development; neuronal networks; oscillations; sensory cortices; prefrontal cortex

## Introduction

The mammalian cerebral cortex is made up of billions of neurons. In our endeavor to understand normal function and, conversely, dysfunction of this region of the CNS, researchers have documented and probed distinct properties of the

constituent neurons, such as morphology, patterns of local and long-range connectivity, gene expression, and intrinsic physiology. Understanding how these neurons acquire their identities and form circuits during development is likely to provide insight not only into how these circuits function, but also how they malfunction in various neurological conditions.

The cortex is made up by two major neuronal classes: excitatory projection neurons (representing ~80% of all cortical neurons) and inhibitory interneurons (~20%) (Fishell and Rudy, 2011; Harris and Shepherd, 2015; Lodato and Arlotta, 2015). The development and assembly of cortical circuits is a highly regulated process. In brief, during early embryonic development, excitatory projection neurons are born from neural stem cells (NSCs) in the dorsally located neuroepithelium, while inhibitory interneurons emerge from the ventrally located ganglionic eminences (Lim et al., 2018). Nascent projection neurons migrate radially from the ventricular zone toward the pia to sequentially (i.e., inside-out) build up the distinct cortical layers (Silva et al., 2019). Inhibitory interneurons, on the other hand, migrate tangentially from their place of origin in the ventral forebrain to reach the emerging cortical plate (Fishell and Rudy, 2011; Lim et al., 2018; Silva et al., 2019). Once at the correct target site, migrating inhibitory neurons enter the cortical plate to form local connections with excitatory projection neurons. According to the complex connectivity rules enacted during development, these classes and

subclasses of neurons are interconnected into cortical circuits, where synaptic inputs are integrated to produce appropriate outputs. The resulting balance between excitation and inhibition (E/I balance) is thought to be critical for physiological cortical circuit function.

Neocortical circuits are capable of dynamically changing throughout life, yet maintaining a fine-tuned balance between stability and plasticity. How neurons assemble into circuits that encode inputs, representations, behavioral states, and actions is still poorly understood. Advances in technologies to monitor, control, and manipulate early neuronal activity have only recently enabled researchers to dissect the contribution of distinct neuronal populations to the functional wiring during development and, consequently, to nascent behavior across species. Because of these advances in the last few years, many of the key questions can now be addressed. For instance, how does cortical cell-type diversity emerge during embryonic development and how does cell-type diversity contribute to the physiology of nascent circuits? What are the mechanisms that ensure and govern the formation of interwoven excitatory and inhibitory circuits and E/I balance during neocortical development? Are these mechanisms general for all neocortical areas or do they differ in relationship to the function/inputs? How do the early patterns of coordinated activity in neocortical areas map onto cortical topography? How does E/I imbalance during development result in life-long miswiring and dysfunction? While most insights originate from rodent models, which are highly amenable to early investigation and genetic interventions, recent advances in human induced pluripotent stem cells (hiPSCs) have the potential to bridge the gaps in our knowledge and help resolve the mechanisms necessary for human brain development *in utero*.

In this article, we review evidence that has accumulated during the last few years regarding the dynamic role of neuronal populations in the development of functional neocortical ensembles, with particular emphasis on the cellular hubs of disease-related miswiring. First, we review recent data on how highly diverse populations of projection neurons emerge. Second, we extract the principles of connectivity development and circuit function as assessed by early patterns of electrical activity (e.g., network oscillations). For this, we focus on the whisker barrel cortex, arguably the best understood developing sensory cortical area in rodents, before switching to prefrontal cortex (PFC), the core of limbic circuitry underlying higher cognitive abilities. Third, we discuss how deviations from these principles cause aberrant network activity and disease-relevant dysfunction. Finally, we introduce pioneering work that aims to translate our understanding in rodents to human brain development, which has, over the centuries, been less accessible to research.

### Generating cellular diversity in the developing cerebral cortex

The cerebral cortex is composed of an extraordinary number of neurons and glial cells. Recent work has highlighted a remarkable heterogeneity in pyramidal cells and interneurons (Ecker et al., 2017; Lein et al., 2017; Zeng and Sanes, 2017). In this section, we mainly focus on principles driving the generation of the former, which are projection neurons (i.e., they often send their axons for long distances), but we refer the reader to a number of recent reviews discussing interneuron heterogeneity (Wamsley and Fishell, 2017; Lim et al., 2018).

The cerebral cortex emerges from neuroepithelial stem cells, which initially amplify their pool but then transform into radial

glial progenitor (RGP) cells. RGPs are the major neural progenitors in the developing cortex and their division dynamics along temporal lineage progression determine the final number of neurons in the mature cortex (Taverna et al., 2014; Lodato and Arlotta, 2015; Beattie and Hippenmeyer, 2017). The developmental programs controlling projection neuron genesis need to be precisely implemented and regulated. Impairments in NSC proliferation lead to alterations in the cortical cytoarchitecture, which is thought to be an underlying cause of neurologic diseases (Barkovich et al., 2015; Silbereis et al., 2016).

NSCs differ from most other stem cell niches in that they are required to create a huge variety of distinct neuronal subtypes in a temporally and spatially controlled manner. While the definition of the complete extent of cellular diversity awaits deeper sequencing, recent efforts using single-cell RNA sequencing have started to establish a comprehensive cell atlas of the cerebral cortex (Rosenberg et al., 2018; Saunders et al., 2018; Zeisel et al., 2018). To produce this diversity, NSCs undergo temporal changes across multiple time scales. Within hours, they can react to extrinsic signals, which change their fate in a concentration- and time-dependent manner. Within days, they pass through distinct intrinsic temporal identities to generate different neuronal subtypes over time (Telley et al., 2019).

Although major efforts in the past have established a rough framework describing NSC lineage progression and the generation of cortical cell-type diversity, the precise cellular and molecular mechanisms that underlie this process are still mostly unknown (Holguera and Desplan, 2018). What is the quantitative and qualitative output of a single cortical NSC and how is the output potential modulated during development, across evolution, and in disease? Which genetic, epigenetic, and niche-derived factors regulate cortical stem cell lineage progression? And on a more general level, how do progenitor stem cells instruct the overall fate of distinct lineages, which may on their part contribute locally to establish specificity of neuronal connectivity in defined cortical circuits?

To approach the above fundamental questions, lineage tracing in combination with genetic manipulations can provide conceptual and mechanistic insights. A unique strategy enabling the analysis of NSC lineage progression is Mosaic Analysis with Double Markers (MADM) technology (Zong et al., 2005; Contreras et al., 2020). MADM offers a genetic approach to visualize and concomitantly genetically manipulate single clones and small subsets neurons, and it provides single-cell resolution of progenitor division patterns and potential *in vivo*. Recent MADM-clonal analysis suggests a deterministic nature of RGP behavior (Gao et al., 2014; Beattie et al., 2017) (Fig. 1A). RGPs initially undergo symmetric divisions, which increase the RGP population, then switch to asymmetric divisions, which produce one committed neuron and one RGP. The neurogenic potential of individual RGPs, as they switch from symmetric proliferative division to asymmetric neurogenic division, is fixed, with a unitary output of ~8 or 9 neurons per individual RGP (Fig. 1A). Upon completion of neurogenesis, a defined fraction of individual RGPs proceed to gliogenesis in which ~1 in 6 neurogenic RGPs produces glia. Interestingly, while the unitary RGP output is fixed, the laminar distribution of projection neurons within a single clone can vary significantly. While ~50% of clones include projection neurons in all cortical layers, the other 50% display more heterogeneous distribution patterns (Llorca et al., 2019). These findings raise the question of whether clonal diversity relates to functional properties in

**Figure 1.** Developing circuits of neocortex. **A**, A model for NSC lineage progression based on MADM-based lineage tracing experiments. RGP initially undergo symmetric amplification divisions. The neurogenic potential of individual RGPs, as they switch from symmetric proliferative division to asymmetric neurogenic division, is overall predictable with an output of  $\sim 8$ –9 neurons per individual RGP (light blue dotted box). Upon completion of neurogenesis, a defined fraction of individual RGPs proceed to gliogenesis, whereby  $\sim 1$  in 6 neurogenic RGPs maintains the potential to produce glia, and establishing the postnatal SCN. cortical microcircuits (Fig. 1B). In this regard, subtle quantitative differences in clonal architecture could be physiologically relevant (Fang and Yuste, 2017). Based on the above foundations, it will be important in the future to determine the precise role of cell lineage in the assembly of cortical microcircuits (Li et al., 2012; Ohtsuki et al., 2012; Yu et al., 2012; Maruoka et al., 2017) and how cell-type diversity at the single-cell transcriptome level affects physiological properties in canonical cortical microcircuits (Cadwell et al., 2020) (Fig. 1B).

### Wiring of cortical circuits and emergence of oscillatory activity: lessons from sensory cortices

Once generated, the highly diverse cortical neurons densely connect with each other, forming circuits. One of the key steps in the assembly of the canonical cortical circuit is the emergence of coordinated excitatory and inhibitory activity, mediated by pyramidal cells and local GABAergic interneurons, respectively, to enable efficient information processing throughout life (Froemke, 2015; Maffei, et al., 2017). This is made even more challenging by the fact that pyramidal cells and GABAergic interneurons arise from distinct neurogenic niches (Greig et al., 2013; Marin and Muller, 2014; Wamsley and Fishell, 2017). Assembly of the earliest circuits of neocortex is thus dependent on numerous molecular mechanisms that regulate the migration and

integration of these cell types in the developing cortical plate (see previous section) throughout early life (Kriegstein and Noctor, 2004; Jabaudon, 2017). Once neurons reach their destination, they begin to establish synapses to form circuits; these early steps are guided by interactions between genetically defined molecular programs and neural activity driven by sensory input.

To date, fundamental research using genetically modified mice has largely focused on the circuits that underpin emergent perception in primary sensory areas because these are malleable to external influences and can readily be used to dissect the contribution of genetics and environment to development. The rodent somatosensory system in particular has been used as a model for circuit assembly (Fig. 1). The diversity of neuronal components and broad timeline for the maturation of the cortical circuit in this area are well understood (Erzurumlu and Gaspar, 2012; Yang et al., 2018). One of the key reasons for this is the prominent relationship between the whisker receptive fields in the periphery and the topographic representations of the vibrissae at every stage of the subsequent sensory pathway from the brainstem to the thalamus, and ultimately in the barrel cortex (Petersen, 2007) (Fig. 1C). This topography develops during early development through the interplay of genetic programs and neuronal activity.

Initial studies in rodents revealed that the barrel cortex displays patterned activity *in vivo* well before the onset of active

whisking in the second postnatal week. Spontaneous oscillations, termed spindle bursts, are observed even in the absence of thalamic afferents (Garaschuk et al., 2000; Dupont et al., 2006; Lischalk et al., 2009), suggesting an intracortical origin. However, accumulating experimental evidence indicates that the sensory thalamus is spontaneously active at embryonic stages, and decreasing the excitability of thalamic neurons from embryogenesis onwards leads to an expansion in barrel columns during the first postnatal week (Antón-Bolaños et al., 2019). Recent findings indicate that wavelike activity can originate in the thalamus itself during late embryonic development (Antón-Bolaños et al., 2019), but it can also originate in the whisker pad from spontaneous whisker movements and passive interactions of pups with littermates in the nest (Yang et al., 2009; Akhmetshina et al., 2016; Dooley et al., 2020) (Fig. 1B). Regardless, the data indicate that thalamic inputs are fundamental for restricting the spread of cortical activity and for the emergence of functional topography in the somatosensory cortex. However, it is unclear whether sensory-evoked activity involves the same cortical circuits as those underlying spontaneous oscillations. Further exploration of these circuits, in line with other fields in neuroscience, should make every effort to be aware of behavioral state. To date, most studies have been performed under anesthesia with the recognition that the behavioral repertoire of neonates is limited, and largely dominated by active sleep (Seelke and Blumberg, 2010). However, it is increasingly apparent that differences are observed in nascent cortical activity according to the sleep-wake cycle (Del Rio-Bermudez et al., 2020; Dooley et al., 2020), with active sleep state providing an ideal environment for sensory signaling.

Behavioral state aside, one key question regarding the patterns of coordinated activity in the developing sensory cortices is how they map onto specific cell types. *In vivo* calcium imaging in combination with genetic strategies has allowed the longitudinal tracking of activity patterns in defined populations of GABAergic interneurons and pyramidal neurons. Although the majority of interneuron classes and pyramidal neurons are spontaneously active toward the end of the first postnatal week, coactivation and participation in network events greatly differ among subtypes (Che et al., 2018) (Fig. 1D,E). For example, interneurons derived from the caudal ganglionic eminence, including both vasoactive intestinal peptide (VIP) and layer 1 (L1) interneurons, exhibit infrequent spontaneous activity. Moreover, although L1 interneurons show low-frequency spontaneous activation at the single-cell level, these calcium-mediated events are widespread and highly synchronous. In contrast, VIP interneurons show limited correlated activity at these early stages. The broad recruitment of caudal ganglionic eminence-derived L1 interneurons is in stark contrast to the topographic activation of interneurons derived from the medial ganglionic eminence. Subsets of medial ganglionic eminence-derived interneurons, including parvalbumin (PV) and somatostatin (SST)-expressing INs, as well as pyramidal neurons are organized in spatially and functionally segregated clusters, or assemblies (Duan et al., 2020; Modol et al., 2020). Synchronous activity within these assemblies protects interneurons from apoptosis, contributing to the emergence of a balanced ratio of excitatory to inhibitory neurons (Duan et al., 2020). Assembly organization in the first postnatal week is most prominent among interneurons that innervate perisomatic regions of pyramidal cells, consistent with the early role for these cells in circuit development (Anastasiades et al., 2016; Modol et al., 2020). Such an arrangement is not found in supragranular SST and L1 interneurons, which display minimal assembly organization at these stages.

In addition to exhibiting spontaneous activity, interneuron subtypes are recruited differentially by sensory inputs (Fig. 1). During the first postnatal week, these inputs efficiently recruit both infragranular SST (Marques-Smith et al., 2016; Tuncdemir et al., 2016) and L1 interneurons (Fig. 1D), the latter through the activation of NR2B-containing NMDA receptors (De Marco Garcia et al., 2015; Che et al., 2018). Sensory-driven activation of L1 interneurons is fundamental for the restriction of ongoing pyramidal cell activity and the sharpening of barrel fields. Decoupling of L1 interneurons from the thalamus leads to enlarged barrels in L4 and long-lasting defects in sensory discrimination (Che et al., 2018). Thus, direct and indirect (Ghezzi et al., 2020) thalamic innervation of superficial interneurons provides an inhibitory gating mechanism to refine sensory maps (Fig. 1D). In contrast, sensory inputs to supragranular fast-spiking interneurons and pyramidal cells are not prominent in the first postnatal week (Bender et al., 2003; Daw et al., 2007). In agreement with these observations, sensory deprivation does not affect pyramidal cell synchronization, and whisker stimulation fails to recruit perisomatic-innervating interneurons at postnatal days 7–9 (Golshani et al., 2009; Che et al., 2018; Modol et al., 2020). Thus, some interneurons and pyramidal cells show functional topography during spontaneous activity, whereas others are recruited by whisker stimulation during development. However, it is unclear how these patterns regulate the fidelity of interneuron-pyramidal cell connectivity to shape barrel column organization throughout cortical layers.

Across early development, GABAergic innervation of pyramidal cells in somatosensory cortex is largely confined to the layer in which the pyramidal cell is located with one prominent exception: translaminal efferent synaptic connections from L5 interneurons that transiently innervate the subplate/L6b (Ghezzi et al., 2020), then L4 (Marques-Smith et al., 2016) (Fig. 1D), before targeting pyramidal cells in L2/3 before the onset of active whisking (Anastasiades et al., 2016). It has been proposed that SST interneurons are the main contributors to this transient, sequential translaminal innervation of cortical layers. This is consistent with the role of this subtype in local circuit development and synaptogenesis (Dupont et al., 2006; Oh, 2016; Tuncdemir et al., 2016). Moreover, SST interneurons originate early during neurogenesis and preferentially populate infragranular layers and thus are ideally suited to direct inside-out formation (i.e., deep layers before superficial layers) of the mammalian neocortex (Butt et al., 2005). Silencing GABAergic transmission from SST interneurons during the first postnatal week reduces the occurrence of spontaneous spindle bursts and associated multiunit activity *in vivo* (Baruchin and S.J.B.B., unpublished data) consistent with delayed thalamic innervation of L4 spiny stellate neurons observed *in vitro* (Marques-Smith et al., 2016). Such silencing also affects the response to sensory stimulation; this does not occur when VIP interneurons are silenced.

Despite the apparent importance of SST neurons in the development of thalamocortical innervation in the barrel cortex, it is wrong to think that any particular neuronal subtype has a privileged role in early development. Indeed, recent endeavors have highlighted the contribution of other GABAergic interneurons to circuit maturation and plasticity. These include VIP interneurons (Miyoshi et al., 2010; Miyoshi and Fishell, 2011), which are generated at later embryonic ages. As such, it is somewhat surprising that VIP interneurons contribute to the earliest neonatal circuits, forming synaptic connections onto both infragranular medial ganglionic eminence-derived interneurons and pyramidal cells within the first postnatal week, during the critical period for

**Figure 2.** Early oscillations as a hallmark of an emerging network. **A**, Schematic showing the location of mPFC in the neonatal rodent brain. **B**, Early oscillations (osc) in L2/3 pyramidal cells include transient bouts of  $\beta$ -low  $\gamma$  ( $\sim 15$  Hz) rhythmic oscillations. **C**, Development of GABAergic interneurons parallels the emergence of higher-frequency oscillations. **D**, Brain organoids derived from hiPSCs provide a model system for exploring early rhythmic oscillations in human networks. **E**, At 2 months, synchronous single-unit spiking is observed. This gradually becomes more complex (**F**), such that at  $\sim 6$  months (**G**) 2–3 Hz oscillations are observed, followed by (**H**) complex oscillations with the emergence of GABAergic signaling.

plasticity in L4 (Vagnoni et al., 2020) (Fig. 1E). Furthermore, the soma location of these cells in supragranular layers and their early synaptic interaction with the infragranular neuronal types (Fig. 1D,E) identifies the presence of a GABAergic network that spans the depth of neonatal cortex, providing a template for circuit development.

### Wiring of cortical circuits and emergence of oscillatory activity: lessons from PFC

The rodent barrel cortex is a highly specialized, topographically organized columnar circuit. This raises the question of whether the wiring scheme described across development for this sensory cortex applies to other neocortical areas. Of particular interest to our understanding of the mechanisms of neurodevelopment disorders is the mPFC (Fig. 2A). The rodent PFC, despite the lack of structural homology, has certain functional homology with the primate and human prefrontal areas (Carlén, 2017; Chini and Hanganu-Opatz, 2020). In mammals, the PFC is considered the core brain circuitry for complex cognitive processing. Knowledge of how distinct types of prefrontal neurons organize into early circuits and generate early patterns of activity is more limited than our understanding of developing sensory circuits. But some information about PFC development has been acquired by monitoring prefrontal activity at neonatal age during sleep and sleep-like conditions mimicked by some anesthetics (Chini et al., 2020). Discontinuous theta (4–12 Hz) discharges and transient bouts of  $\beta$ -low  $\gamma$  (12–20 Hz) rhythmic oscillations, an early prefrontal activity signature with important functional correlates (Brockmann et al., 2011; Bitzenhofer et al., 2017b; Chini et al., 2020), have been detected. This fast activity relies on pyramidal cells residing within prefrontal L2/3 (Bitzenhofer et al., 2020a, 2020b; Chini et al., 2020) that are boosted by excitatory drive from the hippocampus (Ahlbeck et al., 2018) (Fig. 2B). This oscillatory motif persists and smoothly evolves from the first postnatal week through adulthood, gradually becoming longer, faster (the average frequency increases from  $\sim 15$  Hz up to  $\sim 50$  Hz),

and of higher amplitude (Bitzenhofer et al., 2020a). These activity changes parallel the unfolding of inhibitory feedback and alterations in inhibition dynamics (Fig. 2C). It is conceivable that inhibition shifts from an early environment in which SST interneurons dominate the GABAergic landscape, to one in which PV-expressing interneurons progressively gain relevance, as previously shown in the barrel field (Marques-Smith et al., 2016; Tuncdemir et al., 2016). Indeed, across the first three postnatal weeks, the strength of SST to pyramidal cell synapses decreases, whereas the opposite occurs for PV interneurons. Of note, early bouts of  $\beta$ - $\gamma$  activity are also present in the rodent barrel (Minlebaev et al., 2011; Yang et al., 2013) and visual cortices (Hanganu et al., 2006; Colonnese et al., 2010), yet distinct mechanisms underlie their generation.

### Developmental miswiring as disease substrate

Understanding how circuits comprised of excitatory, glutamatergic pyramidal cells and locally projecting, inhibitory GABAergic interneurons come online across the layers of neocortex is the prerequisite for identifying the key points, both in space and time, that are particularly vulnerable to perturbations. Severe pathologies with high clinical incidence have been proposed to result from developmental disturbance of synaptic connectivity and E/I imbalance.

In several developmental mouse models of mental disorders,  $\beta$ - $\gamma$  prefrontal oscillations are impaired from the first few postnatal days until adulthood (Xu et al., 2019; Chini et al., 2020; Xu et al., 2020). Severely simplified dendritic arborization, as well as decreased spine density and firing rate of L2/3 pyramidal cells underlie these abnormalities. Investigation of the upstream mechanisms of these deficits highlighted a third cell type, in addition to pyramidal cells and interneurons, with critical relevance for shaping the developing circuits. Microglia, the professional phagocytes of the brain, control the developmental elimination of excess synaptic connections, in a process called synaptic pruning. But excessive pruning as result of hyperactive microglia has been identified as the source of structural and

functional deficits in neonatal mouse models of mental disorders (Chini et al., 2020; Comer et al., 2020). It is therefore tempting to speculate that the interplay between activity and microglial phagocytosis might be one of the mechanisms through which early activity sculpts developing prefrontal circuits (Hughes and Appel, 2020).

Reduced activity of L2/3 pyramidal cell during development is deleterious, but the opposite effect is equally detrimental. For instance, a protracted but subtle increase of L2/3 pyramidal cell firing across the first two postnatal weeks results in long-term prefrontal microcircuit disruption and E/I imbalance that worsens over time (Bitzenhofer et al., 2020b). Similar deficits have also been described in mouse models of autism spectrum disorder, which are characterized by increased prefrontal activity (Richter et al., 2019; Medendorp, 2020).

Abnormal development of neocortical inhibitory neurons is also relevant to disease. Recent work suggests that the impact of developmental perturbations in GABAergic interneurons stems from their dense connectivity with both pyramidal cell and other GABAergic interneuron populations (Cardin, 2018). GABAergic inhibition plays key roles in regulating postnatal cortical plasticity by controlling the timing and extent of critical period plasticity in cortical circuits (Hensch et al., 1998; Fagiolini and Hensch, 2000). Inhibitory synaptic plasticity can also constrain plasticity at excitatory synapses during the initial postnatal period (L. Wang and Maffei, 2014). In rodent models, the first few postnatal weeks are thus a key period during which modest perturbations of synaptic inhibition have devastating long-term consequences for mature cortical circuit function. Indeed, abnormal development of excitatory pyramidal cell and altered pyramidal cell-pyramidal cell connectivity have been identified as consequences of inhibitory dysregulation in several neurodevelopmental disorders, including autism spectrum disorder and schizophrenia. Disruption of GABAergic signaling through altered firing of interneurons, loss of GABAergic synapses, or loss of GABAergic interneurons themselves leads to circuit-level disruption of pyramidal cells and activity levels.

Loss of key signaling pathways for GABAergic interneuron development, such as the *Nrg1/ErbB4* pathway, leads to disruption of synaptic connectivity between inhibitory and excitatory neurons, increased pyramidal cell firing rates, and abnormal cortical activity patterns (Fazzari et al., 2010; Wen et al., 2010; Del Pino et al., 2013; Marques-Smith et al., 2016) as well as disruption of long-range functional connectivity (Tan et al., 2019). Likewise, the developmental loss of *MeCP2* from GABAergic interneurons alters local circuit connectivity, elevates cortical firing rates, disrupts patterns of cortical oscillatory activity, and causes seizures (Chao et al., 2010; Ito-Ishida et al., 2015; Mossner et al., 2020). Furthermore, several studies have found that loss-of-function mutations in the gene for the sodium channel *Nav1.1* specifically in interneurons impairs interneuron excitability and leads to disinhibition of pyramidal cells, altered circuit connectivity, and ultimately to seizure (Favero et al., 2018). *Ube3a* mutations likewise lead to seizure as a result of E/I imbalance (Wallace et al., 2012). Interestingly, long-term alteration of the E/I balance in the adult cortex of genetic models of autism spectrum disorder may partially reflect compensatory changes to offset the impact of developmental perturbation (Antoine et al., 2019).

Although past work has largely focused on the developmental role of the largest population of GABAergic interneurons, the fast spiking, PV-expressing cells, recent evidence indicates a previously unappreciated role for other interneuron populations, the SST-, 5HT3a-, and VIP-expressing cells, in cortical circuit

development (Fig. 1D,E). Loss of SST interneurons following *Satb1* deletion leads to altered cortical synaptic connectivity and early mortality (Close et al., 2012), further suggesting a critical function for these cells in early life (Marques-Smith et al., 2016; Tuncdemir et al., 2016). Perturbation of layer 1 5HT3aR interneurons by deletion of *Lynx1* prevents the development of tonotopy in primary auditory cortex (Takesian et al., 2018). Finally, disruption of early postnatal activity in the sparse VIP interneuron population, because of either *ErbB4* or *MeCP2* mutations, causes disinhibition of SST interneurons, loss of behavioral state-dependent cortical regulation, and elevated tonic firing of pyramidal cells, along with disruptions in cortical sensory responsiveness and  $\gamma$ -band oscillations (Batista-Brito et al., 2017; Mossner et al., 2020). Similar perturbations result from conditional deletion of the transcript factor *Prox1* in the same population of interneurons (Vagnoni et al., 2020). Together, these findings suggest not only that GABAergic inhibition from multiple sources is critical for experience-dependent fine-tuning of cortical circuits during postnatal maturation, but also that perturbation of these GABAergic circuit components contributes to cortical dysfunction in neurodevelopmental disease.

### Human iPSC-derived cortical organoids as a model for neocortical oscillatory circuit development

Because most of the mechanistic studies addressing developmental wiring have been done in animal models, it is unclear how translatable these observations are to the human brain. Although significant progress has been made in understanding the development of functional brain networks in infants and children, our understanding of human brain development *in utero* remains largely a mystery. Therefore, hiPSCs have been used to develop brain organoids that mimic early human neurodevelopment at the cellular and molecular levels (Paşca, 2018). Until recently, however, it has been unclear whether these organoids develop functionally dynamic neuronal networks (Trujillo et al., 2019).

One clear hallmark of functioning networks is the presence of neural oscillations (Buzsáki and Draguhn, 2004), which are a ubiquitous signal across brain regions and species (Bullock et al., 2003). Interregional coupling of low-frequency (<40 Hz) oscillations facilitates information transfer (Varela et al., 2001) and temporal spike synchrony (Fries et al., 1997), whereas faster oscillations are implicated in local circuit processes (Cardin et al., 2009; X. J. Wang, 2010). Neural oscillations are correlated with numerous perceptual, cognitive, and behavioral processes (Schnitzler and Gross, 2005); and oscillatory disruptions are similarly widespread, being present in nearly every major neurologic, psychiatric, and developmental disorder (Voytek and Knight, 2015). Yet very little is known about the developmental origins of human neocortical oscillations. Because so many developmental neurocognitive disorders are associated with oscillatory disruptions (Le Van Quyen et al., 2006; Chini et al., 2020), understanding how oscillations develop, and what might disrupt that development during early stages of human embryogenesis, is critical.

Recently, it has been found that hiPSC-derived cortical organoids form small-scale, functional, oscillatory networks (Trujillo et al., 2019) (Fig. 2D–H). Very early in the neural development phase, cortical organoids exhibit highly synchronous single-unit spiking, unlike what is seen in healthy, developed neocortex (Fig. 2E,F). After several months, however, this activity profile spontaneously develops 2–3 Hz oscillations (Fig. 2G) that, like oscillations seen in rodent data reviewed above, become more variable in frequency, time, and space with further

development. This shift toward oscillatory complexity coincides with the development of inhibitory neuronal populations (Fig. 2H); blockade of GABAergic signaling does not interfere with overall spiking activity but impairs oscillatory activity. This establishes a causal role for GABA for the maintenance, but not initiation, of oscillations and shows that oscillatory network development is likely dependent on glutamatergic and GABAergic interactions. This is consistent with predominant models for oscillatory generation through E/I interactions (Buzsáki and Wang, 2012).

The separation of oscillations into different frequency bands is particularly striking given the important role that multifrequency interactions play in human neural network functioning and cognition (Canolty and Knight, 2010). Specifically, in humans, low-frequency oscillations rhythmically modulate high-frequency (>100 Hz) activity, a surrogate of population spiking (Mukamel et al., 2005). This phase-amplitude coupling likely plays an important role in human cognition, including working memory (Johnson et al., 2018) and goal maintenance (Voytek et al., 2015). In cortical organoids, similar phase-amplitude coupling was observed: specifically, the phase of ~3 Hz oscillations was comodulated with the power of high-frequency activity (Trujillo et al., 2019).

Notably, hiPSC-derived cortical organoids appear to recapitulate the electrophysiological developmental trajectory seen in preterm infant EEG. Using a machine-learning model trained to predict human neonatal age from comparable EEG features, the developmental timeline of cortical organoids can be predicted from the presence, absence, and strength of electrophysiological features, including oscillatory power. While the functional equivalence between human neocortex and cortical organoids cannot be proved, these results are encouraging: hiPSC-derived human cortical organoids spontaneously develop neural oscillations that exhibit spatiotemporal complexity, in which low-frequency oscillations interact with high-frequency activity. The development of these complex electrophysiological features mimics what is seen in preterm infant EEG. While these results are far from conclusive, they provide converging lines of evidence that support the use of cortical organoids as a model for studying early human neurodevelopment.

### Conclusions and open questions

Increasing knowledge of the genetic diversity of cortical neurons gives us better access and understanding of early neuronal circuits (Di Bella et al., 2020). However, it will be crucial in future studies to determine how genetic cell-type diversity translates into cellular phenotype and physiological function at the microcircuit level. Although the existence of activity patterns in the neocortex has long been observed, evidence that these patterns dictate emergent connectivity and later function has remained elusive. Accumulating evidence from sensory and limbic cortices indicates that select neuronal populations participate in sensory-evoked and spontaneous network activity and that these activity patterns control specific aspects of early cortical development. Additional research will be needed to further dissect the diversity of neuronal, and particularly GABAergic subtypes, in emergent circuits.

Although RNA sequencing has been instrumental in revealing early subtype identity (Mayer et al., 2018), gaining genetic access to these immature populations remains challenging. This is particularly difficult for fast-spiking interneurons, frequently identified by their PV expression status, which becomes evident only in the second postnatal week (del Rio et al., 1994). Early

identity markers, such as *Mef2c* (Mayer et al., 2018) and *Tac1* (Wamsley et al., 2018), hold promise for the intersectional targeting of this population. The respective roles of the distinct populations of GABAergic interneurons in the early postnatal maturation of cortical circuits remain to be fully elucidated. In addition, the impact of synaptic interactions among the different GABAergic populations on cortical maturation has only recently been identified and remains to be explored. It will be important to match activity patterns revealed by calcium imaging to those recorded with microelectrodes *in vivo* and neurotransmitter uncaging in slices. Going forward, it will be important to determine whether spindle bursts, long oscillations, and  $\beta$ - $\gamma$  oscillations entrain different populations of developing cortical neurons in functional ensembles and what role they have in the development of adult circuit function and behavior. Future investigations will bring us closer to the understanding the rules governing cortical development.
