Abstract

Fe_3GaTe_2, a recently discovered van der Waals (vdW) ferromagnet, demonstrates intrinsic ferromagnetism above room temperature, necessitating a comprehensive investigation into the microscopic origins of its high Curie temperature (T_C). In this study, we reveal the electronic structure of Fe_3GaTe_2 in its ferromagnetic ground state using angle-resolved photoemission spectroscopy (ARPES) and density-functional theory (DFT) calculations. Our results establish a consistent correspondence between the measured band structure and theoretical calculations, underscoring the significant contributions of the Heisenberg exchange interaction (J_{ex}) and magnetic anisotropy energy (MAE) to the development of the high T_C ferromagnetic ordering in Fe_3GaTe_2. Intriguingly, we observe substantial modifications to these crucial driving factors through doping, which we attribute to alterations in multiple spin-splitting bands near the Fermi level. These findings provide valuable insights into the underlying electronic structure and its correlation with the emergence of high T_C ferromagnetic ordering in Fe_3GaTe_2.

The discovery of intrinsic ferromagnetic order in low-dimensional systems has provided a valuable platform for investigating fundamental magnetic phenomena and advancing the development of spintronic devices. Van der Waals (vdW) ferromagnets exhibit a range of intriguing magnetic properties, such as large magnetic anisotropy, the quantum anomalous Hall effect, strongly correlated spin systems, and long-range magnon excitations[1–6]. Moreover, their persistent magnetism down to monolayer presents promising opportunities for constructing innovative spin-based devices, including spin field-effect transistors and magnetoresistance memories[7–9]. Finding ferromagnetic materials that retain their magnetic properties at or above room temperature, such as $CrTe_2$ and $Fe_{5-x}GeTe_2$, holds significant implications for spintronics device applications[10–18].

Recently, a record-high T_c of approximately 350-380 K has been discovered in single crystal Fe_3GaTe_2, a vdW layered ferromagnets[19], which is much higher than that of much studied its sister material Fe_3GeTe_2[20]. It also exhibits notable magnetic properties, including substantial perpendicular magnetocrystalline anisotropy, high saturation magnetic moment, and a large anomalous Hall angle, all persisting above room temperature. Consequently, this unprecedentedly high T_c of Fe_3GaTe_2 has sparked immense interest, resulting in extensive research efforts primarily focused on investigating its basic magnetic properties and exploring spin-dependent electron transport in Fe_3GaTe_2 based devices[19,21–24]. However, the underlying microscopic mechanism responsible for the high T_c ferromagnetic behavior in Fe_3GaTe_2 remains elusive. In particular, the electronic structure in its ferromagnetic ground state has not been carefully investigated, which would provide crucial information to delineate the similarities and differences in Fe_3GaTe_2 and Fe_3GeTe_2[2,3,5,25] systems to reveal the key physical parameters that enable high-temperature two-dimensional (2D) ferromagnetic order.

62   In this study, we report the electronic structure of Fe_3GaTe_2 single crystal in its ferromagnetic

63   ground state using angle-resolved photoemission spectroscopy (ARPES) and first-principles

64   density functional theory (DFT) calculations. Our experimental results of band structure

65   demonstrate a good overall agreement with our DFT calculations. There are notable changes in

66   both experimental and calculated low-energy electronic structures of Fe_3GaTe_2 compared with

67   Fe_3GeTe_2[2,3,5,25] due to the changes in the valence of Ga and Ge, although both materials share

68   similar characteristics in a large energy window. To understand the mechanism of high T_c 2D

69   ferromagnetism deeper, we delve into the fundamental driving factors based on our ARPES results,

70   focusing particularly on the contributions of the Heisenberg exchange-coupling interaction (J_{ex})

71   and the magnetic anisotropy energy (MAE). Intriguingly, doping significantly influences these

72   physical parameters, resulting in a reversal of the MAE direction and the emergence of in-plane

73   magnetic ordering upon hole-doping. Our findings contribute to a comprehensive understanding

74   of the electronic structure and ferromagnetic mechanism in Fe_3GaTe_2 while also suggesting the

75   potential control of magnetic interactions through doping.

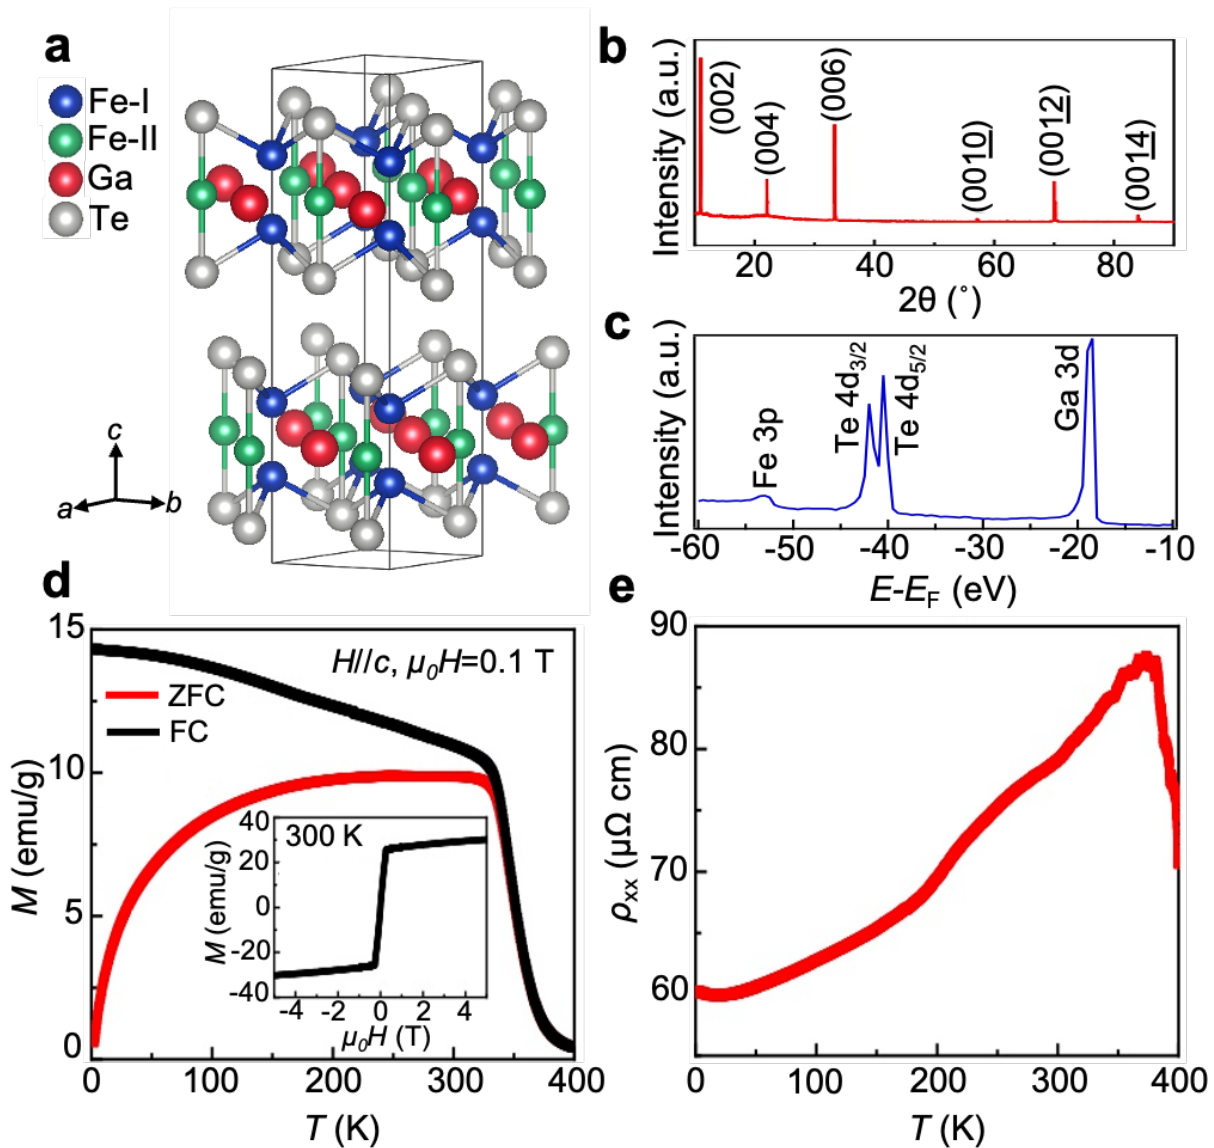

Figure 1. Above room-temperature van der Waals layered ferromagnet Fe₃GaTe₂. (a) Crystal structure of Fe₃GaTe₂. The rectangular box denotes the crystal unit cell. (b) The x-ray diffraction (XRD) patterns of Fe₃GaTe₂ single crystal. (c) Core level spectrum of bulk single crystal Fe₃GaTe₂, showing Fe 3*p*, Te 4*d*, and Ga 3*d* peaks. (d) Temperature-dependent out-of-plane magnetization of Fe₃GaTe₂, measured under zero-field cooling (ZFC) and field cooling (FC). Inset shows magnetic moment as a function of the magnetic field at 300 K. (e) Temperature-dependent resistivity of Fe₃GaTe₂ from 2 K to 400 K.

85

86   Fe$_3$GaTe$_2$ is in a layered hexagonal crystal structure of a space group of *P6$_3$/mmc* (No. 194),

87   identical to that of well-known Fe$_3$GeTe$_2$[19], schematically shown in Fig. 1 (a). The Fe atoms are

88   located in two inequivalent sites, denoted as Fe-I and Fe-II with different magnetic moments.

89   Fe$_3$Ga layers are sandwiched by the vdW-bonded Te layers on top and beneath. The slabs of

90   Fe$_3$GaTe$_2$ are stacked along the *c*-axis with the weak vdW interaction. The x-ray diffraction (XRD)

91   analysis confirms the single-crystalline nature of the synthesized Fe$_3$GaTe$_2$ without any impurities

92   (Fig. 1 (b))[19]. The lattice constants we obtained from the XRD results are $a = b = 4.09(2)$ (Å) and

93    $c = 16.07(2)$ (Å). The core level spectrum exhibits characteristic peaks of Fe 3p, Te 4d, and Ga 3d

94   (Fig. 1 (c)). The temperature dependence of magnetization of Fe$_3$GaTe$_2$ single crystals exhibits a

95   typical ferromagnetic behavior with $T_c \sim 380$ K (Fig. 1(d))[19], and the M ($\mu_0 H$) at 300 K also

96   confirms the hard ferromagnetism of Fe$_3$GaTe$_2$ when H//c (inset of Fig. 1(d)). In addition, it can

97   be seen that Fe$_3$GaTe$_2$ single crystal shows a metallic behavior at low temperatures with an

98   inflection point near T_C, which could be due to the suppression of spin-disorder scattering. All of

99   these results are consistent with the results of the previous report[19].
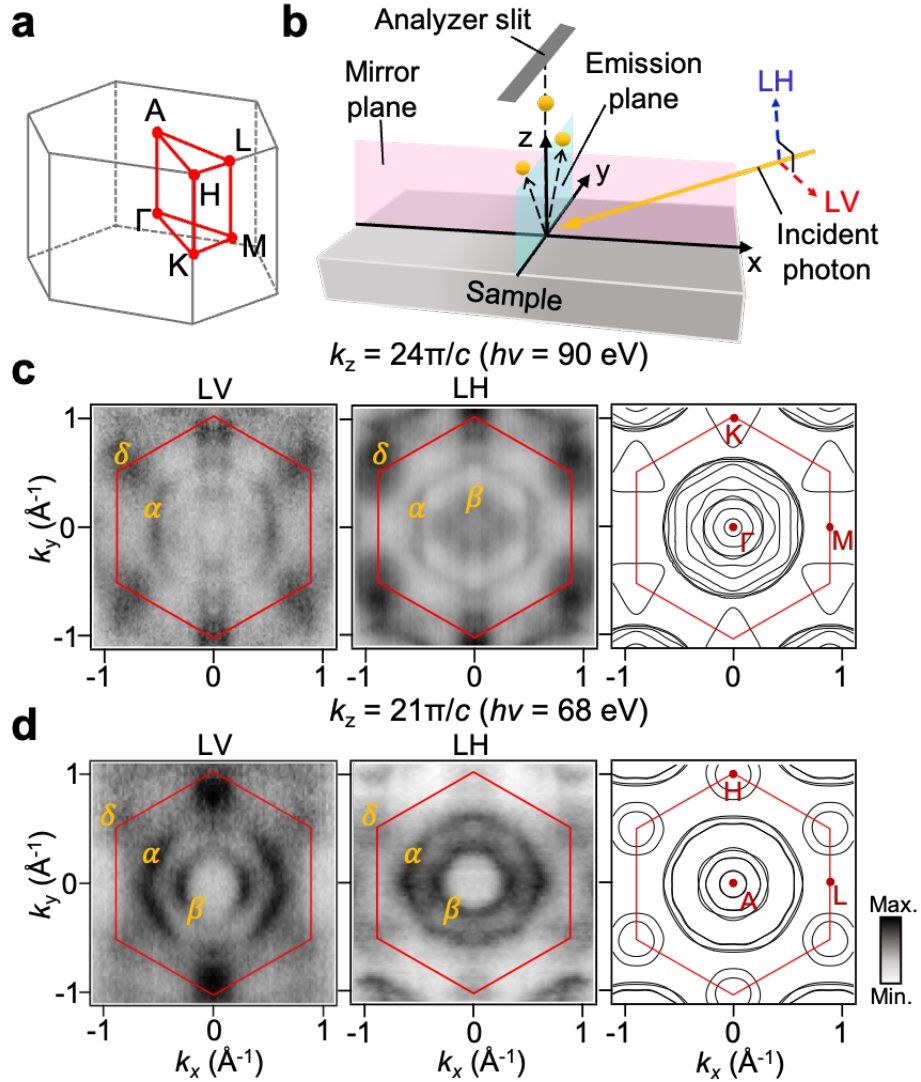

Figure 2. The Fermi surface map of the ferromagnetic Fe₃GaTe₂. (a) Three-dimensional (3D) Brillouin zone (BZ) of Fe_3GaTe_2 showing high symmetry points. (b) Schematic illustration of polarization geometry of the ARPES measurement. Linear horizontal (LH) and linear vertical (LV)-polarizations of light are defined with respect to the synchrotron light source. The analyzer slit is perpendicular to the mirror plane and parallel to the emission plane. (c), (d) Fermi-surface maps at $k_z = 24\pi/c$ and $21\pi/c$, respectively, corresponding to the photon energies of 90 and 68 eV, acquired using LV and LH polarized photons. The band notations (δ, α, and β) are labeled to describe the distinctive band features. The rightmost panels in (c) and (d) display the Fermi surface calculated by DFT. The region enclosed by the red hexagon represents the first Brillouin zone (BZ).

7

112   In order to investigate the nature of the magnetic properties of Fe_3GaTe_2, we performed ARPES

113   measurements and DFT calculations on Fe_3GaTe_2 in its ferromagnetic ground state at 10 K (Figs.

114   2 and 3). By utilizing synchrotron-based ARPES measurements, we were able to tune the energy

115   and polarization of photons, allowing us to capture selective band orbitals at different high

116   symmetry points along the Γ-A direction. Despite the weak interlayer coupling characteristics of

117   vdW layered materials, we observe a significant k_z dispersion, comparable to that of Fe_3GeTe_2

118   (Figs. S1 in SI)[25]. However, we did not find a clear periodicity in the k_z dispersion, also similar to

119   the case of Fe_3GeTe_2, due to the large lattice constant along the c-direction that makes the

120   periodicity along k_z comparable to the k_z broadening in the photoemission process, as well as strong

121   photon energy dependence of photoemission cross-section of different orbitals. However, by

122   comparing the orientation of the main Fermi surface (FS) around the center of the BZ with the

123   results of DFT calculations, we were able to unambiguously define two photon energies

124   corresponding to high-symmetry points, Γ and A. Figs. 2c and 2d show the FS maps obtained

125   using both linear vertical (LV) and linear horizontal (LH) polarized lights at photon energies of 90

126   eV ($k_z = 24\pi/c$, Γ point, Fig. 2c) and 68 eV ($k_z = 21\pi/c$, A point, Fig. 2d), along with the

127   corresponding calculated FS. At $k_z = 24\pi/c$, we observe multiple hole pockets (labeled as α and β

128   bands) around the Γ point, with one of the outer pockets (α band) exhibiting a hexagonal shape

129   aligned with the same orientation of Brillouin zone (BZ). There also exist triangular electron

130   pockets around the K points (δ band). On the other hand, at $k_z = 21\pi/c$, we observe distinct double

131   hole pockets (α and β bands), with the outermost hexagonal pocket (α band) rotated by 30 degrees

132   relative to the 2D BZ, along with two circular electron pockets around the K points (δ bands). Both

133   30 degrees rotation of the hexagonal pocket (α and β bands) and the change in the number of

134   electron pockets around K points (δ band). The calculated FS at the corresponding k_z values

135 exhibits the same characteristic features, demonstrating the presence of hole and electron pockets

136 around the Γ and K points, respectively, as well as the rotation of the outer hexagonal hole pockets

137 (α and β bands) as k_z varies.

138

139
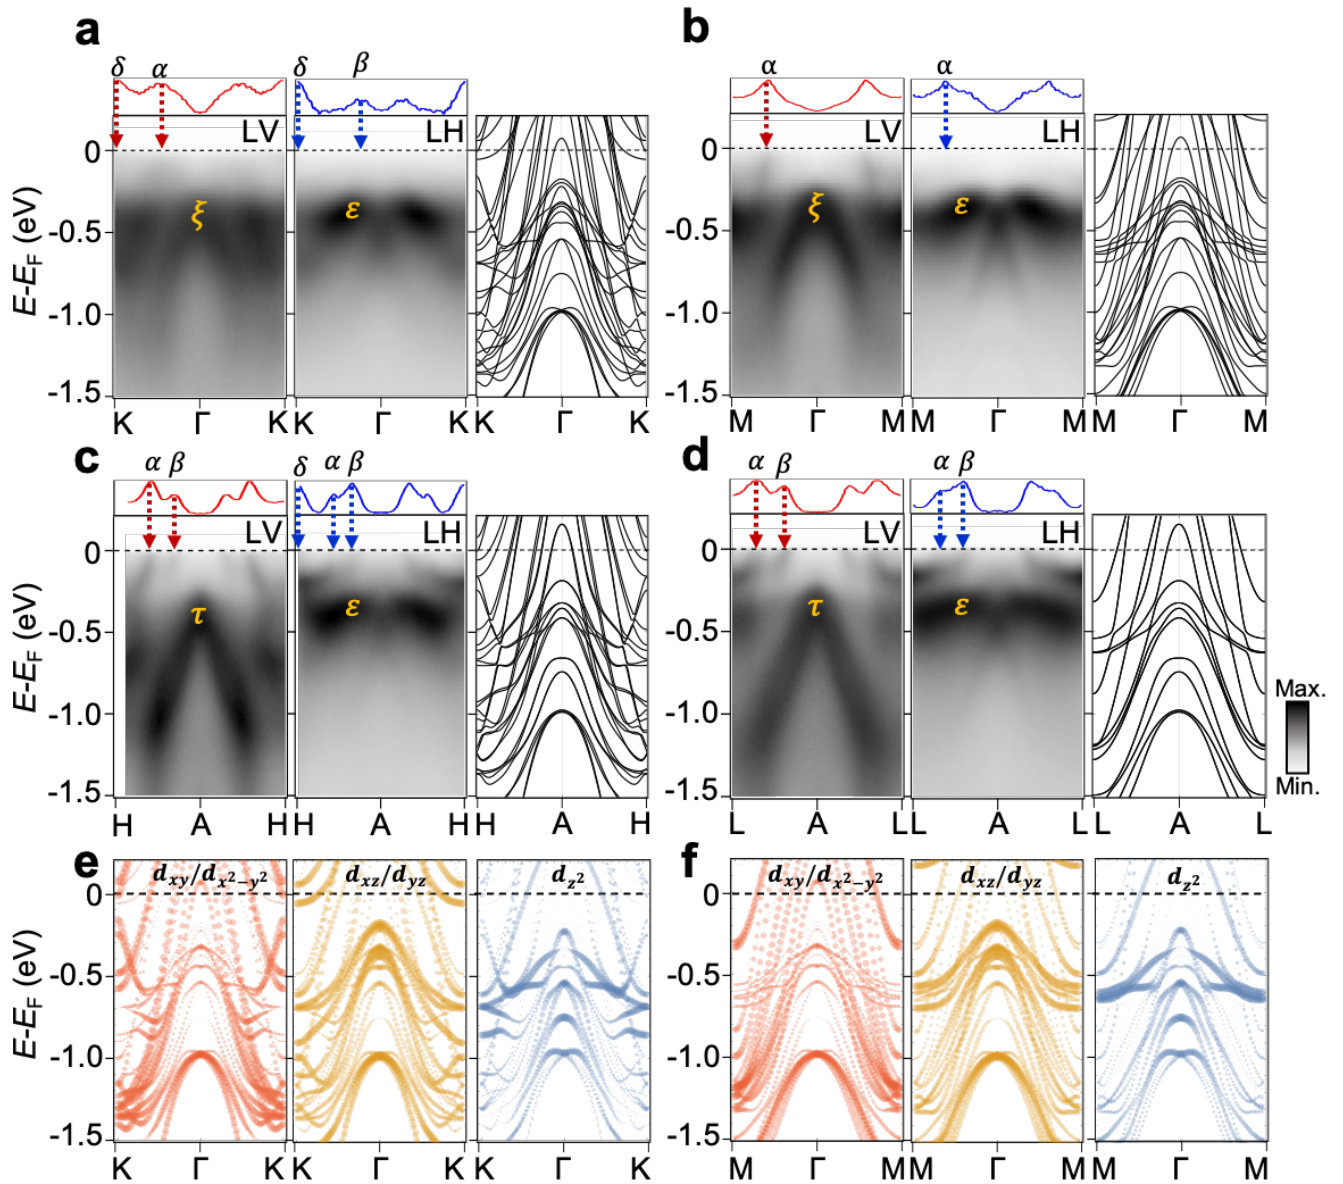

Figure 3. Polarization-dependent ARPES band structures with orbital-resolved band calculation of Fe₃GaTe₂. (a)-(d) The ARPES band dispersions along high-symmetry lines: (a) Γ-K, (b) Γ-M, (c) A-H, and (d) A-L (two left panels), along with corresponding DFT band structures

9

143   (rightmost panels). The upper panels show momentum distribution curves (MDCs) at E-E_F = -50
144   meV, providing the band features near the Fermi level. The orbital-resolved band dispersions along
145   the high-symmetry lines (e) Γ-K and (f) Γ-M are obtained by DFT projected with the
146    $d_{xy}/d_{x^2-y^2}$, d_{xz}/d_{yz}, and d_{z^2} orbitals from Fe-I and Fe-II atoms. The orbitals are grouped
147   according to the point group C_{3v} and D_{3h} of the Fe-I and Fe-II atomic sites, respectively.
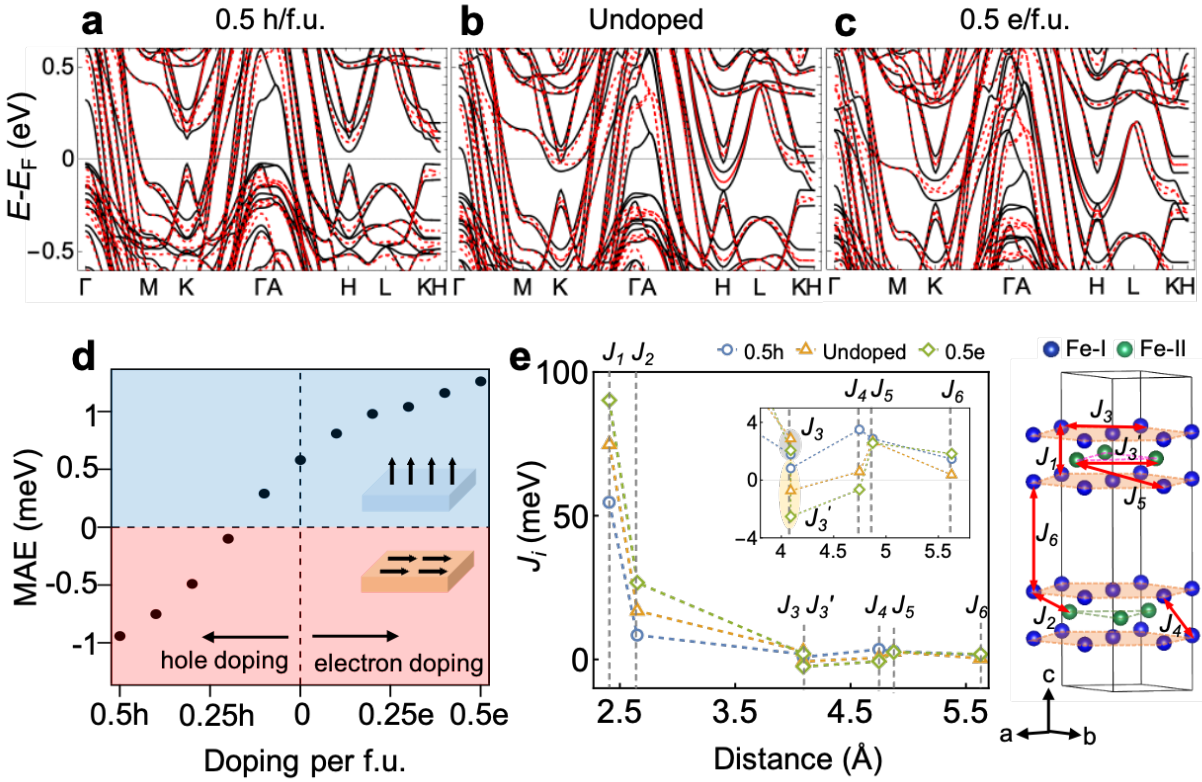

148

149

150   To gain a deeper understanding of the electronic structure of Fe_3GaTe_2, we now show photon

151   polarization-dependent band dispersions along the high-symmetry lines (Figs. 3a-d). Overall, the

152   bands around the Fermi energy are mainly derived from the Fe-d derived bands shown from the

153   partial density of states (Fig. S3) and depending on the symmetry of the d-orbital with respect to

154   the mirror plane (Fig. 2(b)), polarization dependent ARPES intensity is expected. Thus, the distinct

155   polarization dependence enables us to elucidate the orbital characteristics of the main bands. The

156   lambda(Λ)-shaped dispersive bands around the Γ point (ξ band) and the A point (τ band) are

157   predominantly manifested with LV polarization, suggesting that the ξ and τ bands are primarily

158   composed of the d_{xy} and d_{yz} orbitals (odd for M_{xz}) defined according to the measurement geometry

159   (Fig. 2b), as supported by the calculated orbital-resolved band dispersion (Figs. 3 e-f and Figs. S4

160   in SI). Conversely, the low-dispersive band (ε band) is predominantly observed with LH

161   polarizations primarily composed of the d_{xz}, d_{z^2}, and $d_{x^2-y^2}$ orbitals (even for M_{xz}), indicating

162   that the ε band is mainly originated from the d_{z^2} orbital based on the calculated orbital-resolved

163   band dispersion (Figs. 3 e-f and Figs S4 in SI). To provide a clearer visualization, we present the

164   δ, α, and β bands near the Fermi level through momentum distribution curves (MDCs) at E-E_F =

165   -50 meV right above the experimental band dispersions in Fig. 3a-d. The MDCs unveil electron

166   pockets (δ band) at K and H points, along with multiple hole bands (α and β) in all high-symmetry

167   lines, consistent with the results of the DFT calculation (the rightmost panels in Figs. 3 a-d).

168   Additionally, we observe variations in the band dispersions corresponding to different photon

169   energies (see Figs. S2 in SI for the details).

170   Compared with Fe_3GeTe_2[2,3,5,25], we find that the major features of the band structures, the hole

171   and electron pockets at around Γ-A and K-H lines, respectively, are shared between Fe_3GaTe_2 and

172   of Fe_3GeTe_2[2,3] except the position of chemical potential. At the Fermi level, there is a decrease in

173   the size of the electron pockets around the Brillouin zone boundary, while the size of the hole

174   pockets around the Γ-point increases, as we move from Ge to Ga. This observation leads us to

175   speculate that the electronic structure of Fe_3GaTe_2 closely resembles that of Fe_3GeTe_2 doped with

176   one hole/f.u.[2]. This speculation is consistent with that Ga has one less electron than Ge. However,

177   the big increase of T_C in Fe_3GaTe_2 contradicts the previous report of the decreased T_C in Fe_3GeTe_2

178   upon hole doping[2]. This discrepancy suggests that the origin of the large increase of T_C in Fe_3GaTe_2

179   system goes beyond the simple changes in chemical potential and electronic structure from Ga

180   substitution. We, therefore, further investigate the relationship between the electronic structures

181   and T_C by obtaining Heisenberg exchange energies (J_{ex})[26] and MAE, based on the accordance

182   between the theoretical and experimental band dispersions. Moreover, as the magnetic properties

183   of Fe_3GeTe_2, such as T_C, MAE, and coercive field, are reported to be sensitive to doping, we present

184   the dependence of the magnetic properties of Fe_3GaTe_2 on the chemical potential shift. This is of

185   importance in potential device applications since the weak vdW interaction between layers allows

186   changing the chemical potential by gating for thin film Fe_3GaTe_2[13,27–29].

Figure 4. Doping-dependent electronic and magnetic properties of Fe₃GaTe₂ calculated by DFT. (a-c) DFT band structures with (a) 0.5h doped, (b) undoped, and (c) 0.5e doped Fe_3GaTe_2. The doping value is defined by the number of electrons added or removed per formula unit. The black solid lines and red dashed lines are band structures for the out-of-plane and in-plane magnetization, respectively. (d) Magnetocrystalline anisotropy energy (MAE) per Fe atom as a function of doping. The positive and negative signs represent perpendicular and in-plane magnetic anisotropy, respectively. (e) Heisenberg exchange parameters J_i are shown as a function of distances for the 0.5h/f.u.-doped, undoped, and 0.5e/f.u.-doped Fe_3GaTe_2. The exchange parameters are defined in the figure on the right, where only Fe-I (blue) and Fe-II (green) atoms are shown with red arrows denoting the pair of Fe atoms corresponding to each exchange parameter. The shaded planes perpendicular to the c-axis are formed by connecting Fe-I atoms.

Fig. 4 shows the dependence of the band structures with respect to three representative doping cases (0.5h/f.u., undoped, 0.5e/f.u.). In all cases, there is substantial spin-orbit-coupling driven

12

204 band splitting where the degeneracy of the bands with in-plane magnetization (red dashed lines) is

205 lifted with out-of-plane magnetization (black solid lines). For the undoped case, there are hole

206 pockets around the Γ and A points (α, γ, η, and β bands) and electron pockets around the K and H

207 points (δ bands), which are enlarged and reduced with hole and electron doping, respectively.

208 Particularly, we have discovered that the low-dispersive bands along the K-H high symmetry line

209 make significant contributions to the perpendicular magnetocrystalline anisotropy (PMA)[2]. These

210 low-dispersive bands along the K-H line do not cross the Fermi energy for hole doping, whereas

211 the number of low-dispersive bands crossing the Fermi energy along the K-H line increases for

212 electron doping. This suggests a strong dependence of the magnetocrystalline anisotropy energy

213 (MAE) on doping.

214   Fig. 4(d) presents the MAE as a function of doping in which the MAE of the undoped Fe_3GaTe_2

215 (0.55 meV/Fe or $2.3 \times 10^6 \, J/m^3$) is close to the experimental value ($4.79 \times 10^5 \, J/m^3$) at 300 K[19]. More

216 interestingly, we find the sign change in MAE around 0.2h/f.u., suggesting the control of

217 magnetization direction by gating. This switching in magnetization direction could lead to an

218 interesting change in transport properties. Since the anomalous Hall effect (AHE) in the planar

219 geometry requires out-of-plane magnetization and the majority of the AHE is contributed from the

220 splitting of the nodal line connecting K and H points[3], control of AHE by external gating is

221 expected.

222   In addition to controlling AHE by changing the magnetization direction, we expect a large

223 modulation of the Curie temperature with respect to doping. Fig. 4 (e) presents the Heisenberg

224 exchange parameters for the undoped as well as hole- and electron-doped Fe_3GaTe_2, consistent

225 with the previously reported exchange parameters[21]. We find that for the undoped case, the nearest

226 neighbor exchange interaction (J_1) is 75 meV about 1.9 times larger than that of Fe_3GeTe_2 (40

227   meV)[30] that accounts for the increase in T_C of 380K compared with Fe₃GeTe₂ of 220-230K[21,31,32].

228   The relatively larger J_1 exchange parameter of Fe₃GaTe₂ could be induced by the structural

229   difference associated with the decreased c-lattice constant of Fe₃GaTe₂, about 1.5% smaller than

230   that of Fe₃GeTe₂[33–36], where the distance between two Fe-I ions corresponding to the J_1 parameter

231   decreases by 2.8%. This is further supported by orbital decomposition of the J_1 exchange

232   interaction dominated by the Fe-d orbitals extended along the out-of-plane direction, consisting of

233   ferromagnetic interaction between Fe-d_{z^2} orbitals (43 meV) and between Fe-d_{xz}/d_{yz} orbitals (39

234   meV) with small antiferromagnetic interaction between $d_{xy}/d_{x^2-y^2}$ orbitals (-7 meV).

235   With doping the exchange parameters (J_1 and J_2) mainly contributing to stabilizing the

236   ferromagnetic ordering increase with respect to electron doping and vice versa for hole doping.

237   Combined with MAE dependence, we expect a substantial modulation in T_C by doping and even

238   vanishing T_C for an ultrathin film with easy plane anisotropy by destroying the long-range order[37].

239   The large increase in the exchange parameters suggests that the substitution of Ge to Ga cannot be

240   simply considered as the change in the electron number but rather induces a substantial change in

241   the magnetic properties leading to much higher T_C[38].

242   In summary, we systematically investigated the electronic structure of Fe₃GaTe₂ single crystal

243   in its ferromagnetic ground state using ARPES and DFT calculations. We observe qualitative

244   similarities in electronic structure between Fe₃GaTe₂ and Fe₃GeTe₂, while significant energy level

245   differences also stand out. Despite substantial variations in ferromagnetic transition temperatures,

246   minor changes in electronic structure and chemical potential exist, necessitating the consideration

247   of other critical parameters. Therefore, our research elucidates the noteworthy contributions of the

248   Heisenberg exchange interaction (J_{ex}) and magnetic anisotropy energy (MAE) in the formation of

249   the high Curie temperature (T_C) in Fe₃GaTe₂. Based on the DFT calculations, we anticipate that

250　the magnetic properties can be manipulated through doping, as substantial alterations in MAE and

251　J_{ex} are expected to occur. Our results suggest the comprehensive mechanism of high T_C

252　ferromagnetic order in Fe_3GaTe_2 and the potential for employing doping strategies to control

253　magnetic interactions in 2D vdW magnets.

254

255　**Methods**

256　**Single crystal growth.** Single crystals of Fe_3GaTe_2 were grown by the self-flux method. Flakes of

257　Fe (99.98 % purity), Ga (99.99 % purity), and Te (99.99 %) in a molar ratio of 1: 1: 2 were put

258　into a quartz tube. The tube was evacuated and sealed at 0.01 Pa. The sealed quartz ampoule was

259　heated to 1273 K for 10 hours and held there for another day. Then the temperature was quickly

260　decreased down to 1153 K within 2 hours, followed by slow cooling down to 1053 K within

261　100 hours. Finally, the ampoule was taken out from the furnace and decanted with a centrifuge to

262　separate Fe_3GaTe_2 single crystals from the flux. The Fe_3GaTe_2 single crystals were stored in an

263　Ar-filled glovebox to avoid potential degradation.

264　**ARPES measurements.** Fe_3GaTe_2 single crystals were cleaved *in situ* in a vacuum of 5 x 10^{-11}

265　Torr. High-resolution ARPES measurements were performed at Beamline 4.0.3 at Advanced Light

266　Source with a sample temperature of 10 K. The energy and angular resolution were set to be ~20

267　meV and 0.1 degrees, respectively.

268　**First-principles calculations.** The first-principles DFT calculations were performed with the

269　Vienna Ab initio Simulation Package (VASP)[39,40]. For the exchange-correlation functional, the

270　generalized gradient approximation (GGA) with Perdew-Burke-Ernzerhof (PBE)

271　parameterization[41] was used. The DFT-D2 method of Grimme[42] was used to include the van der

272　Waals interaction. The choice of the exchange-correlation functional gives the lattice constants in

273 better agreement with experimental data, compared to the PBE and PBE with DFT-D3 vdW

274 correction. (See Table. S2 in SI for the details.)   The projector augmented wave method[43] was

275 used with an energy cutoff of 600 eV. The Γ-centered $16 \times 16 \times 5$ k-point grid was used. The

276 experimental lattice constants were used with the internal atomic coordinates relaxed with a force

277 threshold of 5 meV/Å. Spin-orbit coupling was included. The force theorem[44,45] was used to

278 calculate the MAE. Electron (hole) doping simulations were treated by increasing (decreasing)

279 total electrons with compensating uniform background charge. The magnetic exchange parameters

280 are calculated by the Green's function method as implemented in the TB2J package[46] within a 15

281 x 15 x 3 supercell. In the exchange parameter calculations, the Hamiltonian in the atomic orbital

282 basis is extracted using SIESTA code[47] with norm-conserving pseudopotentials and localized

283 pseudoatomic orbitals. The k-point mesh of 64x64x16 and the real-space mesh cutoff of 500 Ry

284 are used in the SIESTA calculation.
