Recent accelerator data on multiplicity distributions are reexamined within the context of the Feynman fluid analogy. An interpretation of the data put forward is that the diffractive component decreases logarithmically with energy.

The recent data on prong distributions at high energies (50–300 GeV) suggest a reexamination of results based on the Feynman fluid analogy. The previous approach to this problem relied on cosmic-ray data. The available accelerator results differ with the cosmic-ray ones and, presumably, are more reliable. In this note we shall present the results of such a reanalysis together with a possible hint about the energy dependence of the diffractive component of multiparticle production.

We review briefly the method used which is similar to the one of Ref. 2. The reaction studied was \( p + p \rightarrow n \) negative particles \((n = 0\) includes elastic scattering) at a center-of-mass energy \( \sqrt{s} \).

Let

\[ Y = a \ln(s/s_0). \]  

We shall return to the choice of \( s_0 \) shortly. Instead of dealing with the cross sections \( \sigma_n \), we study the partition function

\[ Q(x, Y) = \sum z^n \sigma_n(Y)/\sigma_{tot} \]  

and assume that at large \( Y \) it has the behavior

\[ \ln Q(x, Y) = p(x)Y + s(x). \]

For very large energies the value of \( s_0 \) in (1) is irrelevant; however, for present energies it may be important. (The value assigned to \( a \) is a scale factor and for our purpose is arbitrary.) A hint as to the value of \( s_0 \) may be obtained from the fluid analogy itself. The inelastic average multiplicity, \( \langle n \rangle \), is proportional to the length of the plateau in the one-particle-inclusive distribution, which in turn is the analog of the length of the fluid container, \( Y \). Thus it is plausible that the proper extrapolation of \( Y \) to present energies is to let

\[ Y = \langle n \rangle = -2.9 + \ln s. \]  

The analysis presented below makes this identification. Had we chosen \( s_0 = 1 \) GeV\(^2\), as was done in Ref. 2, none of our conclusions would change. With such a choice (3) is not as well satisfied as with choosing (4) and subsequently the errors on \( p(x) \) are larger.

The values of \( Q(x, Y) \) together with the best fit to (3) are shown in Fig. 1, and the pressure, \( p(x) \), is presented in Fig. 2.

One may now speculate on production mechanisms which would yield such a pressure curve. Following the discussion of Ref. 2, we would conclude that the rising part \((x > 0.8)\) of the pressure curve was due to a multiperipheral mechanism, while the relatively straight section \((0 < x \leq 0.8)\), one could naively say, was due to a mechanism yielding

\[ \sigma_n(Y) = e^{-\eta x} d_n, \]  

with \( \eta \sim 0.2 \) and \( d_n \) independent of \( Y \).

An energy behavior such as \( s^{-0.3} \), which would be implied by a literal interpretation of Fig. 2 and
RECENT HIGH-ENERGY MULTIPLICITY DISTRIBUTIONS IN... 2257

and the results are shown in Fig. 3.⁶ The success of this fit should not be taken as proof of the hypothesis on the logarithmic energy dependence of the diffractive component. The data can be well parametrized with constant diffractive contributions.⁷ As mentioned above it just indicates that the logarithmic decrease is consistent with the data.

I wish to thank Dr. H. Harari, Dr. G. Thomas, and my colleagues at NAL for discussions.
